The edge of a splenic tumour is sharp, not rounded, and is often notched. Its dulness is not so absolute as that of a renal tumour, since the resonance of underlying colon may be conveyed through its thin substance. The dulness is not crossed by the colon, it extends upwards under the ribs towards the axilla, and downwards and inwards towards the umbilicus, in both these respects differing from a kidney tumour.

The collateral evidence — leucocythæmia, and a history of malaria in the splenic, hæmaturia in the renal affection — will assist the diagnosis. Further, in cases of splenic tumour, a resonant area can usually be detected between the

growth and the spinal column behind, this being absent in the case of a renal tumour.

An ovarian tumour is first evident below, can be detected in the pelvis, and its growth is upwards; a renal tumour grows from above and descends. Moreover, an ovarian tumour very rarely has intestine in front of it, but causes resonance in the flanks, where dulness would be most marked in the case of a renal tumour.

Fæcal accumulation produces a doughy, often elongated mass, which is removed by copious enemata. One such enema does not always suffice to remove the fæces, and in doubtful cases diagnosis should be suspended for a while. (*See also ABDOMINAL TUMOURS, DIAGNOSIS OF.*)

Prognosis.—The prognosis of malignant growths is always unfavourable. They cause death from exhaustion, and occasionally from rupture of the growth or a sudden hæmorrhage into its interior. The duration of life is shorter in children than in adults. Life has been occasionally most unexpectedly prolonged, in one case to seven years, and the disease sometimes passes through lengthy periods of quiescence.

Treatment.—In the early stages of the disease an attempt may be made to re-

move the diseased kidney, but so far this operation has not been attended with great success. All other treatment must be palliative. Pain may be relieved by opium and warm local applications. Hæmaturia, if excessive, should be treated by gallic acid, ergot or acetate of lead internally, or by the application of ice to the growth itself. Coagulation of blood in the urinary passages often produces intense suffering from impaction of the clots in the urethra; such clots should be pushed back into the bladder by a catheter, and afterwards broken down and washed away by injections of warm water.

ROBERT MAGUIRE.

KIESTEIN is the iridescent pellicle which sometimes forms on the surface of the urine after it has been allowed to stand for twenty-four hours or more; after a further lapse of time it falls to the bottom of the glass as a thick white flocculent precipitate. It consists chiefly of mucus, fat and crystals of triple phosphate. It derives its name from its supposed dependence upon pregnancy, in the later stages of which it is commonly present; but it is not a necessary accompaniment of pregnancy, and has been met with apart from that condition, and even in the urine of men.

L

LABIA, DISEASES OF THE.—

The labia may be the seat of **chancres**, which are often accompanied by much œdematous swelling. The swelling often remains after the chancres have healed; and the presence of persistent œdema of one labium should arouse a suspicion that there may have been a chancre.

Erysipelas may attack the labia like any other part of the body.

An **inflammation** of the labia is sometimes seen resembling erysipelas in the extensive swelling and redness that it produces, but differing in that it does not spread. This affection, in favourable cases, lasts a few days and then subsides, but it may be so severe as to produce sloughing. This is seen after acute fevers, such as typhus and small-pox, and after delivery. The inflammation may follow a wound, the swelling being great because of the abundance of loose cellular tissue in the part, but sometimes it occurs without a history of violence, or the discovery of a wound and without pregnancy or

previous illness. It is usually bilateral; a fact against its being simply the result of traumatism.

Treatment.—Inflammation of the labia should be treated by rest, and the application of an evaporating lotion (liq. plumbi acet. 3ss, spt. vin. rect. 3ss, aq. Oj). If the part become gangrenous, and the gangrene shew any tendency to spread, the slough should be separated, and the part freely canterized and then kept clean by frequent washing with an antiseptic lotion.

Abscess—usually of one labium only—may occur. It is generally in Bartholin's gland, and is often due to gonorrhœa, but may be the result of injury. It is easily identified, presenting itself as a tender, fluctuating, non-reducible swelling of the labium. If left alone, an abscess of Bartholin's gland will burst, discharge, close and refill; and this sequence of events will be repeated indefinitely until effectual treatment is adopted.

The *treatment* is to dissect out the

gland. If the surgeon be able to carefully dress the wound himself, it will be enough to cut a large piece out of the wall of the gland; but even when this is done, unless the aperture be kept open by careful dressing, it may close and the abscess refill.

Epithelioma is seen on the labium as a warty growth, accompanied by destructive ulceration, which shows no sign of healing.

The *treatment* is to remove the growth and a good margin of healthy tissue with the platinum knife of Paquelin's cautery. If the growth be advanced, the inguinal glands on the corresponding side will be affected. If these, although enlarged, are yet movable, they should be removed at the same time as the growth.

Innocent growths, as lipomata and molluscum fibrosum, are met with in the labia. The labia may also be enlarged by elephantiasis.

Growths of this kind can only be treated by removal, and this is indicated if their bulk be enough to cause inconvenience.

The labia also may be the seat of various skin affections.

Herpes, when present, runs its usual course, and only requires dry and sedative applications—*e.g.*, powdering with bismuth, or the application of ung. plumbi subacet. co., or, if pain be severe, of bismuth. oxychlor. gr. xxx, morph. hyd. gr. x, vaselin ʒj.

Eczema is often seen on the labia, especially in elderly, plethoric, gouty women, or in the subjects of diabetes. It is best treated by purgation with antacid remedies (mag. sulph. ʒj, mag. carb. gr. x, spt. am. arom. ℥xx, aq. ʒj, t.d.), rest, the avoidance of alcohol, and a restricted diet. For local application either ung. plumbi subacet. co. or ung. zinci, or ung. hyd. nit. and ung. zinci, p. æq., may be used, the first being preferred if the parts be very sore, the last if the condition seem a chronic and indolent one.

Warts are often seen on the labia, as well as on the skin around. The non-syphilitic warts are acuminate, not flat and overhanging. They are associated with uncleanliness and unchastity; they are proof of the former, but not of the latter.

Treatment.—If small, they should be kept dry by the use of a powder of calomel and oxide of zinc. If large, they may be cut off with scissors, hæmorrhage being arrested by pressure and perchloride of iron, or with Paquelin's cautery.

Condylomata, Mucous Tubercles, Syphilitic Warts (secondary) are moist,

flat, broad, overhanging white patches. They may become ulcerated.

Treatment.—Black wash should be applied locally, and mercury given internally.

The labia may also be the seat of so-called "*lupus*" (*q.v.*). A labium may be swollen by a thrombus or hæmatoma (*q.v.*). *Boils* occur sometimes on the labia. They are distressing by the pain they produce, and the suspicions that they sometimes suggest; but they are not otherwise important, and require no treatment special to this part.

Hydrocele of the Labium is a tumour formed by patency of the canal of Nuck, so that the labium contains a process of peritoneum filled with fluid. If the canal be largely open a piece of bowel or omentum may come down; if small, the sac only contains fluid. The channel of communication may become closed, so that the fluid cannot be pressed back into the abdomen. It requires to be carefully diagnosed from a hernia. It is usually recommended to treat it like a hydrocele in the male, by injection of iodine. But bearing in mind the possibility of erroneous diagnosis, and also of the peritoneal communication being not quite closed, probably the safer practice is to cut down upon, open, and remove the sac.

G. E. HERMAN.

LACTATION.—The functional activity of the mammary glands.

These glands begin to become more vascular, to grow, and to secrete, early in pregnancy (*q.v.*). In the two or three days after delivery their development rapidly increases, and the secretion of milk becomes abundant. The older authors (in pre-thermometric times) supposed that the development of mammary activity was accompanied with fever, which they called "milk fever." But accurate observation of the temperature has shown that the secretion of milk is not attended with fever.

It is common for the breasts to be painful and tender during the fulness which precedes the complete establishment of the secretion, but this pain and tenderness pass off when the flow becomes abundant.

The milk first secreted is called *colostrum*. It is less homogeneous than that produced afterwards, looking like a serous fluid with yellow streaks and spots. On microscopical examination, it is seen to contain "colostrum corpuscles," which are the epithelial cells of the mammary glands full of oil globules. After about the third day these cells burst and set

free the fat globules before they leave the gland, and thus the true milk, a bluish-white, homogeneous fluid, is formed. It is generally believed that the colostrum has a slight purgative effect on the child, but, according to Depaul, the same purgation results if the child be put at once to the breast of a wet-nurse who has ceased to produce colostrum.

Milk contains about 11 per cent. of solid matter. This consists, roughly, of butter $2\frac{1}{2}$ per cent., casein 4 per cent., sugar $4\frac{1}{2}$ per cent., and besides this there is about 0.15 per cent. of salts. The amount of milk secreted daily when lactation is fully established is about 3 pints. During lactation menstruation is commonly suspended, but it is, nevertheless, possible for conception to occur at this time. The secretion of milk spontaneously ceases if the breasts are not regularly emptied by sucking. The usual duration of lactation in this country is about nine months. But in weakly women the secretion frequently ceases spontaneously before this time; and in strong women it will continue almost as long as the stimulus of sucking is applied. In uncivilized countries it is not uncommon for women to suckle children for years. By sucking it is possible to make the breasts of virgins or old women, or even the male breast, secrete milk.

After spurious labour in extra-uterine gestation (*q.v.*) the secretion of milk begins just as after a normal delivery.

There is no drug that has any specific effect either in promoting or checking the secretion of milk. The former purpose is best attained by a diet liberal in quantity and containing plenty of meat and milk; the latter, by a restricted diet, combined with saline purgation. Belladonna and iodide of potassium are often given for the purpose of checking the mammary secretion, but no scientific evidence has been produced that either drug has any effect of the kind, and the action of each is admitted by all to be very uncertain.

Hindrance to lactation may arise on the part of the mother from general debility, so that the breasts soon cease to produce milk. Or the milk may be poor in quality, so that the child does not thrive. It is not possible to estimate the nutritive power or digestibility of a mother's milk by any kind of chemical analysis. The effect on the child is the only test of the suitability of the milk for it.

Lactation may also be hindered by

disease of the nipple, which may be small, flat or sunken. By pulling out the nipple with the fingers (by which erection of the nipple is provoked) it may usually be made prominent enough for a healthy child to seize. In the worst cases its prominence may be increased by Kehrer's operation. Soreness of the nipple may hinder suckling. This usually comes on in the first few days, and, if properly treated, gets well within the first fortnight. It usually commences with the formation of small vesicles at the apex of the nipple. These quickly break and dry into brown crusts, underneath which, when detached by sucking, excoriations are found. There are also sometimes deep fissures running transversely round the nipple. These are rarer, they are more painful, and take longer to heal.

The treatment is to apply glycerin of borax to the sore nipple, to protect it during suckling by a nipple shield, and to carefully dry it after suckling. To prevent sore nipples, it is well to wash the nipple night and morning during the last few weeks of pregnancy with equal parts of brandy or whisky and water, and to carefully dry it after suckling.

In the case of premature children suckling may be impossible, because the child lacks strength to seize the nipple. In that case it is best to draw off the milk by a pump, and give it to the child with a spoon.

G. E. HERMAN.

LARYNGISMUS STRIDULUS
(*Spasmodic Croup; Spasm of the Glottis*).—A spasmodic affection of the larynx.

Symptoms.—The essential feature of the disorder is a liability to sudden attacks of complete arrest of breathing, lasting a few seconds, and followed by a crowing inspiration. The affection is almost peculiar to the first two or three years of life. Attacks are said to be most liable to come on as the child awakes from sleep; perhaps, more correctly, the attack awakens him, and although supposed always to take place at night, they are in reality almost, if not quite, as common in the daytime. The child may be playing, apparently in his usual health, when he suddenly stops, perhaps makes a little noise in the throat, and struggles for breath, the head is thrown back, the mouth is open, the hands are clenched, and the chest fixed. In this state the patient remains a few seconds, according to the severity of the attack. The face meanwhile becomes livid and then of an ashy hue, whilst the lips and tongue become

more or less black. The spasm terminates as suddenly as it commences, with one or more long, loud, crowing inspirations, and the child may at once resume his play or be fretful or sleepy. There is no loss of consciousness.

The length of the attacks and the frequency of their recurrence depend upon the severity of the case; sometimes the child will have one every few minutes, both night and day, at others a single nocturnal attack will constitute the whole malady. In the mildest form the spasm is not complete, one or more laboured inspirations with crowing being all that is observed. On the other hand, the attack may be so severe that the child dies suffocated. A fatal result would, doubtless, be more common were it not that, just as in asthma, the state of asphyxia, when advanced, causes a relaxation of the spasm, and thus allows the glottis to be re-opened. The attack may terminate in a general convulsion, but this is rare. Laryngismus is a constant accompaniment of tetany (*q.v.*), and is also closely associated with "facial irritability," a condition in which contraction of the facial muscles is obtained when the finger is lightly brushed over the cheek, where the facial nerve spreads out just above the zygoma.

Pathology.—Spasm of the adductors of the larynx is the actual condition during the attack, and this is probably of central origin; but whether primary, and therefore a species of epilepsy, or secondary, and consequent on reflex irritation, is still a matter of dispute. It is to be presumed that some affection of the respiratory centre in the medulla is the cause of the spasm, but the exact nature of the change is unknown. It has been justly observed that an attack presents many of the phenomena of an epileptic seizure, but it is noteworthy that if this really be a manifestation of epilepsy it differs from all other forms of that disorder in that the liability to the attacks invariably passes off as age advances. In fatal cases, the post-mortem appearances are those of death from asphyxia (*q.v.*).

Ætiology.—Laryngismus is said to be more common in male children. It is seldom seen before the age of six months or after three years. It is much more common during the winter months. The subjects of the affection are always rachitic in some degree, and are often neurotic, there being also a history of neurotic tendencies in the parents. It is impossible in many cases to determine the exciting cause of an attack, but this

is usually to be found in some error of diet or digestive disturbance, or outburst of passion; indeed, the mothers sometimes describe the seizures as "passion fits." The existence of facial irritability betrays an unusual degree of excitability to stimulation on the part of the seventh nerve, and it is a justifiable assumption that a similar condition of the laryngeal nerves exists.

Treatment.—At the moment of an attack there is not much to be done except to see that the clothes are not too tight around the child's chest. An attempt may be made to relieve the spasm by pushing up the chin, as this would tend to raise the larynx, and possibly to open it; but as a rule the attack is over before much can be attempted. When asphyxia is threatened, tracheotomy may be resorted to, followed by artificial respiration, and the other measures proper to restore suspended animation.

General treatment is all-important; the child should be taken out every day unless the weather be exceptionally bad. The sleeping and day rooms should be thoroughly ventilated, the window being left open for an hour or two at a time; he should be warmly clothed, but the clothes should not be too tight; every night and morning he should have a tepid bath, and the front of the neck should at the same time be sponged with cold water. The diet should be regulated, and any digestive disturbances corrected by appropriate treatment. If the child be rickety, cod-liver oil should be given with steel wine. If the treatment be carried out on these lines the liability to the attacks will certainly diminish.

JOHN ABERCROMBIE.

LARYNGITIS, ACUTE.—Acute inflammation of the mucous membrane of the larynx.

Symptoms.—When this disease occurs in the adult, the first symptom complained of is, usually, a sense of discomfort and irritation referred to the larynx, accompanied by a dry, tickling cough, and hoarseness or loss of voice. There is pain on pressure over the larynx and some discomfort in swallowing, and in severe cases dyspnoea is present.

These symptoms are sometimes preceded by those of an ordinary nasal or pharyngeal catarrh, and are ushered in by chilliness and rise of temperature; the pulse is frequent and full, and the face flushed. If the disease advance unchecked, especially if serous infiltration

(œdematous laryngitis) occur early, the countenance becomes anxious, or pale—or somewhat livid; the pulse feeble and irregular, and the usual signs of carbonic acid poisoning show themselves. The amount of obstruction to the entrance of air is indicated by the noisy, stridulous breathing and marked respiratory excursions of the larynx, and the great activity of the muscles of respiration.

In children, owing partly to their tendency to laryngeal spasm, and partly to the narrowness of the glottis, dyspnoea is usually present, and comes on in paroxysms, so that a child who goes to bed with only slight catarrhal symptoms and a little hoarseness, may awake in the night with a start, in great terror and distress, from difficulty of breathing, a condition constituting one variety of the *croup* of the old authors.

On making a laryngoscopic examination, the mucous membrane of the larynx, especially that covering the ary-epiglottic folds, is found to be swollen, forming, in some cases, pyriform swellings, sometimes reducing the rima glottidis to a mere chink; the epiglottis in such cases is found to be swollen and erect. The vocal cords are also swollen and much congested, and usually their mobility is impaired, either from inflammatory infiltration of the muscles acting upon them, or from swelling of the soft parts. If the inflammation goes on to suppuration, a more or less localized tumour may be detected, and the colouring of the pus, which has formed, may even be recognized through the mucous membrane.

Diagnosis.—In the adult the diagnosis of acute laryngitis is easily made, but in the child there may be considerable difficulty, as just in those cases in which a laryngoscopic examination is most required is there the greatest difficulty in making one with any degree of success.

Acute catarrhal laryngitis in the child has to be differentiated from spasmodic croup or laryngismus stridulus and from laryngeal diphtheria. From the former it is to be distinguished by the presence of fever and hoarseness, and by its onset being usually ushered in with coryza, and by the absence of carpo-pedal contractions. The diagnosis from laryngeal diphtheria is more difficult, but in that affection there is generally some membranous deposit to be seen on the pharynx, there is swelling of the lymphatic glands beneath the angle of the jaw, and albuminuria; the symptoms are of a more asthenic type, and the disease usually occurs in epidemics. It is well, however,

not to be too eager to give a definite opinion at the commencement of a case.

Prognosis.—Simple catarrhal laryngitis almost invariably runs a favourable course in the adult, and even in the child, though the symptoms are more urgent, recovery takes place in a very large proportion of the cases. In œdematous laryngitis, on the other hand, the prognosis is extremely unfavourable, especially in the form associated with erysipelas. The observation of Hippocrates that if the erysipelas proceed from within outwards recovery usually follows, whilst if the disease extend from the surface internally, death is the result, has been confirmed by modern experience.

Pathology.—Acute laryngitis differs in its pathology in no respect from inflammation occurring in other mucous membranes.

Ætiology.—The mild form of acute laryngitis usually comes on from catching cold, or it may result from the overuse of the voice. More severe forms may be met with in connection with the exanthemata, especially measles, or they may result from the spread of inflammation from neighbouring parts, such as the pharynx. Œdematous laryngitis has been met with in Bright's disease, but Dr. George Johnson denies its frequent connection with this disease. Traumatic laryngitis, as its name implies, depends on injuries to the larynx, such as may occur from scalds, from corrosive poisons, or from the impaction of foreign bodies.

Treatment.—The most important factor in the treatment of acute laryngitis is the attainment of functional rest. In endeavouring to fulfil this indication, the twofold functions of the larynx (*i.e.*, phonatory and respiratory) must be borne in mind. Any reasonable patient will readily understand the necessity of abstaining from talking, so that one function of the larynx can be held more or less in abeyance. Only very partial rest can be obtained for the other function, but this is to be sought for by keeping the patient as quiet as possible; in severe cases he should be confined to bed, so as to diminish the frequency of the respirations. The temperature of the room should be about 65° F. and the air moistened by means of steam from a bronchitis kettle, and the addition of a teaspoonful of the compound tincture of benzoin to the water in the kettle has a sedative effect; or an inhaler may be used with the same quantity of the tincture in a pint of water.

The diet should be of an unstimulating nature and semi-solid, so as not to cause trouble in swallowing—bread and milk, rice, sago, tapioca, beef-tea and mutton broth are the best. If the bowels be confined, a saline aperient is indicated. A diaphoretic, such as half an ounce of solution of acetate of ammonium, with twenty minims of the spirit of nitrous ether, made up to an ounce with camphor water, may be given every four hours. If the patient be very feverish, twenty minims of antimonial wine, or four or five of tincture of aconite may be added to the mixture. If cough be a troublesome symptom, the addition of half a drachm of the compound tincture of camphor and the same amount of the oxymel of squills will generally give relief. Should signs of œdema of the larynx manifest themselves, the patient should have ice to suck, and an ice-bag collar should be placed round the neck; if, in spite of these precautions, improvement does not set in, the œdematous tissue should be scarified. This procedure is facilitated by previously spraying the larynx and pharynx with a 10 per cent. solution of the hydrochlorate of cocaine. If scarification fail to relieve the patient, or only does so temporarily, tracheotomy should be performed without delay.

F. DE HAVILLAND HALL.

LARYNGITIS, CHRONIC.—Chronic inflammation of the mucous membrane of the larynx.

Symptoms.—The symptoms complained of are all referable to the larynx, the patient experiences a sense of uneasiness and tickling there, which causes a frequent desire to clear the throat; the expectoration is usually scanty, consisting chiefly of small pellets of mucus. The voice is always more or less affected, varying from slight degrees of hoarseness up to complete aphonia. The hoarseness is generally worse when the voice is first used, especially in the morning; after a little use it regains some amount of power, but fatigue is soon felt if talking be continued for any time.

On making a laryngoscopic examination, the cords will be found to have lost their normal whiteness and to vary in colour from a pale pink to a bright red, but the colour is never so intense as in acute laryngitis. Sometimes only one cord is affected, indeed the congestion may be confined to a portion of one cord. Viscid mucus will usually be found adhering to the laryngeal membrane, especially in the arytenoid commissure, and on phonation

the cords may stick together momentarily. Accompanying the congestion there is occasionally loss of mobility in the cords, or defective tension, so that on phonation the cords do not come into apposition, but leave an oval gap between them.

Diagnosis.—As laryngeal tuberculosis in the early stages usually presents the appearances of a chronic laryngeal catarrh, it is important that in cases of any standing the lungs should be carefully examined and the sputa submitted to microscopic examination for bacilli. The diagnosis from malignant disease is at times very difficult, but the occurrence of thickening and congestion of one cord, with defective mobility of the same, in persons over forty, should give rise to serious suspicion that a growth may be present.

Pathology.—The changes ordinarily met with in chronic inflammation of mucous membranes are found in chronic laryngitis.

Etiology.—The causes of chronic laryngitis are practically the same as those producing the acute form of the disease; indeed, chronic laryngitis is very commonly preceded by an acute attack. Over-use of the voice, excessive smoking and drinking, are predisposing conditions. Impeded nasal respiration has only recently attracted attention as a cause of chronic laryngitis, yet in the writer's opinion it is a very potent one. Atrophic rhinitis, which is so frequently accompanied by a dry and glistening condition of the pharynx (pharyngitis sicca), also leads to chronic catarrh of the larynx. Persons whose occupations expose them to the inhalation of irritant particles, to sudden change of temperature, or who are called upon to use their voices in the open air, are especially liable to chronic laryngitis.

Treatment.—The only treatment of any avail in the more obstinate forms of chronic laryngitis is the direct application of astringent remedies to the larynx by means of the brush. A solution of chloride of zinc 15 to 30 grains in an ounce of water, with the addition of 20 minims of dilute hydrochloric acid, which renders the salt more soluble, is the best; this should be applied daily. In the event of spasm being excited by the application, the patient should be told to hold his breath and then to breathe through the nose; if this is not sufficient, sipping a little cold water will usually have the desired effect. If the chloride of zinc fail to cause improvement, a stronger astringent must be tried; for this purpose there is nothing better than a solution of nitrate of silver. It is customary to begin with

a solution of 10 grains to the ounce, and to gradually increase the strength, if necessary, up to 90 grains to the ounce. The writer has used nitrate of silver solution with some degree of caution since he saw a case of argyria resulting from the application, extending over some weeks, of a solution of nitrate of silver to the pharynx. In cases in which it is not possible to use the brush an astringent spray may be tried—the hand-ball spray apparatus being employed to generate the spray. The following solution is one of the best:—R Zinci chlor. gr. xij, acid. hydrochlor. dil. ℥xv, tinct. limonum ℥iij, aquam ad ℥vj; ft. sol. Or 3 grains of tannic acid in an ounce of water, or 1 to 3 grains of the perchloride of iron to the ounce of water may be used. Inhalations of creasote, or of the oil of the Scotch fir, are sometimes found of use. Attention should be directed to any of the causal conditions, such as excessive smoking or drinking, the over-use of the voice, or constipation.

If, after the removal of congestion, the voice remain feeble, the use of electricity, either in the form of the continuous or of the interrupted current, is to be recommended. In some cases of long-standing laryngitis benefit has resulted from a course at Ems or Aix-les-Bains.

As regards general treatment, the patient's health must be improved as much as possible; coddling undoubtedly increases the tendency to laryngeal catarrh, so that the neck should not be wrapped up; at the same time allowing the beard to grow has often a very beneficial result. Sponging the chest and neck with cold water in cases where a cold bath is not taken, is of great service; regular exercise should be enjoined, and hot and crowded rooms avoided.

When the laryngeal secretion is scanty and viscid the chloride of ammonium inhaler is of use, and compressed tablets of chloride of ammonium with borax or chlorate of potassium may be advantageously sucked in the intervals.

The necessity for free nasal respiration should not be overlooked, as many cases of chronic laryngitis result from obstruction to the nose by polypi, or other morbid conditions; as a consequence air enters the larynx without having been previously warmed and moistened by passing through the nostrils.

F. DE HAVILLAND HALL.

LARYNGOSCOPE.—This instrument is now so well known that a detailed description of it is unnecessary.

Some physicians prefer the reflecting mirror fixed to a band which encircles the head, others have a preference for the form in which the reflector is fixed in a spectacle frame; the latter is perhaps the most convenient.

The lime-light is the best means of illuminating the interior of the larynx; Mackenzie's rack-movement lamp is a very convenient arrangement, but a duplex lamp with crystal oil will answer all ordinary requirements. The electric light has not yet come into general use for laryngoscopic purposes.

In making a laryngoscopic examination, the patient is seated opposite the physician: the light is on the right side of the patient, level with his ear; and the reflector is adjusted so as to throw a cone of light directly upon the pharynx. The under surface of the laryngeal mirror is heated to prevent moisture condensing on it, and its temperature should be tested with the hand before introducing it into the patient's mouth. The patient should be directed to breathe quietly during the examination, and to say *eh*, *ah*, or *e* when told. The physician then grasps the patient's tongue, which should be enveloped in a handkerchief or piece of linen, with his left hand, the thumb being above. The mirror should now be introduced and passed to the back of the mouth, so that it presses backwards and upwards against the uvula, care being taken not to touch the surface of the tongue. The patient may now be told to vocalize. Thanks to the introduction of cocaine, it is possible to examine with ease patients who have very irritable fauces, as, after painting a 10 per cent. solution of this drug on the soft palate and adjacent parts, the sensibility of the mucous membrane is, in about two minutes, almost entirely lost.

It must be borne in mind that the image which is seen on the laryngeal mirror is inverted, so that the anterior part of the larynx is seen at the posterior part of the mirror, but that there is no lateral change—that is to say, the vocal cord which is seen on the *patient's* right is the right cord.

It is desirable that a laryngoscopic examination should be made methodically. The first glance should be directed to the colour of the mucous membrane, as the mere presence of the mirror sometimes sets up congestion. Having satisfied one's self as to the colour, attention should now be paid to the motility of the cords, and, finally, note should be taken

of the presence of new growths, ulcers, or other morbid appearances.

F. DE HAVILLAND HALL.

LARYNX, LUPUS OF.—This, although a somewhat rare disease, would be discovered more frequently if the larynx were examined in all cases of lupus of the face. The result of systematic examination goes to prove that the larynx is affected in about 6 or 7 per cent. of the cases.

Symptoms.—Inasmuch as lupus of the larynx is not in its early stage a painful affection, it may be overlooked unless a laryngoscopic examination be made. Usually, however, there is hoarseness, sometimes going on to complete aphonia, and, when the soft parts become infiltrated, dyspnoea may supervene. If the epiglottis be destroyed, the patient frequently has difficulty in deglutition, cough being excited by the entrance of food into the larynx. On examination, in some cases, the mucous membrane of the pharynx and epiglottis has been found extremely pale. The epiglottis is usually irregularly enlarged, and shows, not infrequently, a considerable loss of substance. The general appearance of the interior of the larynx is rough, thick, and granular, and has a worm-eaten appearance.

The *diagnosis* of primary lupus of the larynx is very difficult, some laryngologists go so far as to say that one can never be sure of lupus of the larynx unless one find lupus elsewhere. It requires to be distinguished from epithelioma, syphilis, and phthisis of the larynx, but in this there is usually no great difficulty except as regards the latter affection. The greater age of patients with epithelioma, the more unequal surface and harder character of the growth, and the fact that it is commonly unilateral at the commencement, will aid in the diagnosis. Syphilitic affections of the larynx generally run a more rapid course, partake more of the nature of loss of substance than of new formation, and are usually speedily benefited by iodide of potassium. The slow progress of the case, the absence of pain, and the little effect it has on the general nutrition will alike serve to differentiate lupus from syphilis and phthisis of the larynx.

Prognosis.—Apart from the risk of suffocation, either from acute oedema, which is exceedingly rare, or from gradual infiltration of the soft parts, lupus of the larynx is not of immediate danger to life, since it increases slowly, and may

remain stationary for years, but, though not a very fatal disease, its complete and permanent cure is a matter of extreme rarity.

The *pathology* and *etiology* of this disease are the same as for lupus of the skin. The larynx may be affected primarily, but usually the affection is secondary to lupus of the face, nose or mouth.

Treatment.—For constitutional treatment, reference must be made to the article on LUPUS. Applications of a solution of perchloride of iron, 120 grains to the ounce, have been attended with great success. Semon has employed the galvanocautery for burning down the lupoid tissue, and has obtained permanent cure. Solutions of lactic acid (20 to 60 per cent.) have also given good results.

F. DE HAVILLAND HALL.

LARYNX, NEUROSES OF.—

Nervous affections of the larynx may be due either to

(A) Altered conditions of the motor nerves, including (1) *paralysis* and (2) *spasm*.

(1) PARALYSIS may affect the abductor, adductor, and tensor muscles of one or on both sides of the larynx.

Bilateral Paralysis of the Abductors (*crico-arytenoidei postici*).—This is a very grave condition and may at any moment cause imminent peril to life.

Symptoms.—The breathing is markedly affected, inspiration being prolonged and stridulous, while expiration is comparatively easy. Any slight exertion causes dyspnoea, and may render the patient more or less cyanosed. The voice is not much altered, though there is often slight hoarseness. The larynx is seen to move up and down with respiration—the so-called “respiratory excursions” of the larynx. Laryngoscopically the cords are found to be sucked together during inspiration, leaving between them a chink of two or three millimetres in width; during expiration the glottis is wider than during inspiration. The cords are generally somewhat congested.

Diagnosis.—The symptoms given above, together with the laryngoscopic appearances, suffice for the diagnosis. In some cases ankylosis of the crico-arytenoid joints may simulate bilateral paralysis of the abductors, but in these cases there is usually some alteration in the configuration of the parts.

Prognosis.—Eliminating hysterical cases, paralysis of central origin is generally incurable. Tracheotomy may pro-

long the patient's life, but as a rule he will be unable to dispense with the canula.

Morbid Anatomy.—Semon has pointed out that there is a distinct "proclivity of the abductor fibres of the recurrent laryngeal nerve to become affected sooner than the adductor fibres, or even exclusively, in cases of undoubted central injury or disease of the roots or trunks of the pneumogastric, spinal accessory, or recurrent nerves."

Degenerative changes may be found in the brain or in the recurrent nerves, and the striation of the posterior crico-arytenoids may be indistinct and the muscles pale in colour and infiltrated with fat.

Ætiology.—In some instances the paralysis is myopathic in origin and arises from a chill. Pressure upon both pneumogastric or both recurrent laryngeal nerves may produce the condition, and the pressure of an aneurysm upon one pneumogastric nerve has been known to cause bilateral paralysis of the abductors.

This paralysis has been found associated with tabes in several instances; it may be an indication of commencing bulbar paralysis, and has been met with in syphilitic and other affections of the brain.

Males are more frequently affected than females. This form of paralysis is rare until adult age has been reached.

Treatment.—Galvanism, massage, and the subcutaneous injection of sulphate of strychnine have been recommended, but are almost always ineffectual. Syphilis and aneurysm, the two most common causes of this condition, are both benefited by large doses of the iodide of potassium, and this drug may often be given with advantage. If attacks of dyspnœa occur, tracheotomy should be performed, and even in cases in which the subjective symptoms become less marked tracheotomy is necessary, unless the improvement be accompanied by an increase in the diameter of the glottis.

Unilateral Abductor Paralysis.

Symptoms.—Paralysis of one abductor is usually accompanied by a certain amount of hoarseness or roughness of the voice. Though the breath may be short on exertion, dyspnœa is not a marked symptom.

Laryngoscopically the affected vocal cord will be seen to be immobile in the median line. After a time the adductors not uncommonly also become paralysed; in this event the cord will occupy the cadaveric position—i.e., midway between abduction and adduction. This is fol-

lowed by relief of the dyspnœa, but the voice undergoes further deterioration.

Diagnosis.—This condition requires to be distinguished from fixation of the cord as a result of disease of the crico-arytenoid joint.

Prognosis.—The affection does not in itself endanger life; the gravity depends upon the fact that it is so frequently due to some grave organic disease.

Morbid Anatomy.—This has been already described under bilateral paralysis of the abductors.

Ætiology.—The most frequent cause of abductor paralysis is pressure upon one pneumogastric or recurrent laryngeal nerve. On the right side this may be brought about by pleural thickening, and on the left, which is more commonly affected, the chief cause is an aneurysm of the transverse aorta.

Bilateral Paralysis of the Adductors (*crico-arytenoidei laterales* and *arytenoideus*).

Symptoms.—There is aphonia, which usually comes on suddenly, and as suddenly disappears. The patient may, however, cough and sneeze quite naturally. When phonation is attempted during a laryngoscopic examination, it is observed that the cords fail to approach the middle line.

Prognosis.—This affection is not attended with any risk to life, and almost invariably terminates with complete restoration of the voice. The writer, however, knows of one case which has resisted the most persevering and energetic treatment, although the vocal mechanism was proved to be perfect by the fact that when the patient was faradised, while under the influence of ether, she called out loudly, but immediately lost her voice on regaining consciousness.

Ætiology.—Anæmia and neurasthenia are the chief causes of bilateral adductor paralysis. It is almost exclusively met with in females, and may occur as a precursor of laryngeal phthisis.

Treatment.—Attempts should be made to improve the general condition of the patient by the administration, for one or two weeks, or longer if necessary, of iron in combination with strychnine. When this has been done, and not until then, the cords should be faradised by means of Morell Mackenzie's electrode, or, if this be not available, by passing the current through the larynx externally.

Unilateral Paralysis of the Adductor Muscles is an extremely rare affection; for a description of it reference must

be made to special works on diseases of the throat.

Paralysis of the Internal Tensors of the Vocal Cords (*thyro-arytenoidei*) is shown by hoarseness and by the elliptical condition of the glottis on attempted phonation. The cords are seen to be relaxed and are usually congested. Overuse of the voice, laryngeal catarrh and anæmia are the chief causes of this condition.

Treatment.—The application of astrin-gents as directed under CHRONIC LARYNGITIS, and the use of the continued or interrupted current and of tonics, are the measures from which most benefit may be expected.

Paralysis of the External Tensors of the Vocal Cords is said to give rise to a rough deep voice, which the patient is unable to modulate in the production of high notes (Gottstein).

(2) SPASM. — Although theoretically spasm may affect any of the muscles of the larynx, it is chiefly in connection with the adductor muscles that it is brought under the notice of the physician. The abductor muscles are more commonly involved in organic disease, whereas the adductors succumb to functional affections.

Symptoms.—A spasmodic contraction of the adductor muscles, with consequent closure of the glottis, is the essential part of laryngismus stridulus, an affection of common occurrence in infancy, which, when met with in the adult, gives rise to much the same symptoms. The patient, usually a young woman, has attacks of difficulty of breathing accompanied by stridor, the voice remaining unaffected. In some cases the spasm persists long enough to cause cyanosis, and, as in childhood, may even cause death. The laryngeal crises which occur in tabes are due to a spasm of the adductors, but the affection is here usually complicated with paresis of the abductors.

Treatment.—When of functional origin, the cold douche, combined with some sternness on the part of the friends, will often suffice to stop the spasm, and the tendency to it may be prevented by the use of the bromides in combination with the ammoniated tincture of valerian or other antispasmodics. If these measures fail, the inhalation of chloroform almost invariably succeeds. There are, however, rare cases in which, to avert death, recourse must be had to tracheotomy.

(B) **Altered Conditions of the Sensory Nerves.**—(1) *Anæsthesia*, (2) *Hy-*

peræsthesia, (3) *Paræsthesia*, (4) *Neuralgia*.

Of these, *Anæsthesia* is the most important condition. It occurs in diphtheritic and bulbar paralysis, in lead poisoning, in epilepsy, and in hysteria. Accompanying diphtheritic paralysis, it may cause serious results, as food may enter the air-passages in consequence of the loss of sensation in the laryngeal mucous membrane. In these cases, patients must be fed by means of the œsophageal tube, care being taken to ensure the tube passing down the œsophagus, and not down the larynx. The administration of iron and strychnine, the latter, if necessary, subcutaneously (gr. $\frac{1}{16}$ to $\frac{1}{15}$), almost invariably has a good effect.

Hyperæsthesia and Paræsthesia frequently occur together in neurotic patients, and sometimes alternate with one another. It must be borne in mind that there may possibly be some underlying cause—*e.g.*, granular pharyngitis, a condition which gives rise to uncomfortable sensations, which may be referred to the larynx. Both hyperæsthesia and paræsthesia of the larynx are aggravated by disordered conditions of the stomach, and may be the expression of irritation reflected from other organs—*e.g.*, the uterus or ovaries.

Treatment.—Attention should be paid to the general health, stomach and other visceral disorders should be appropriately treated, and any local cause of irritation removed, if possible. The bromide of potassium is usually of service; locally, sedatives such as cocaine or morphine may be applied in solution.

Neuralgia of the larynx is a rare complaint, and requires the treatment employed for neuralgic affections of other organs. F. DE HAVILLAND HALL.

LARYNX, OEDEMA OF.—A serous or purulent infiltration of the connective tissue of the larynx in general, and of the ary-epiglottic folds in particular. The term "Edema of the Glottis" is a misnomer; the glottis is a *space*, and cannot therefore become cedematous.

Symptoms.—Difficulty in breathing, which may increase with such rapidity as to threaten life in two or three hours, is the characteristic symptom of edema of the larynx. There is usually also the feeling of a foreign body in the larynx, and there may be difficulty in deglutition; this is the more marked when the epiglottis is much swollen. The voice also becomes weak, or there may be aphonia.

On laryngoscopic examination, the epiglottis may be found to be erect, tense, enormously swollen, and nearly touching the back of the tongue; it is usually of a bright red colour. The ary-epiglottic folds are frequently obscured by the swollen epiglottis, but, if they can be seen, they form plum-like bodies, and may nearly meet in the middle line. In those rare cases in which the œdema is confined to the connective tissue below the cords, red fleshy swellings may be seen bulging from beneath the cords. In the absence of the laryngoscope, the swollen condition of the epiglottis and ary-epiglottic folds may be recognized on making a digital examination.

Diagnosis.—If a laryngoscopic view can be obtained, this is very easy; in its absence it is at times impossible to state with certainty the cause of the obstruction.

The *prognosis* is always grave except in the cases in which the œdema is limited in character.

Morbid Anatomy.—As already stated, the disease consists in an infiltration of the cellular tissue of the larynx with a serous, sero-purulent or purulent fluid. This occurs where the cellular tissue is most lax—i.e., into the epiglottis and the ary-epiglottic folds. The œdema is occasionally limited to the part below the level of the cords, constituting the subglottic variety. The vocal cords themselves are hardly at all affected.

Etiology.—Two forms of the disease have been described—viz., primary and secondary.

Primary œdema comes on suddenly in persons previously healthy, and may arise from a chill, from over-use of the voice, the application of caustics, the use of the galvanocautery, the presence of foreign bodies in the larynx, injuries, swallowing boiling water, and from septic poisoning, the result of defective drainage.

The causes of secondary œdema of the larynx are of an inflammatory, mechanical or dyscrasic nature. It occurs as a complication of infectious diseases, such as erysipelas, small-pox, measles, scarlet fever, typhus or cholera. It is met with in chronic diseases of the larynx, such as tuberculosis, syphilis and carcinoma, and may result from passive congestion in heart and lung affections—e.g., emphysema. The connection of œdema of the larynx with Bright's disease, though insisted on by most writers, is not confirmed on careful examination. Morell Mackenzie investigated 200 cases of

Bright's disease in the London Hospital and did not find a single example of œdema of the larynx, and George Johnson, who speaks with authority both on diseases of the larynx as well as on diseases of the kidneys, does not remember to have seen a case of Bright's disease complicated with œdema of the larynx as a direct result. It is probable, however, that an irritation too slight to cause œdema of the larynx in a healthy individual may suffice to bring it about in an albuminuric patient.

Treatment.—Absolute rest should be enjoined, and the patient forbidden to speak. The writer has found that feeding patients per rectum promotes recovery. Ice pills to suck and an ice-bag to the outside of the larynx should be tried. Bromide of potassium in 20-grain doses every two or three hours has been advocated. Free scarification will often give immediate relief; a 20 per cent. cocaine spray to the pharynx and larynx will facilitate the operation, and may even by itself suffice to give relief. If other measures fail, tracheotomy should be performed, and this should not be deferred until the patient is *in extremis*, but should be had recourse to immediately after the first attack of suffocation experienced by the patient.

F. DE HAVILLAND HALL.

LARYNX, PERICHONDritis OF.—Inflammation of the perichondrium of the larynx leading to death and detachments of a part or the whole of the affected cartilage.

The affection may be primary, but is more often secondary to some other laryngeal disease.

Symptoms.—In primary perichondritis, the first symptom to suggest that the perichondrium is affected is a dull, aching pain, which is increased upon pressure over the larynx. There will be some difficulty in swallowing, especially if, as is usually the case, the cricoid cartilage be implicated. Cough and hoarseness are constant symptoms, and there is dyspnoea in proportion to the degree of obstruction.

At an early stage, laryngoscopic examination may only disclose some swelling of the mucous membrane and perhaps immobility of one vocal cord, and, even when an abscess forms, it is difficult to determine whether or no the perichondrium is affected unless portions of cartilage be expectorated, or a rough area of necrosis be detected by the aid of the laryngeal probe.

In secondary perichondritis the symptoms are less marked, and a diagnosis is often impossible until portions of cartilage have been expectorated, or until perchance a sudden attack of dyspnoea has resulted from the cartilage, suddenly dislodged, becoming impacted in the glottis.

The *prognosis* is very gloomy, as this affection almost always supervenes in the course of some grave disease. If death be not brought about suddenly by spasm of the glottis, by œdema of the larynx, or by the impaction in the glottis of the extruded cartilage, it is due to gradual exhaustion, the pain and discharge giving rise to hectic fever.

Ætiology and Pathology.—Perichondritis is almost invariably secondary to some other affection of the larynx, such as tuberculosis, syphilis, malignant disease, or the ulceration attending typhus and typhoid fevers. The perichondrium is attacked in the progress of the original affection, and is eventually separated from the cartilage by a layer of pus, necrosis being thereby brought about. Perichondritis of the cricoid has been met with in bedridden persons of low vitality. In such cases it has resulted from the pressure of the cricoid against the vertebræ.

Treatment.—This must be directed to warding off the consequences of the inflammation. If an abscess form, it should be opened, and the surgeon must be ready at any moment to perform tracheotomy. In some cases it may be necessary to feed the patient by means of a soft rubber tube or by the rectum.

F. DE HAVILLAND HALL.

LARYNX, SYPHILIS OF.—Syphilitic disease of the larynx may accompany the secondary or tertiary manifestations of the disease, or it may be the result of inherited syphilis.

Symptoms.—In the **Secondary Stage** the patient may complain of hoarseness, which sometimes passes on to complete loss of voice, and a feeling of discomfort in the throat. In a few cases there is an irritating cough.

The laryngoscopic appearances are those of a chronic inflammation. The disease usually runs a tedious course, but presents no characteristic features, so that the diagnosis rests on the discovery of syphilitic lesions in other parts of the body. Condylomata are met with in the larynx, although their occurrence is denied by some writers. They have been seen on the epiglottis, vocal cords and

inter-arytenoid commissure, appearing as oval whitish elevations about three to five millimetres long. They run a rapid course, and hence are doubtless often overlooked.

Tertiary Syphilitic Affections of the larynx are of much more grave import than those met with in the secondary stage, and not unfrequently bring about a fatal termination.

Ulceration is the most common manifestation of tertiary syphilis in the larynx. The ulcer may commence as a superficial loss of substance with a deeply inflamed margin, showing a great tendency to spread laterally. More rarely an ulcer results from the softening and breaking down of a gumma, and the process then extends deeply into the subjacent structures, and may lead to perichondritis with caries, necrosis and subsequent exfoliation of the cartilages. The epiglottis is frequently the seat of ulceration and may be entirely destroyed, and, as a result, there may be attacks of suffocation from food entering the larynx. This, however, rarely happens, as patients are usually able to take food without discomfort in spite of the entire loss of the epiglottis.

A grave danger arises from the formation of cicatrices, consequent upon the healing of the ulcers, a process which may eventually end in stenosis of the larynx. The occurrence of œdema, which may take place at any period during the progress of the disease, may also give rise to alarming symptoms.

Another danger is the tendency to the formation of adhesions between the vocal cords; a web-like membrane may form and unite the cords throughout the greater part of their length, the process in some cases commencing by the cord becoming adherent in the centre. Tracheotomy may become necessary for the relief of this condition.

Sometimes the ulcerative mischief sets up changes in the crico-arytenoid joints, as a result of which ankylosis may occur and the vocal cord may become fixed.

Gummata are but rarely met with, they occur as smooth, roundish swellings, generally only to be distinguished from the surrounding mucous membrane by their elevation, their usual seat being the posterior wall of the larynx.

In some instances perichondritis occurs without previous ulceration of the mucous membrane; if it proceed to suppuration, the abscess which forms may burst in any direction.

In **Inherited Syphilis** the larynx is most commonly affected during the first

six months of life, but the symptoms may not manifest themselves until about the period of puberty.

The classification of lesions into secondary and tertiary, as in the acquired disease, does not hold good. Three forms of laryngeal inflammation may be met with. The first is a chronic superficial laryngitis, in which the changes are limited to the mucosa and sub-mucosa; this may go on to ulceration. In the second form, deep, destructive ulceration occurs similar to that met with in the tertiary stage of acquired syphilis; and the third variety is characterized by the gradual deposit of dense fibrous tissue, which by its contraction may cause stenosis of the larynx.

Diagnosis.—As has already been stated, there is usually nothing in the laryngeal affection of secondary syphilis which would enable one to make a diagnosis in the absence of collateral information; it therefore rests on the presence of luetic affections of the skin and mucous membranes and eyes.

In the tertiary stage the diagnosis has to be made from phthisis and from cancer. The differential diagnosis from phthisis is discussed under the head of TUBERCULOSIS OF THE LARYNX. From cancer the diagnosis is at first sometimes a matter of difficulty, but in the latter a new growth usually precedes the ulcerative stage, the progress is a much slower one, and pain is a more common symptom; still, some doubt so often exists that it is advisable to subject the patient to a course of specific treatment before definitely deciding against syphilis and in favour of malignant disease. But even if the patient improve under treatment, it must be remembered that syphilis and cancer are occasionally associated, and specific treatment may thus produce marked improvement for a time.

Prognosis.—This varies with the stage of the disease. The secondary affections of the larynx, though occasionally troublesome from their chronicity, give no other cause for uneasiness; on the other hand, tertiary syphilis of the larynx may cause death from acute oedema, or the glottis may become suddenly obstructed by portions of cartilage which have exfoliated, or deep ulceration may extend into a large vessel and give rise to fatal hæmorrhage. Lastly, the dangers incidental to stenosis of the larynx, which will necessitate tracheotomy, must be borne in mind.

Even after tracheotomy has been performed, a hyperplastic process may extend from the larynx down the trachea, and

eventually cause death. Though a gloomy picture has been drawn of the possibilities attendant upon syphilis of the larynx, nevertheless marked improvement may take place in cases, apparently desperate, when they are subjected to anti-syphilitic treatment. Ulceration is often arrested, swelling disappears, and the normal outline of parts can again be recognized. In young children suffering from congenital syphilis there is an additional element of danger in the small size of the glottis, and the consequent great risk of death from asphyxia.

Treatment.—As a rule, local treatment is of little avail, but astringent applications, such as 10 to 30 grains of chloride of zinc or 15 grains of sulphate of copper to the ounce of water, may assist in clearing up a syphilitic laryngitis; and in tertiary ulcers of the larynx the insufflation of iodoform or iodol (as advised for laryngeal tuberculosis) has given good results. Constitutional treatment is all-important. In the laryngeal phenomena accompanying the secondary stage of syphilis, it is generally advisable to commence with mercury, which can be given either by inunction of $\frac{1}{2}$ drachm of blue ointment daily, or, internally, in the form of blue pill (gr. j-ij), or grey powder (gr. j-ij), or the solution of the perchloride in drachm doses in a bitter infusion. The dose of any one of the three should be taken two or three times a day.

After some weeks of the mercurial treatment, the addition of 5 grains of the iodide of potassium to the mixture containing the solution of the perchloride is generally indicated.

Cases of tertiary syphilis of the larynx sometimes require the most energetic treatment in order to prevent death from asphyxia due to occlusion of the glottis. Though, as a rule, iodide of potassium in doses of from 5 to 30 grains, or even more, every six hours will effect a speedy improvement, there are cases, and these usually the most threatening, in which the administration of mercury as well as of iodide of potassium is necessary. The patient should remain in bed, the room being kept at a uniform temperature, and every four or six hours he should take 10 to 30 grains of the iodide, and twice daily 20 grains of blue ointment should be rubbed into the axillæ or inner sides of the thigh.

Tracheotomy must, of course, be performed if life be endangered by laryngeal stenosis, but the subsequent removal of the canula is usually a matter of great difficulty. Cases of laryngeal stenosis

consequent on cicatricial contraction have been cured by means of gradual dilatation by bougies, &c., but the writer has not been fortunate enough to have succeeded in such cases. Too much stress cannot be laid on the importance of preventing the formation of adhesions between the cords; this can be done by the daily application, by means of the laryngeal brush, of an astringent such as 10 to 30 grains of nitrate of silver or 10 to 20 grains of the sulphate of copper to the ounce of water, or, if necessary, by the introduction of Schroetter's hollow bougies. F. DE HAVILLAND HALL.

LARYNX, TUBERCULOSIS OF (Tubercular Laryngitis; Laryngeal Phthisis).—A chronic disease of the larynx depending on the presence of tubercle, almost invariably associated with pulmonary tuberculosis.

A few cases have been recorded in which the laryngeal affection was primary, and in which no tubercular lesions were present in the lungs.

Symptoms.—The symptoms of tuberculosis of the larynx are so intimately blended with those of the pulmonary affection that it is difficult at times to assign the due share to each organ; even hoarseness, which might be considered essentially a laryngeal symptom, may be owing to an implication of one of the recurrent laryngeal nerves (more commonly the right), in a lesion of the lungs or of the bronchial glands. Hoarseness is an early symptom of the disease, and frequently passes into complete loss of voice; cough and expectoration are invariably present as the result of the combined laryngeal and pulmonary affection. One of the most painful and characteristic of the symptoms of laryngeal phthisis is dysphagia, due to the swollen and ulcerated condition of the larynx. If the epiglottis, from destruction or otherwise, be unable to close the glottis, distressing attacks of coughing and suffocation ensue upon attempting to take food, so that the patient may suffer greatly from malnutrition. The shortness of breath usually observed in laryngeal phthisis is, in many cases, due to the pulmonary mischief. Dyspnoea of sufficient moment to necessitate tracheotomy is rare, but it may come on at any time from oedema of the larynx or more gradually from fixation of the vocal cords in the median position, a condition simulating bilateral abductor paralysis, and brought about by changes in and around the crico-arytenoid joints.

Laryngoscopically one of the earliest signs to suggest the onset of tubercular disease is pallor of the laryngeal mucous membrane. This may be due simply to general anæmia, but its existence should suggest the necessity for a thorough examination of the lungs. Very frequently laryngeal tuberculosis is ushered in with the signs of a chronic laryngitis, and it is only the presence of lung mischief or the further development of the case which leads to the diagnosis. A very suspicious condition is a serrated appearance of the inter-arytenoid fold of mucous membrane; later on, this may be the seat of an ulcer.

The later stages of laryngeal tuberculosis are very characteristic; the epiglottis becomes thickened and turban-like, and the ary-epiglottic folds form pyriform tumours, the mucous membrane covering the swollen parts being pale. Later on, small ulcers appear, and these may eventually coalesce and give rise to a large patch of ulceration, usually covered with a milky-white secretion. In a few cases tuberculous tumours have been recognized in the larynx, and even removed, during life.

As regards the condition of the vocal cords, it is common to find some congestion and thickening and, in the later stages, ulceration. Loss of mobility in one or both vocal cords is also very frequently observed. This may be due to functional causes, as is the case in hysteria, or degenerative changes may have taken place in the laryngeal muscles themselves; there may be paralysis from pressure upon the motor nerves to the larynx; or, lastly, there may be some mechanical condition, such as swelling of the soft parts, preventing the approximation of the cords, or ankylosis or other disease of the crico-arytenoid joint.

Sluggish action or, as it has been termed, *lameness* of one cord has been thought to point to tubercular disease in the corresponding lung, but this is very problematical.

Diagnosis.—In the early stages, when there is merely pallor of the mucous membrane or congestion of the cords, the diagnosis must, to a large extent, depend upon the result of an examination of the lungs, as there is at this time nothing characteristic in the appearance of the larynx. The pale, puffy swelling of the epiglottis and ary-epiglottic folds is pathognomonic. Where ulceration is the chief feature, syphilis and cancer have to be excluded. The withdrawal of some of the secretion from the larynx by

means of a brush under guidance of the laryngeal mirror, and the discovery of bacilli, will settle the point in favour of tuberculosis. As a rule, the ulcerative process is slower in tuberculosis than in syphilis, the ulcers are smaller, more numerous, and are seated on a paler base. In making a diagnosis, however, it must be borne in mind that syphilis and phthisis may co-exist, and that a case originally syphilitic may take on a tubercular transformation. Ulceration attacking one cord alone is in favour of syphilis. Tuberculosis of the larynx may usually be differentiated from malignant disease by the presence of pulmonary phthisis, the pallor of the pharynx and larynx, the pale, puffy swelling of the arytenoids, and by the fact that, as a rule, both sides of the larynx are implicated. The ulcers of laryngeal phthisis are usually small and multiple, a single large ulcer being more characteristic of malignant disease. The age of the patient will often aid in the diagnosis, as malignant disease is rare under thirty-five, whereas laryngeal phthisis is most common between the ages of twenty and thirty, and three-quarters of the cases, according to Morell Mackenzie, occur under the age of forty. As already mentioned, the discovery of the tubercle bacillus will clinch the diagnosis.

Prognosis.—Though cases of arrest and even cure of tubercular ulceration of the larynx have from time to time been recorded, and especially within the last few years, as the outcome of the recent advances in the local treatment of the disease, nevertheless it must be confessed that the outlook of a patient with laryngeal tuberculosis is a gloomy one. Morell Mackenzie's statistics show that of one hundred cases submitted to post-mortem examination twenty-six died in the first twelve months, fifty-six within eighteen months, and seventy-five within two years, and only twelve lived upwards of two and a-half years. Since these figures were compiled the state of affairs has somewhat improved, though it cannot yet be said that the treatment of this condition is attended with much success.

Pathology.—At the autopsy there will usually be found swelling of the mucous membrane, due to cellular infiltration of the mucosa and sub-mucosa, associated with tubercles, which in rare cases have been described as constituting small nodules on the surface of the mucous membrane. The tubercles soon break down, forming superficial ulcers, which, by extending into the deeper tissues, lead

to perichondritis, with necrosis and exfoliation of the cartilages. Tubercle bacilli are found in the secretion bathing the surface of the ulcers, and in the giant-cell systems.

Ætiology.—Laryngeal tuberculosis is met with in about 30 per cent. of the cases of pulmonary tuberculosis, and, as already stated, it is usually secondary to the disease of the lung, though cases have been recorded in which, at the autopsy, tubercular disease of the larynx has been found without any deposit in the lungs. It seems probable that syphilitic ulceration of the larynx may predispose to laryngeal tuberculosis by affording a good nidus for the development of the tubercle bacillus.

Treatment.—The constitutional treatment is the same as that which is found useful in cases of pulmonary tuberculosis, except that high altitudes are not suitable to sufferers from laryngeal phthisis. The local treatment is very important, and of late years encouraging advances have been made in this department, especially in the direction of the destruction of the morbid tissues and the promotion of cicatrization of ulcers. Sedative and antiseptic inhalations are often beneficial. Cocaine has almost superseded morphine as a remedy for dysphagia; it may be applied in a 5 or 10 per cent. solution, by means of either a spray apparatus or brush, five minutes before a meal is taken. The difficulty in swallowing liquids which attends loss of the epiglottis by ulceration may be obviated by placing the patient prone across the bed, with the head hanging over the side, and allowing him to suck milk by means of a piece of india-rubber tubing from a mug placed on the floor (Wolfenden).

Painting the ulcerated surface with a 5 to 20 per cent. solution of menthol in olive oil causes but little discomfort, while it relieves pain and dysphagia and promotes the cicatrization of the ulcers. The insufflation twice daily of a powder composed of iodol (or iodoform) and boric acid, of each 1 grain, and of hydrochlorate of cocaine and hydrochlorate of morphine, of each $\frac{1}{2}$ to $\frac{1}{3}$ grain, after cleansing the surface of the ulcer with an alkaline spray, can be confidently recommended. Lactic acid in a 20 to 60 per cent. solution has been found very useful in destroying the infiltrated tissues and causing the formation of a cicatrix. The application is very painful, but the pain may be lessened by painting a 20 per cent. solution of cocaine over the mucous membrane previously, and by the

use of gargles of ice-water and cold compresses.

Curettage the infiltrated tissues and bases of ulcers has been tried, and the operation may be followed by the application of lactic acid.

Tracheotomy as a curative measure has not received much support; by the great majority this operation is restricted to cases where life is immediately threatened by laryngeal stenosis.

F. DE HAVILLAND HALL.

LARYNX, TUMOURS OF, MALIGNANT.—New formations of a malignant nature growing from the mucous membrane of the larynx.

Intrinsic malignant disease of the larynx includes tumours growing from the ventricular bands, the ventricles, the vocal cords, and the parts immediately below the cords. The term *extrinsic* is applied to growths taking their origin from the epiglottis, the ary-epiglottic folds, the inter-arytenoid fold, &c. The intrinsic form occurs in by far the greater number of cases.

Symptoms.—Hoarseness is one of the earliest symptoms of intrinsic cancer of the larynx, and though it generally increases with the progress of the disease, the voice is hardly ever entirely lost. Pain in many cases comes on very early, but it may be quite absent, of so trivial a nature, or so temporary, as not to form an important feature of the disease. Extension of pain to the ear is in no way pathognomonic of cancer, as it is also present in other chronic laryngeal diseases. Cough is not a constant symptom; there is usually, however, an increased secretion of mucus, and late on in the disease the expectoration as well as the breath of the patient may be offensive.

Hæmorrhage, especially if abundant, points to malignant disease. The degree of dyspnoea will depend on the amount of obstruction to the lumen of the larynx, whereas dysphagia is affected by the situation of the growth, being present when the posterior wall is attacked or the epiglottis implicated. Cachexia, such as is met with in malignant diseases of other organs is not a marked feature of the laryngeal affection.

Objectively, though there is nothing absolutely distinctive in the appearance of laryngeal cancer, still the experienced observer will generally be able to form a correct opinion from an examination of the parts.

Cancer of the larynx is eminently a polymorphic disease, thus it may simulate

a papilloma or a fibroma, and in rare cases the growth is even distinctly pedunculated.

A fringe-like growth attached to nearly the whole length of a cord, and even extending to the ventricular band, the arytenoid cartilage and the ary-epiglottic fold, the other half of the larynx being healthy, is, according to Semon, very suggestive of cancer when it occurs in a patient above fifty. The same observer has rightly emphasized the importance of impaired mobility of the affected cord as a diagnostic sign of cancer.

Malignant growths most frequently spring from the ventricular bands, and the posterior part of the larynx is attacked by preference.

In the later stages of the disease the soft parts of the larynx may become infiltrated, and finally perichondritis may result, and the malignant growth may even penetrate the skin and appear externally. Enlargement of lymphatic glands is very rare with intrinsic, common with extrinsic cancer of the larynx.

Diagnosis.—Age is an important factor in arriving at a conclusion; thus, in a patient above thirty-five, in whom a laryngeal growth is detected, the *possibility* of this being of a malignant nature should be contemplated, and after the fiftieth year the *probability*. The position of the growth at the posterior part of the larynx, and the immobility of the affected cord, have been already mentioned as diagnostic points in favour of cancer. Microscopic examination of portions of the growth, removed for the purpose, or expelled by cough, is only of decisive value when the growth is found to be malignant; a merely negative result is of little or no significance.

For the diagnosis of malignant disease of the larynx from syphilitic and tubercular affections of that organ, the articles on SYPHILIS and TUBERCULOSIS OF THE LARYNX may be consulted.

Prognosis.—Intrinsic carcinoma of the larynx is not so quickly fatal as the extrinsic form; still, death may occur within the year, but on the other hand it does not usually occur under eighteen months, and may even be delayed three, four or more years. In extrinsic carcinoma the duration of life is considerably shorter.

Morbid Anatomy.—Malignant tumours of the larynx include the sarcomata and the carcinomata, the latter occurring much more frequently than the former. The anatomical peculiarities of these growths in the larynx differ in no respect from similar growths elsewhere, and it

need only be said that epithelioma (squamous-celled carcinoma) is by far the most common form of malignant disease affecting the larynx.

Treatment.—When once the diagnosis of malignant disease has been satisfactorily established it is not advisable to attempt to remove the growth *per vias naturales*, though in a few cases in which this procedure has been carried out the patients have been free from recurrence for upwards of two years, and Schnitzler has recorded a case in which the patient was alive and well twenty-one years after the intra-laryngeal removal of a tumour diagnosed clinically and microscopically to be epithelioma.

In cases which are not suited for more radical treatment, and in which dyspnoea is an urgent symptom, tracheotomy will in a large number of instances prolong the duration of life.

Partial excision of the larynx for malignant disease, if undertaken at an early period, promises to be a very successful operation, and is attended with but slight immediate risk to the patient, whereas complete removal of the larynx has yet to justify its performance, as the mortality due to the operation is very great, and the after results have been anything but satisfactory. Many of the patients, so far from being bettered by the operation, were placed in a worse position by it.

In the event of no operative treatment being determined on, attempts may be made to relieve the pain and dysphagia by insufflations of morphia, gr. $\frac{1}{8}$ to $\frac{1}{2}$, or the application of a 20 per cent. solution of cocaine by means of the spray or brush. In some cases it may be necessary to feed the patient *per rectum*.

F. DE HAVILLAND HALL.

LARYNX, TUMOURS OF, NON-MALIGNANT.—Growths of a benign character, projecting from the mucous membrane of the larynx.

All the growths met with in other organs of the body may have their counterpart in the larynx. According to Morell Mackenzie, papillomata are by far the most frequent, sixty-seven out of a hundred cases being deemed to be of this nature; fibromata come next in frequency with eleven cases. Cysts are comparatively rare.

Symptoms.—The symptom which is most commonly complained of is some alteration in the voice. This may vary from slight hoarseness up to complete aphonia. The degree of loss of voice does not depend upon the size of the growth: a

small sessile tumour will often cause much greater hoarseness than a larger tumour, which, by being pedunculated, does not interfere with the vibration of the cord to the same extent. Should the pedicle be long, and the polyp freely movable in the respiratory current, the condition of the voice will vary very much, according to the position of the polyp; at one moment the patient may be able to speak in a natural voice, at the next he may be almost aphonic, on account of the growth being caught between the cords. Cough is not a constant symptom. The majority of patients with laryngeal growths are free from it, but in a certain number it is a very troublesome complaint, being hacking or irritating in character. Dyspnoea depends almost entirely on the size of the growth, and to a less extent on its position. For example, tumours springing from the margin of the glottis are much more likely to cause dyspnoea than those originating from the epiglottis, and which consequently obstruct the air-passage less. Dysphagia is only met with in cases where, on account of the size of the growth, there is some mechanical interference with the act of swallowing, or when it is seated on the epiglottis. Pain is almost invariably absent.

Diagnosis.—This is usually to be effected by means of the laryngoscope, and may be confirmed by the microscopic examination of portions of the growth expectorated by the patient or removed by the surgeon. The diagnosis between malignant and non-malignant growths is discussed under the former heading. The condylomata of secondary syphilis are to be distinguished by the rapidity with which they disappear under treatment. Gummata and the excrescences met with in tertiary syphilis might possibly mislead, but attention to the general condition of the larynx, and the help furnished by constitutional symptoms, should prevent error; the same holds good in the case of tubercular infiltration or tubercular tumours. But the possibility of the co-existence of tertiary syphilis or phthisis and an independent papilloma, or other growths in the larynx, should be remembered. In a case of phthisis with hoarseness observed by the writer, the appearances were at first those of a chronic laryngitis with thickening of the left vocal cord, and were compatible with the diagnosis of laryngeal tuberculosis, secondary to pulmonary phthisis. After an interval of three years a growth the size of a small cherry was found attached to one of the

vocal cords, occupying about two-thirds of its length. The results of treatment proved that the laryngeal condition was quite unconnected with that of the lungs.

Prognosis.—This has to be considered with regard to (1) the danger to life and (2) the state of the voice. The danger to life is comparatively small, as even in those rare cases in which the growth cannot be removed *per vias naturales* there is always the possibility of recourse to tracheotomy, and if this operation be not unduly postponed the risk to life is small.

As regards the voice, greater caution is needed in expressing an opinion. Some growths may after a time remain stationary, and cease to give trouble. A distinguished singer, who had a sessile growth (probably a fibroma) seated on the left cord, is known to have pursued his profession without any apparent damage to the voice. A single growth, especially if pedunculated, can generally be so completely removed that the restoration of voice may be confidently predicted; on the other hand, in the case of multiple and recurrent papillomata the prognosis is much less favourable. Thanks to the introduction of cocaine, the operative procedures for the removal of laryngeal growths have been greatly facilitated.

Pathology.—Papillomata are composed of a basis of connective tissue supporting blood-vessels, and covered with epithelium. They may be sessile or pedunculated, and either single or multiple. They often present a cauliflower-like appearance, and most commonly grow from the vocal cords. Papillomata are generally of a pinkish colour, but they may be greyish or white.

Fibromata consist of firm, dense, fibrous tissue but sparingly supplied with blood-vessels. The surface is usually smooth, and the colour varies from white to pink. When growing on a vocal cord a fibroma can often only be recognized by its shape, as in colour it is indistinguishable from the cord. Fibromata may be sessile or pedunculated, and are usually oval or round.

Cysts generally spring from the epiglottis, or from the laryngeal ventricles, and vary in size from a pin's-head to a bantam's egg (Semon). They may be classed among retention-cysts.

Etiology.—Any cause of irritation seems sufficient to serve as the starting-point of non-malignant growths in the larynx, hence chronic laryngitis is the most frequent precursor. Congenital growths have been described.

Treatment.—Recent experience has fully confirmed the following statement enunciated at the International Medical Congress of 1881:—"Every benign laryngeal tumour ought, if possible, to be removed *per vias naturales*, and only if an experienced laryngologist has established the inexpediency of this method may the extra-laryngeal operation be adopted." Of the various methods of removal, Morell Mackenzie's cutting forceps are most generally serviceable, but the galvano-caustic loop will at times render valuable assistance. Painting or spraying the pharynx and larynx with a 20 per cent. solution of the hydrochlorate of cocaine greatly facilitates intra-laryngeal operations. All caustic applications to benign growths in the larynx are to be condemned; they can do no good, and may, by exciting spasm or inflammation, render tracheotomy necessary. Some growths, notably fibromata, as already mentioned, after a time remain stationary, and may not require treatment. The fear, which has been expressed by some writers, that repeated attempts at the removal of benign new growths by the endo-laryngeal method may result in the conversion of benign into malignant growths, in consequence of the irritation to which they may have been exposed, has been shown to be utterly groundless. The collective investigation started by Semon, as editor of the *Centralblatt für Laryngologie*, has resulted in the collection of 10,747 cases of benign new formations in the larynx, and of these, 8216 were operated on by the endo-laryngeal method. A transformation of growths apparently benign into malignant is reported in 32 out of the 8216 cases; therefore, in less than a $\frac{1}{2}$ per cent. of all operation cases. But when these 32 cases come to be carefully analysed, in only 4 was the evidence absolutely in favour of this transformation; of the remainder, in some it was probable, in others very dubious. Moreover, it must be borne in mind that this transformation of benign into malignant growths is reported in cases which were never subjected to operative interference.

F. DE HAVILLAND HALL.

LATERAL SCLEROSIS, AMYOTROPHIC.—A combined system-lesion of the lateral columns and anterior grey matter characterized clinically by motor weakness and rigidity of limbs, with early supervention of muscular atrophy and involvement of the nuclei in the medulla oblongata.

Symptoms.—The disease begins with weakness and rigidity of the arms, soon followed by general wasting of the muscles, with fibrillar twitchings. Contractions rapidly supervene in the upper limbs. The arm is applied to the side of the body, the forearm is semi-flexed and pronated, and the hand and fingers flexed. Much force is required to overcome this permanent rigid state, and such attempts excite pain.

In a few months the wasting becomes extreme, but the spasm still persists, though possibly to a less degree. The muscles of the neck sometimes become stiff and then feeble, so that the head is flail-like, falling forwards or backwards or to one or the other side.

Within a year the lower limbs become weak and rigid, presenting the usual features of spasmodic paralysis. Wasting of the lower limbs, however, is by no means constant, as is the case with the upper extremities. In the third stage bulbar paralysis supervenes, the face, lips, tongue, pharynx and larynx becoming involved. Throughout the disease the tendon reflexes are much exaggerated, and clonus is readily elicited. The bladder and rectum remain unaffected, and sensation is unimpaired.

Diagnosis.—It may be here remarked that Charcot's contention, that the grouping of symptoms just mentioned constitutes a definite morbid state, has not been universally accepted. Leyden, Gowers, and others are of opinion that cases of amyotrophic lateral sclerosis belong to the category either of lateral sclerosis with consecutive muscular atrophy or to progressive muscular atrophy with degeneration of the pyramidal tracts, and that the extension of the lesion in one or the other case is accidental.

It is, however, pretty generally admitted that symptoms referable to disease of the lateral columns and of the anterior grey matter occur in the order already described, and that in such cases early implication of the medulla oblongata takes place.

The clinical account above given indicates the points of difference between amyotrophic lateral sclerosis and the two affections with which it may be confounded—viz., lateral sclerosis and progressive muscular atrophy. As regards the disease under consideration, it should be stated that the loss of power precedes the wasting, and that the atrophy attacks all the muscles of a limb simultaneously. In progressive muscular atrophy, the weakness and

muscular wasting, occur together and are proportional; the atrophy, moreover, attacks the muscles according to their physiological grouping.

Prognosis.—According to Charcot, death ensues within three years from the commencement—sometimes earlier.

Morbid Anatomy.—The direct and crossed pyramidal tracts in the cord, the anterior pyramids of the medulla, and the pyramidal tract at some levels higher up have been found sclerosed. The anterior grey matter of the cord and the nuclei in the medulla are atrophied, and the nerves proceeding from them degenerated. The affected muscles undergo great atrophy, with degenerative changes.

Etiology.—On this point nothing definite is known.

Treatment.—No remedies seem to have any influence on the course of the disease. The treatment can only be palliative.

W. B. HADDEN.

LATERAL SCLEROSIS, PRIMARY (Spasmodic Tabes Dorsalis; Spasmodic Spinal Paralysis).—A disease characterized clinically by paralysis of the limbs, with rigidity and increased tendon-reflexes, and absence of sensory and nutritive disorders.

The anatomical change is a primary sclerosis of the pyramidal tracts.

Symptoms.—The disease begins gradually with weakness of the legs, followed by dragging of the feet, muscular twitching, and later on by muscular rigidity. The spasm, at first intermittent, finally becomes permanent. The lower extremities become fixed in a position of extension, the thighs being strongly adducted, and the feet in the position of talipes equino-varus.

The characteristic spastic gait is now evident. During progression each lower limb is brought forward as a whole, the knee being stiff and the toes dragging along the ground. As the ball of the foot rests on the ground, clonus of the limb is set up by extension of the calf muscles. In this way the gait has imparted to it a peculiar jerking or hopping character.

As the disease progresses, the lower limbs become weaker and stiffer, and walking may become impossible.

In occasional cases, the extensor spasm gives way to flexion, temporary at first, and finally becoming persistent. The affected limbs are from an early period liable to spasmodic contractions and tremblings, and later on clonus of the limb can be readily excited by slight stimuli, and may even occur spontane-

ously. Increased tendon reactions, with ankle and knee clonus, are present throughout, though in the later period they are often difficult to obtain in consequence of the intensity of the spasm. The plantar reflex is either normal or slightly increased. Not uncommonly the weakness and rigidity extend upwards, involving first the muscles of the back and abdomen and then the upper extremities. When the latter are implicated, the rigid condition is that of flexion. The arm is fixed to the side of the body, the forearm pronated and semi-flexed, and the wrists and fingers strongly flexed.

It must be mentioned that the muscles do not undergo atrophy, and that their electrical reactions are either normal or slightly diminished.

Subjective feelings of numbness, tingling and the like are not infrequent, but sensory disorders, properly speaking, are absent. The sphincters are rarely affected, and sexual power is as a rule preserved.

The progress of the disease is liable to many variations, and its course is essentially chronic. Sometimes the lower limbs alone are involved, and the affection may never become extreme. In rare instances the disease has a hemiplegic distribution, and now and then the upper limbs are attacked before the lower.

Diagnosis.—Slowly increasing weakness of the lower limbs with rigidity occurs in various morbid states, and it is often impossible to determine the exact nature of the lesion. A careful inquiry should be made into the mode of commencement of the attack. An acute onset followed by slowly advancing paraplegic rigidity suggests a focal lesion followed by descending degeneration of the pyramidal tracts.

An examination of the back should always be made. The presence of an angular curvature would of course be practically conclusive against a primary lateral sclerosis. The existence of localized tenderness or of rigidity of the spine, apart from irregularity, should excite the suspicion of caries.

Again, in disseminated sclerosis a spasmodic paraplegia is not uncommonly the first indication of the disease, and it may be the sole condition for a long time. Sooner or later, however, other symptoms usually arise, such as nystagmus, tremors of the hands, head or tongue, or affection of speech, which will enable one to pronounce a definite diagnosis.

Hysterical paraplegia with spasm may be mistaken for lateral sclerosis. In the former, however, ankle and knee clonus, although sometimes present, have not the same persistency as in organic disease, and it is asserted that the contraction is more fixed than in lateral sclerosis. Practically, however, there is often considerable difficulty in diagnosing between these conditions, and the difficulty is increased by the probability that in prolonged cases of functional spasm of the lower limbs organic change occurs in the lateral columns.

The diagnosis of a primary system lesion of the pyramidal tracts is often a matter of great difficulty, and the presence of this condition should not be entertained until all other morbid states, of which spasmodic paraplegia forms a part, are excluded. This however is frequently impossible, and hence the existence of primary lateral sclerosis often cannot be positively affirmed.

The difference between primary lateral sclerosis and amyotrophic lateral sclerosis will be found under the description of the latter.

Prognosis.—The disease is usually slowly progressive, and extends over many years. In rare cases improvement to a considerable extent has been recorded, and it has even been asserted that recovery has taken place.

Morbid Anatomy.—The direct and crossed pyramidal tracts are sclerosed, and their upward prolongations in the medulla, pons, crura, and cerebral hemispheres as far as the motor cortex, have been found degenerated.

Etiology.—Males are more commonly affected than females, and the onset usually occurs between the ages of twenty and fifty. Syphilis, injury to the back, exposure to wet and cold are alleged to have some share either as predisposing or exciting agents.

Treatment.—Prolonged rest, massage of the limbs, and Turkish baths are useful. Bromide of potassium, cannabis indica, opium and belladonna have little effect, and that merely temporary. Electricity, nux vomica, and strychnine are contra-indicated, as they tend to cause increased spasm. The treatment by suspension (*see under LOCOMOTOR ATAXY*) deserves a trial.

W. B. HADDEN.

LEAD, Poisoning by (Plumbism ; Saturnism).—For convenience of description this subject may be considered under the following headings :—

ACUTE POISONING BY LEAD.**A. Accidental and Suicidal.****B. Acute Poisoning of Lead Workers.****CHRONIC POISONING BY LEAD.**

ACUTE POISONING BY LEAD.—A. Accidental and Suicidal.—The salts of lead are not often chosen by the would-be suicide, and cases of accidental poisoning are by no means common.

The acetate or sugar of lead is the salt most often taken, but its poisonous properties are feeble, and recovery has followed when an ounce has been swallowed.

Symptoms.—The chief symptoms are a metallic taste, with dryness and burning in the mouth, followed by vomiting and pain in the abdomen. The pulse is small and frequent, the urine is scanty, and cramps and pains in the limbs are complained of.

Prognosis.—Recovery is the usual termination in such cases.

Post-mortem Appearances.—The mucous membrane of the stomach and intestines is generally coated with a thick layer of whitish or yellow mucus, and may show traces of inflammation. Lead may be found in various organs on chemical examination (*vide infra*).

Treatment.—Vomiting should be encouraged, and the stomach washed out. Dilute sulphuric acid (℥xxx in water) or the sulphate of magnesia or soda (℥ss) should be at once administered, freely diluted with water, or all three may be given together. The patient should be allowed to drink freely of milk, or white of egg and water. If there be severe pain a hypodermic injection of morphine (gr. $\frac{1}{4}$) should be administered, and poultices applied to the abdomen. Subsequently a course of iodide of potassium is advisable with a view to eliminate the metal from the system.

B. Acute Poisoning of Lead Workers.—Although the more common effect of the absorption of the metal upon those engaged in lead works is to produce the symptoms described under Chronic Poisoning, nevertheless cases of a very acute and fatal character are occasionally met with.

Symptoms.—The first symptom observed is anæmia, which rapidly increases in degree, and is followed by vomiting, colic, and headache. A blue line quickly appears on the gums. Optic neuritis is often present, and there may be neuroretinitis, and either diplopia or amblyopia. The temperature may be slightly

raised. After an illness perhaps of only a few days' duration, the patient may be suddenly seized with acute cerebral symptoms, such as convulsions of an epileptiform character, and delirium. On recovery from the fits the mental condition of the patient may simulate that produced by taking an excess of alcohol (Stephen Mackenzie). The convulsions may recur, and be followed by coma and death.

Prognosis.—This is very grave in cases marked by the presence of acute cerebral symptoms, especially convulsions and coma, but recovery has been known to take place after convulsions even when double optic neuritis was present. Recovery is usually complete in the non-fatal cases.

Morbid Anatomy.—In the most acute cases no alterations of the viscera can be found after death other than an hydræmic condition of the brain (Oliver).

The other morbid appearances are described under Chronic Poisoning.

Etiology.—All observers agree that there is in these very acute cases a predisposition on the part of the individual, and probably the predisposition also runs in families. Those recently employed in lead works are much more likely to suffer than old hands. Dr. Stephen Mackenzie has suggested that the attacks of acute toxæmia are more frequent in the winter than in the summer. Such cases have been more often met with in females than males, but it is somewhat uncertain whether, for equal numbers, women employed in lead works are affected more or less than men.

Treatment.—Acute cases such as those above described do not occur in lead works under proper medical supervision, where careful and systematic examination of all new hands is enforced, and such an examination should be made compulsory by legal enactment. Any such employé showing signs of poisoning should be recommended to adopt some other occupation.

The sulphates of magnesia and soda should be freely administered, with opium or morphine by subcutaneous injection if colic be present. When the symptoms are acute, iodide of potassium should not be given, as the toxic effects may be thereby increased, owing to the sudden liberation of lead which has been fixed in the tissues and which then passes into the blood.

The subsequent treatment is similar to that described in the following section.

CHRONIC POISONING BY LEAD.—Lead may gain entrance into the body in a

variety of ways, but only the most common can be mentioned here.

Persons engaged in lead works, and those who handle the metal or its alloys in the course of their occupation—such as painters, compositors, typefounders, and white enamellers—naturally suffer most frequently; but in many cases of chronic poisoning the occurrence may be described as accidental.

The drinking water may be contaminated in passing through leaden pipes, and the first pint of beer drawn in the morning, if it have remained all night in lead pipes, will, in time, poison the regular early tippler. Wines or beverages (*e.g.*, cyder) may contain the metal from the use of leaden presses in the process of manufacture; fine particles of lead may become mixed with the flour if the cracks in the stones of a corn-mill have been filled up with the metal; and acid foods may dissolve it out of the glaze on vessels in domestic use.

Symptoms.—The primary effect of the presence of lead in the body is the production of anæmia, which is followed later by a cachexia to which the name of “saturnine” has been given.

The other effects of lead may be conveniently described under the headings of the respective systems.

Digestive System.—The so-called *blue line* on the gums is due to the deposit of fine particles of sulphide of lead in the papillæ of the gums, and first appears as a single row of distinct black spots, which subsequently increase in number. The metal is absorbed from the blood, and, after conversion into a sulphide by the action of the sulphuretted hydrogen in the albuminous matters which are either contained in the tartar or deposited between the gum and the tooth, it is fixed in and around the vessels of the papillæ. A similar deposit of sulphide of lead may form in the mucous membrane of the upper or lower lip where it comes into contact with an accumulation of tartar on the teeth. The blue line may form very rapidly, in a few days even. The line, when once formed, remains for a considerable time, possibly for as long as a year (Gowers); but on this point there is some divergence of opinion. When absent, the blue line may sometimes be produced by the administration of iodide of potassium if lead be present in the system, as this salt combines with the metal to form a soluble iodide.

Constipation is one of the early symptoms of this condition, and is usually associated with such signs of dyspepsia

as vomiting, a furred tongue, and foul breath.

Colic (*colica pictorum*), perhaps, comes next in order of frequency; but in acute cases vomiting usually precedes colic and constipation. The attacks are marked by excruciating abdominal pain, which is, as a rule, relieved by firm pressure. The abdomen is hard and retracted. The pulse is slow, and the arterial tension is raised. Although doubted by some observers, the pain is probably actually due to spasmodic contraction of the colon, and the attack is therefore truly “colic.”

Nervous and Muscular Systems.—Pains in the limbs are of common occurrence, and are often neuralgic in character; the muscles may be tender on pressure. In the ætiology of neuritis (*q.v.*), or, as it is generally termed, “peripheral neuritis,” lead plays an important part.

Dr. Gowers distinguishes two varieties of lead paralysis—the “degenerative” and the “primary atrophic” forms. In the former, which is the one most frequently met with, the loss of power precedes the wasting, and the muscles present the reaction of degeneration. In the latter, the weakness and wasting come on simultaneously, and proceed *pari passu*, and faradic and voltaic irritability are both lessened in proportion to the wasting.

The musculo-spiral nerve is usually the first attacked, the result being a paralysis of the extensors and supinators of the forearm—an affection commonly known as “wrist drop” or “dropped hand.” The affected muscles are wasted and paralysed; the hand hangs from the wrist; the fingers are flexed, and cannot be extended; if placed with the palm downwards on the table, the patient is unable to turn the hand over. It is especially to be noted, however, that the supinator longus—which is also a flexor of the forearm when the elbow is bent to a right angle—and, when the leg is affected, the extensor ossis metacarpi pollicis, usually escape.

It is by no means uncommon to meet with cases in which the paralysis has not advanced to the extent just described, and which are only marked by a certain degree of weakness of the affected muscles.

In the “primary atrophic” form the muscles forming the thenar eminence, the interossei and the lumbricales are especially likely to become involved, and fibrillary tremor may be present, as in progressive muscular atrophy.

Both arms are commonly affected; but the right, probably because it is the one

most employed by a painter in his work, usually suffers most.

Sometimes the muscles about the shoulder are the first to be attacked; the deltoids, the dorso-scapular muscles, and the trapezii then become atrophied and paralysed. The legs may also become affected, the extensor longus digitorum and the peronei, the analogues to the muscles of the arm which chiefly suffer, being most often attacked. The tibialis anticus muscle usually escapes.

In rare cases the affection may be widespread, and involve nearly all the voluntary muscles.

Melancholia, mania and, especially, epileptiform convulsions are prone to occur in advanced degrees of the chronic affection, and such cases may end fatally with delirium and coma.

The *electrical reactions* in the "degenerative" form are those of peripheral neuritis. To faradism the reaction with both nerve and muscle is absent, whilst the galvanic current applied to the muscle gives reactions which are more marked than in health—i.e., the reaction of degeneration is present.

In the "primary atrophic" form the muscles still act to faradism, although the irritability is lowered in proportion to the wasting, the voltaic irritability is lowered in a similar manner, but is sometimes more marked than the faradic, and there may be qualitative change (Gowers).

Circulatory System.—If gout be present as a complication, and it is a very common one, the high arterial tension will necessarily entail a liability to degenerative changes in the myocardium and the walls of the arteries.

Respiratory System.—A marked tendency to attacks of asthma has been observed in the subjects of plumbism.

Urinary Organs.—The liability to gout involves a corresponding proneness to chronic interstitial changes in the kidneys.

Diagnosis.—In doubtful cases, the blue line on the gums is the most important evidence of the presence of lead in the system. The "primary atrophic" form of lead paralysis is often closely simulated by progressive muscular atrophy; but the more common variety—i.e., the degenerative—may be distinguished from progressive muscular atrophy by the absence of the fibrillary tremor of the muscles and by the marked difference in the electrical reactions. In progressive muscular atrophy the galvanic and faradic irritability of the muscles usually diminish as the atrophy progresses, and,

when this is extreme, no reaction may be obtained with either form of stimulation, even with the strongest currents, but these conditions are not invariable. (The electrical reactions in the two forms of lead paralysis have already been described.) Again, in the former disease the muscles are affected according to their physiological grouping; whilst in the latter the paralysis corresponds to the anatomical distribution of the nerves. Lastly, in this form of plumbism the paralysis precedes the atrophy, whereas in progressive muscular atrophy the loss of power is usually in proportion to the wasting of the muscles.

Prognosis.—This is almost invariably favourable in lead colic; but there is a marked liability to subsequent attacks unless the cause be removed.

Cases of lead paralysis of the "degenerative" form and limited to the muscles of the forearms, if submitted to electrical treatment in the early stage of the affection, usually recover completely. If, however, the wasting and degeneration of the muscles have advanced in degree, and the affection be widespread, the loss of power may be permanent, and as already stated, the presence of cerebral symptoms adds greatly to the gravity of the prognosis in such cases.

The course of the primary atrophic form is very chronic, and such cases may never recover completely (Gowers).

Pathology and Morbid Anatomy.—It is now generally recognized that the explanation of the various paralytic affections met with in lead poisoning is chiefly to be sought for in the condition of the peripheral nerves, certainly in the common or "degenerative" form of the affection. The "primary atrophic" form is possibly dependent upon changes in the spinal cord.

On microscopical examination the nerves present the appearances generally met with in peripheral neuritis, for which the article on NEURITIS may be consulted. The degenerative changes sometimes affect the anterior roots of the nerves. The changes in the spinal cord are usually limited to the anterior cornua, the ganglion cells of which have in several cases been found to have undergone atrophy.

The changes observed in the brain in cases marked by cerebral symptoms have not presented any uniformity.

The affected muscles are wasted, brittle and of a pale-yellowish colour. The fibres are narrower than normal, and in advanced stages all traces of muscular tissue may disappear.

Treatment.—Prophylaxis is obviously of the first importance.

As already stated in the section on Acute Poisoning of Lead Workers, the medical examination of persons recently employed in lead works is of the greatest importance. Absolute personal cleanliness, extending to the condition of the finger-nails, the use of a working suit of clothes, a daily warm bath after work, provision for the taking of meals outside the works, and the use of respirators where the air is charged with particles of the metal, are the chief preventive measures which should be enforced in all lead works. It is generally found that the employés endeavour to evade these regulations, and in the best-managed works the enjoyment of certain privileges is restricted to those who rigidly observe them. "Treacle beer" and sulphuric acid lemonade as beverages are of service in preventing the effects of the metal.

Constipation should be relieved by occasional doses of sulphate of magnesia.

Colic is best treated by the application of hot dry fomentations to the abdomen, frequently renewed. The bowels should be cleared by castor oil, with each dose of which from 5 to 10 minims of tincture of opium may be usefully combined, the dose of the latter being in proportion to the severity of the pain. Sulphate of magnesia is also an excellent purgative in such cases, and may be administered, after the more acute symptoms have subsided, in combination with iodide of potassium, the soluble iodide of the metal which results being eliminated by the action of the purgative.

Lead paralysis is best treated by massage to the affected muscles, and the application for about ten minutes daily of the constant current. The treatment should be persevered with for long periods. J. K. FOWLER.

LEPROSY (Lepra).—A chronic, transmissible, specific, bacillary and exclusively human disease, characterized by the formation of neoplasms, which develop in definite elective sites, especially in the skin and certain mucous membranes, in the nerves, in related lymphatic glands and in certain viscera.

When the leprosy formations exclusively or mainly affect the skin, mucous membranes and corresponding lymphatic glands, the disease is spoken of as *cutaneous* or *tuberculated leprosy*; when the neoplasms are localized in the nerves, the terms *nerve*, *non-tuberculated* or *anæsthetic*

leprosy are employed. These two phases are rarely met with in pure forms, and the above terms are usually applied according as the one or the other set of symptoms predominates.

In many cases the two phases are present in fairly equal proportions, or both are well marked, constituting the complete manifestation of the disease process; to this condition the term *mixed leprosy* is applied. Sometimes nerve leprosy follows upon the tuberculated form, and more rarely the latter supervenes on the former.

The term "anæsthetic" leprosy, so frequently used, is not a good one, since more or less anæsthesia is always present in tuberculated leprosy. So also with regard to the name "eruptive, macular or spotted" leprosy; a macular eruption is common to both tuberculated and nerve leprosy, though each phase of the disease has its own pathognomonic macular eruption.

Initial Lesion.—Although observers have described various appearances in sores or wounds or at points of the skin which were supposed to be the sites of inoculation, there is no definite form of *primary* or *initial lesion* known, comparable to that of syphilis.

The exact methods and channels of the introduction of leprosy into the system are to a great extent undetermined.

The *incubation* or *latent period* has remarkable features, and may be very prolonged—up to twelve or twenty years or more. It very commonly lasts from three to six years. The bacillus, even when introduced into the body, appears to remain quiescent until suitable conditions, not at present understood, arise for its germination, and the evolution of the disease is then irregular.

Premising that only a certain proportion of cases of *non-tuberculated* or *nerve* leprosy remain purely such throughout their course, and that in most cases of *tuberculated leprosy* nerve symptoms sooner or later supervene, it is nevertheless convenient to describe the symptoms of each phase separately.

Tuberculated Leprosy.—*Prodromal Stage.*—The most constant premonitory symptoms are dyspeptic troubles, marked drowsiness, lethargy and pyrexia, but such symptoms are too indefinite to be of any value for diagnostic purposes.

The *eruptive stage* is characterized by the evolution of a pathognomonic macular eruption of an erythematous type. The maculæ are rounded or oval in outline, abruptly limited, hyperæsthetic and of

any size from a shilling to a saucer. They are situated most frequently on the cheeks, temples or forehead, where they may excite considerable œdematous swelling, or on the anterior aspect of the forearms or the outside of the thighs (Hillis). The earliest maculæ may disappear and be succeeded for some weeks or months by fresh crops.

On the sites where these maculæ existed or still remain, or elsewhere, tubercles then commence to form. They occur either singly or in groups, and slowly enlarge to the size of a pea or a hen's egg, gradually becoming anæsthetic. They may also coalesce to form more or less extensive areas.

Tubercles may remain practically unchanged for a long time, only deepening notably in colour and acquiring a more or less admixture of a brown tint, or becoming livid or slightly desquamating; or they may resolve, soften and disappear spontaneously, leaving pigment stains. Suppuration or necrosis may occur, and indolent, sharply cut, shallow ulcers form, which discharge a thin pus, and eventually leave, when they heal, more or less anæsthetic scars. This suppuration and ulceration of the tubercles occurs more especially in half-starved and unhealthy subjects, and in the later stages of the disease, when the ulceration may take on a phagædenic character.

Outbursts of such tubercles occur in successive crops at irregular intervals, several times yearly as a rule, but, as Hillis has observed, with diminishing frequency, and after five or six years they cease to occur.

These outbursts are preceded by the *acute* softening of some tubercles, and a systemic infection takes place, characterized by signs quite peculiar to the tuberculated form of leprosy, viz., rigors, swelling and tenderness of the lymphatic glands, symptoms which the lepers regard as their sentinels. The temperature sometimes rises to 105° F., the pulse is quickened, there are subjective skin sensations, with pain, tenderness and swelling of the joints and limbs, tenderness over the liver and spleen, and gastro-intestinal disturbances, such as thirst, vomiting and irregularity of the bowels. The discharges from ulcers dry during this period. In a few days these symptoms subside on the outburst of a crop of tubercles.

Though tubercles may occur anywhere, the sites of predilection for the earlier deposits are the face, forehead, ears and nostrils.

The tuberculated leper presents a

highly characteristic physiognomy, which is first expressionless and aged, and later, from the loss of eyelashes and eyebrows, fierce and staring. Hence arose the old terms satyriasis, leontiasis, and elephanti-
tiasis.

The eyebrows and other parts of the face and ears become greatly thickened, and there is accompanying œdema. The cheeks and chin are pendulous, the nose broadened and depressed, the lips swollen and everted, the ears stuck out, the eyelids ectropic, and the skin generally becomes greasy.

The hair on the face, as on the pubis and elsewhere, falls out only where the neoplasms form, so that the hair on the scalp is preserved. Tubercles form on the back and sides of the fingers and hands, the feet and toes, and extensor aspect of limbs. The extremities become much swollen, more or less livid, the hands spade-like and clumsy, and the legs œdematous and eventually hypertrophic, simulating elephantiasis arabum. The palms and soles are dry, scaly, fissured, but not anæsthetic, and the growth of the nails is interfered with in various directions by the formation of the neoplasm in the bed of, and around, the nail.

The related lymphatic glands enlarge, often to a great extent, and become the seat of leprous neoplasms.

The mucous membranes of the nose, lips, cheeks, tongue, palate, fauces, pharynx and larynx may become studded with tubercles, which may ulcerate.

As the disease progresses the leper acquires a characteristic snuffling, and the voice becomes harsh, toneless, nasal and croaking, and later aphonia may result.

After several years of progress the velum, palate and epiglottis may be destroyed and the cartilages of the larynx involved, leading to dangerous laryngeal stenosis. The destruction of the nasal cartilages causes much deformity. The exposure of the eyeball and the formation of neoplasms in the cornea, sclerotic and iris lead to various lesions of the globe, which often result in loss of sight.

The visceral mucous membranes, with the exception of the rectum and large intestine, are scarcely at all involved, the lesions there giving rise in the later stages to a dangerous form of diarrhœa, simulating dysentery. In all advanced cases of tuberculated leprosy, changes associated with the presence of the bacillus have been found in the larger viscera, such as the lungs, the liver, the spleen

and the bowels, and the testicles. The central nervous system remains intact, or is only rarely involved, and secondarily to the peripheral nervous system.

It is important to notice that when the disease commences before puberty the mental and physical development is retarded, menstruation is long delayed, and the testes atrophy. The testes seem to be peculiarly prone to attack in tuberculated leprosy, even from an early stage of the malady. So the disease, as a rule, progresses, until death ends the scene.

Nerve Leprosy (Anæsthetic Leprosy) is characterized by the progressive formation of the special neoplasm in the peripheral sensory nerves, and to some extent in the motor branches also. The implication of the peripheral nervous system is probably primary.

The Prodromal Stage.—Vague pains, rendered more intense by pressure, are experienced along the course of certain nerves. Feelings of numbness of the extremities, a want of grasping power, tremor and the formation of small and numerous bullæ as distinguished from the large and solitary ones of later stages (Hillis) are symptoms occasionally met with in this stage. For some months these symptoms may be the only evidence of the onset of the disease.

The eruptive stage is characterized by the gradual evolution on the back, shoulders, nates, extremities and the face, of fairly well-defined persistent maculæ, mostly circular in shape, but not raised above the surface. They vary in diameter from $\frac{3}{4}$ inch to 3 inches, and are often symmetrically placed. They do not disappear on pressure.

Nerve leprosy is a very chronic disease, and the macular eruption may remain in this condition for one or two years, and certain cases apparently abort at this early stage. Later, the maculæ begin to spread and tend to coalesce into irregular patches, which, as they enlarge, become *anæsthetic*; the centre pales and the borders may, by comparison, be raised, dark and wrinkled.

Independently of the anæsthesia of the maculæ, large tracts of the surface may also become anæsthetic from implication of the cutaneous nerves.

There will be distinct loss of feeling in the extremities, and the characteristic impairment of nerve influence which is first evidenced in the terminal and pre-terminal segments of the extremities, spreads centrally.

Meanwhile, or from an early stage, tropho-neurotic changes appear in the

extremities, and almost invariably first by a contraction of the little finger.

The subsequent progress of the case is an intensification and wider distribution of these changes. The anæsthetic macular eruption spreads over the body and limbs, and analgesia, more or less deep, sets in. Distinct enlargement may usually be felt along the course of various nerves. Large solitary bullæ form on the extremities, and often leave an ulcer or a white scar. The various tropho-neurotic lesions increase; for instance, a characteristic intractable ulcer appears beneath the foot and at the heel, and the well-known distortions and mutilations proceed in the hands and in the feet. Necrosis and caries of the phalanges and other bones of the hands and feet are not uncommon, gangrene may occur, and in these ways all the fingers and toes may be lost. Later on, various muscular paralyses occur.

There remains only to add that the skin generally becomes atrophied, the glands in the groin sometimes enlarge, and the temperature is much depressed, especially in the advanced stages. The mucous membrane of the mouth and pharynx is rarely, but that of the nose is occasionally, implicated, and absorption of the nasal bones may occur. It is also important to note that the testes do not show the same tendency to be affected as in tuberculated leprosy, but they atrophy if the disease commences before puberty. Nerve leprosy is a much milder and less exhausting affection than tuberculated leprosy; it commences earlier as a rule, and the duration averages fifteen years or more.

Diagnosis.—Animal and vegetable parasitic diseases, elephantiasis arabum, yaws, malarial fevers, syphilis and tuberculosis are frequent complications of leprosy. Experience also shows that it is necessary to insist on the fact that syphilis, tuberculosis and tuberculated leprosy are absolutely distinct affections, and that the one cannot be evolved out of the other. Tuberculated leprosy may easily be confounded with sarcoma of the skin, mycosis fungoides, and especially syphilis, and it should be remembered that the colour of a syphilide is no guide in dark races, and that syphilis, leprosy and tuberculosis alike lead to deformities of the nasal region.

Prognosis.—Although leprosy is not invariably fatal, the disease, in the majority of cases, ends in the death of the subject, either directly during the febrile paroxysms, or indirectly from exhaustion, lardaceous disease or intercurrent affections. Tuberculated leprosy is a far more severe

disease than nerve leprosy, and has a greater tendency to complications.

Pathological Anatomy.—The characteristic new formation met with in the various organs and tissues in leprosy has the ordinary structure of "granulation tissue," consisting of cells separated by a sparse fibrillary framework and freely permeated by blood-vessels. The cells are very persistent, and do not readily tend to undergo changes ending in the ulceration of the neoplasm. The younger ones are mostly rounded, and like lymph-corpuscles. After a time they undergo degenerative changes, and in the process of softening and absorption of the neoplasm the cells vacuolate freely, acquire several nuclei, and tend to enlarge to the extent of four or five times their original volume. Pale granular cells form, and may become irregular in shape. The changes are best seen in the more superficial parts. Finally, they disintegrate and leave deep-brown pigmentation and thickening of the connective tissue, which is probably a result of secondary irritation.

In the peripheral nerves, irregularly distributed, greyish, semi-translucent, fusiform swellings are formed, chiefly where the nerves are most exposed. The new formation is present in the interstitial connective tissue of the nerves, and even beneath the neurilemma and around and between the primitive nerve fibres. If this be absorbed early enough, function may be re-established, but, if not, parenchymatous neuritis and atrophy of nerve fibres result.

The "tubercle" of the skin consists of tracts of granulation tissue extending from the subcutaneous fat to near the rete, following the direction of the framework of the blood and lymph vessels, and especially concentrated around them, and giving rise to secondary irritative or atrophic changes in the papillæ, skin glands, hairs and nerves.

The special bacillus, discovered by Hansen, of Bergen, and first stained by Neisser, of Breslau, is found in great abundance in all the lesions of leprosy.

The bacillus *lepræ* closely resembles in appearance the *B. tuberculosis*, and differs only in some slight details of design, measurement, conduct with colouring reagents, and in the greater numbers present. Unna concludes, from his special method of preparation, that the bacilli lie in the lymphatic system.

Ætiology.—Leprosy is a widespread disease chiefly of hot countries, but occurs under the most diverse conditions of climate, soil, diet, race and unfavour-

able hygienic surroundings. There is no evidence that it arises *de novo*. It is not engendered in the air, soil, water, or in aliments, nor, as far as observation has gone, do any of these ever contain the specific bacillus. All theories to the contrary have been completely demolished by the collection of facts from various parts of the world. The discovery of the bacillus *lepræ*, the analogies of leprosy with the infective granulomata, and the fact that the disease is only propagated by transmission from man to man have caused a general acceptance of the parasitic theory, although the complete chain of proof established by Koch for tuberculosis is as yet wanting in the case of leprosy.

Leprosy has been, and is, most prevalent amongst those races and nations where the freest communication with lepers is allowed by public opinion and law, and has declined coincidently with the moral and material amelioration of the people—i.e., as better hygienic conditions prevailed, and the habits of the population afforded less opportunities for contagion.

The exact method and site of its introduction into the system is unknown, but there is no difficulty in imagining its entrance through the skin or mucous membrane by means of discharges containing bacilli, and coming directly from the neoplasms or from coincident eruptions of the leper's skin, as syphilides, vaccinia, scabies, yaws, &c. There is much evidence produced by Hillebrand, Hillis, Arning, Grainger Stewart and others to show that careless and indiscriminate vaccination may be a medium, and Arning has found the bacillus *lepræ* in the lymph and vaccinal crusts of vaccinated lepers. Possibly the bacillus may also be inhaled. Heredity can only play a small part in the propagation of leprosy, as it acts probably only in the limited sense applicable to syphilis.

As regards sex, males are affected in excess.

Treatment.—At the present time no specific for leprosy has been discovered. A liberal diet, cleanliness, exercise and good hygienic surroundings are essential, and a residence in a healthy, temperate climate is said to retard the course of the disease and mitigate its severity. Tonics are useful at times, and quinine in large doses is serviceable in the febrile attacks. Sulpho-ichthyolate of sodium or ammonium has not met with much favour in England. The Gurjun and Chaulmoogra oils are unquestionably of service. The

latter should be given at first in doses of from 5 to 10 minims in capsules, or in emulsion with milk thrice daily, after a meal, and gradually increased as long as it is tolerated. The drug may be continued over a long period. In a similar manner an emulsion of Gurjun oil, made with an equal part of lime-water, should be persistently given, commencing with 2-drachm doses.

Local Treatment.—Warm baths, plain or medicated, should be systematically used, and the prolonged rubbing in of bland or stimulating oils or liniments containing carbolic acid, salicylic acid, Gurjun or Chaulmoogra oils is very beneficial. Obstinate neoplasms may be dissipated by the application of stronger remedies, such as salicylic acid as a 10 per cent. paste or ointment, or in solution with oleic acid. Unna strongly advocates the use of ichthyol, pyrogallol, chrysarobin and resorcin. The choice and the strength of the application will vary with the site of the neoplasms, the degree of reaction of the skin and the extent implicated. Pyrogallol must be used with caution and to limited surfaces. These substances can be applied as ointments, pigments or plasters. In leprosy surgical operations are constantly required for the removal of disfiguring neoplasms about the face and ears, and especially the eyes, and in various secondary affections of the eyeball; for necrosed bone or cartilage, abscesses, sinuses, or ulcers; for amputations of digits and even greater portions of the extremities; and for the relief of pain and tropho-neurotic deformities by nerve-stretching. The obstinate and extensive ulcerations that so maim and enfeeble the leper should be treated on ordinary surgical principles. Electricity is also of signal service in the tropho-neurotic conditions of nerve leprosy. Lastly, the distressing symptoms in the nose, mouth and throat must be attended to by the daily use of tampon ointments, medicated sprays and steam inhalations, gargles and collunaria, and the constant swallowing of infective material prevented. It must not be forgotten that these discharges from the bowels and from ulcerations, unless properly dealt with, may prove the source of contagion to others. This is not the place to enter into a discussion as to the advisability or practicability of isolating lepers, but it is evident, on the one hand, that a bad case of leprosy in a poor man can only be suitably treated when the patient is under control, and, on the other, that the isola-

tion of a leper under suitable conditions must be for the advantage of the community, though its practicability is another question.

T. COLCOTT FOX.

LEUCIN is one of the products arising from the decomposition of nitrogenous bodies. It may be extracted from almost any of the viscera by the action of caustic alkalies or by boiling with sulphuric acid. It is present in the urine of persons suffering from acute yellow atrophy of the liver, appearing under the microscope as round balls like drops of oil, with or without radiating marks or concentric rings.

LEUCOCYTHÆMIA (*Leukhæmia*; *Leukæmia*).—A comparatively rare disease of the blood, characterized by a disproportionate increase of white corpuscles, differing from leucocytosis in being a permanent and progressive change, and in being associated with a corresponding (but not necessarily proportionate) diminution of red corpuscles.

Leucocythæmia was discovered almost simultaneously in the year 1845 by Hughes Bennett and Virchow. The latter applied to it the term "leukhæmia," or "white blood;" the former first described it as "suppuration of the blood," and subsequently gave it the name leucocythæmia.

The condition is marked by symptoms referable in part to the anæmic state thus induced, and in part to the mechanical effects of the accumulation of leucocytes in the blood-vessels. It is associated in the majority of instances with marked enlargement of the spleen, and, according to many authorities, this splenic variety is the only true form of the affection. But there are cases, as Virchow early pointed out, where the spleen is not enlarged, but where there is a general hyperplasia of lymphatic glands and lymphoid tissue (*leukhæmia lymphatica*). These cases differ from lymphadenoma (Hodgkin's disease) only in the characters of the blood, and hence, according to the view taken of the relation of this to the glandular change, they may be regarded either as cases of Hodgkin's disease with leucocytosis or else as lymphatic leucocythæmia. It is for this reason that the adherents of the latter view style Hodgkin's disease "pseudo-leukhæmia." A third variety was established by Neumann—viz., *leukhæmia myelogenica*—but such cases are often only examples of the splenic variety in which the bone-marrow is secondarily implicated.

Changes in the Blood.—The blood is paler than normal, having when seen in bulk almost the tint of strawberry cream. On microscopical examination it is found to contain a great excess of leucocytes. Instead of the normal proportion to the red of about 1 : 300, there may be as high a proportion as 1 : 20, or even higher, the white corpuscles sometimes actually outnumbering the red. Cavafy and others have observed that most of the leucocytes lose their power of amœboid movement, as if they were no longer living, which suggests an explanation of their retention within the blood-vessels. Further, if, as seems probable, the red corpuscles are derived from leucocytes, the increase in the number of the latter may account for the diminution in that of the former.

The leucocytes vary considerably in size, and these variations have been employed to differentiate the various forms of the disease; for example, a predominance of large cell-forms is said to characterize splenic leukaemia, whilst a preponderance of small (lymphoid) corpuscles is thought to indicate lymphatic leukaemia. An interesting fact is the presence in the blood after death of colourless pointed crystals, which were discovered by Charcot and Robin. Similar bodies were detected by Leyden in the sputa of patients suffering from spasmodic asthma, and they are therefore known as Charcot-Leyden crystals (*see* EXPECTORATION).

Changes in Viscera.—In a vast majority of cases the spleen is enlarged, and with the advance of the disease this organ continues to increase in size, so that at death it may reach downwards as far as the pubes, and to the right considerably beyond the middle line. On section, the organ has a mottled appearance, being paler than natural, whilst there is often no evidence that the Malpighian bodies are more affected than the rest of the splenic pulp. Occasionally, however, these bodies stand out as prominent white nodules. The change appears to be a hypertrophic one, and the sinuses and blood-vessels are filled with leucocytes. Generally there are scattered through the organ numerous hæmorrhagic foci. In advanced stages the spleen becomes firm from fibrous thickening of the trabeculae.

Besides the spleen, the other lymphoid glands in the body may be swollen and hyperplastic, especially the mesenteric and retro-peritoneal glands. The marrow of bones, especially of the sternum, is

in some cases also markedly hyperplastic.

But in spite of the occurrence of cases with but slight splenic affection and predominance of the medullary change, it is questionable whether there is a distinct myelogenic form, some authors attributing the change in this tissue to a secondary rather than a primary process. Indeed, in well-marked cases most of the organs of the body exhibit a leukaemic infiltration. The liver, for instance, may be enormously enlarged by a diffuse infiltration of leucocytes and fibrin between the lobules, and the kidneys may be similarly affected and swollen. Foci resembling infarcts have been found in the lungs.

There may be effusion in the serous sacs.

The *symptoms* of leucocythæmia are in many respects like those of pernicious anæmia, but they are more insidious in their onset. The patient, for some months past, may have been feeling languid, weak and incapable of exertion, with perhaps some shortness of breath. Then there may be pain in the left side, or pain and tenderness over the sternum (in the myelogenic form); or a liability to epistaxis and other hæmorrhages. There may be no pronounced anæmia, and the colour of the skin may become sallow or pigmented. [It is possible that, in some recorded cases of marked cutaneous pigmentation, the coloration may be due to arsenic, which is largely given in leucocythæmia.]

On examination, in the ordinary form the enlarged spleen is readily made out, for it may have attained considerable dimensions before the patient seeks relief. Its enlargement is found to be uniform—projecting below the ribs; and the well-defined notch on the anterior margin, the mobility with the diaphragm, and the continuity of its dulness with that of the normal splenic area enable its true character to be readily determined. Perhaps, also, the liver will be found slightly enlarged. An examination of the blood clinches the diagnosis.

As the case progresses, not only do the liver and spleen continue to enlarge and the relative proportion of leucocytes in the blood to increase, but other symptoms make their appearance. Thus, hæmorrhages may occur beneath the skin, as well as from mucous membranes, and in the retina (leukaemic retinitis). There is pyrexia, either with considerable remissions, or it may present almost an intermittent type. In a well-marked case

observed by the writer fourteen years ago, the patient suffered from rigors and an almost quotidian type of intermittent pyrexia. There is frequently diarrhoea, and maybe vomiting. Together with this there is increasing emaciation, and dropsy may supervene. Well-marked ascites is present in some cases. The urine is usually free from albumen, but is generally loaded with lithates, and often deposits crystals of uric acid. There may be hæmic murmurs at the heart. Pericarditis and pleurisy are not uncommon as complications. The intellect is unaffected, but in some cases cerebral hæmorrhage occurs.

Death is usually due to slow and gradual exhaustion.

The duration of the disease is from one to two or three years.

The *pathology* of the disease is still a matter of dispute. What precise share is taken by the spleen, and to what extent a primary lymphatic or myelogenic leucocythæmia occurs, are points equally unsettled. The theory most tenable at present is that, for some reason or other, the spleen and other hæmopoietic organs fail to convert the leucocytes into red corpuscles. An alternative view is to regard the condition as essentially a disease of the leucocytal elements of the blood, a malignant growth of this fluid tissue, and to refer *all* the visceral changes to the results of this. It has even been suggested to be an infective disease, but as yet bacteriology has made no discoveries in support of such a view.

The *ætiology* is very obscure. It is a disease mostly of adult life, but has been met with in quite young children. It is far more common in males than females. Various causes have been assigned in individual cases, such as over-exertion, exposure to cold and damp, mental worry or emotional disturbance, but obviously these and the like cannot be considered essential. In a certain proportion of cases the disease would seem to have some relation to previous malarial poisoning.

Treatment.—As with pernicious anæmia so here, very little can be done, but the drug on which most reliance is to be placed, and from which the best results have been obtained, is the same in the two diseases, viz., arsenic, administered by the mouth or subcutaneously. Quinine, reputed to have a special action on the leucocytes, may also be given, with or without iron. Iodide of iron has also been prescribed. At one time some rather striking results were recorded of

the effect of phosphorus, but the anticipations raised of its efficacy have not been fulfilled. Transfusion has met with no success. Inhalations of oxygen deserve, perhaps, a more extended trial than has been given them. The use of oxygen in the treatment of this disease was introduced by Kirnberger in 1883, on the theoretical ground that the impaired oxygenation arising from deficiency in red corpuscles led to defective metabolism. He records the successful treatment of a case—a boy, ten years old—with great splenic enlargement and a proportion of w.b.c. to r.b.c. as 1 : 90. Although arsenic was also given in this case, health was not restored until the oxygen inhalations had been fully tried (see *Year Book of Treatment*, 1884, p. 89. For an interesting comparison between the action of arsenic and oxygen in leukhæmia, see *ibid.* 1889, p. 109). Splenectomy has been proposed and actually performed in a few cases, but with almost invariably fatal results (death being due to hæmorrhage). It is difficult to see the rationale of so formidable an operation on any theory of the disease, and its performance should be strenuously discountenanced.

SIDNEY COUPLAND.

LEUCODERMA (Vitiligo; Leucopathia; Leucasmus).—An acquired disease characterized by the appearance of smooth white patches of skin with well-defined borders, more or less symmetrically distributed.

Rounded spots of small size, on a level with the surrounding skin, first appear, most commonly on the trunk, backs of the hands or genitals; these increase peripherally, and coalesce to form variously shaped and often very extensive areas of disease, the boundary line of which is always convex outwards. Around the white patches pigmentation is generally excessive, the line of demarcation being usually abrupt; the healthy skin is thus apt to be mistaken for the seat of disease, and is the main cause of the disfigurement on account of which the patient frequently seeks for advice. If the scalp be affected the hair upon the patch usually becomes white (canities).

The disease is never unilateral, but its symmetry is not usually so perfect as to suggest a primary central nervous affection. Tactile and thermic sensibility, sweat and sebaceous secretion, and all other functions of the affected skin are invariably intact. Neuralgia and pruritus occasionally precede its appearance,

and the writer has observed two cases in which pruritus was a very distressing symptom throughout; one of these subsequently died of acute pemphigus.

Diagnosis.—The condition may be mistaken for partial albinismus, chloasma, morphaea, lepra, for patches of pigment atrophy after the disappearance of macular or papular syphilides, or even for spots of psoriasis blanched by chrysarobin.

The *pathology* of the disorder consists in the absence or diminution of the normal pigment in the mucous layer of the skin; degenerative changes in the corresponding peripheral nerves have been described.

Ætiology.—The disease commonly begins in early adult life, affects chiefly "neurotic" persons and those with dark skins, and is generally progressive, but may become stationary; some authors consider gout a predisposing cause. It may develop after acute diseases, especially the exanthemata, in the course of syphilis and various chronic nervous disorders (tabes dorsalis, alcoholism, neuralgiæ), or may occasionally start from a cicatrix, while it may complicate morphaea, Addison's disease, and area. Leucoderma is common in some districts of India where lepra is prevalent, and may even complicate it; there is, of course, no relation between the two diseases.

Treatment is never of permanent benefit. A temporary return of pigmentation may follow the application of a mustard plaster, but more benefit is usually obtained by the removal of the excessive pigment in the surrounding skin by weak corrosive sublimate lotions or by peroxide of hydrogen.

J. J. PRINGLE.

LEUCORRHŒA (The Whites).—

The popular synonym for leucorrhœa is applied by women to most discharges which are not blood-stained. Before describing the abnormal discharges to which this term is applied it may be useful to draw attention to the normal secretions from the parts concerned. The secretions that normally flow from the female genitals are—(1) Mucus from the Fallopian tubes and the body of the uterus. This is colourless, transparent like white of egg, and does not differ, so far as is known, from mucus in other parts of the body. (2) The secretion of the glands in the cervix uteri. This is clear like white of egg, but rather more tenacious. (3) The secretion from the vagina. In the healthy virgin white flakes are seen lying between the vaginal

rugæ. These flakes are formed by the mingled secretions from the uterus and tubes, cervix and vagina, but what relative amount is furnished by each we do not know. (4) The secretion from mucous follicles situated in the vestibule between the clitoris and meatus urinarius, and also from the glands of Bartholin. These pour out a glutinous mucus having a peculiar odour.

There is also some mucus secreted by the urethra, and there is the secretion from the sudoriparous and sebaceous glands of the skin of the labia. The secretion from the glands about the vulva is often seen inspissated in yellow flakes lying in the furrow between the labia majora and minora, and under the preputium clitoridis.

The mucous secretions, taken as a whole, are scanty in the virgin, more copious in those accustomed to sexual intercourse, still more abundant in those who have had many children, and greatest in quantity during pregnancy. In conditions of debility the discharges are increased. After the climacteric they diminish.

Catarrh of the genital as of any mucous membrane is not uncommon, and often disappears after a few days without any treatment, but in weakly women it is apt to become chronic. Whether this slight leucorrhœa comes from the cervix or vagina we do not know, for, as a rule, neither do medical men propose, nor would patients submit to local examination for so slight an ailment.

Leucorrhœa may be divided into three kinds—vulvar, vaginal, and uterine. Of these, the first is most common in children, the second in young women, the third in elderly women.

A white or yellow discharge *in children* is usually the result of vulvitis. It is important (1) because it may cause, and often has caused, suspicion to be thrown on some one of having communicated gonorrhœa to the child; (2) because the irritation it sets up may lead the child to the practice of masturbation.

It is easily cured by syringing the parts with a saturated solution of borax, at first three or four times a day, then, as it gets better, less frequently. The injection may be given with an ordinary glass male syringe.

The most common cause of leucorrhœa in women *during the child-bearing age* is vaginitis following child-bearing. Next comes cervical endometritis, also a result of child-bearing. These two are often combined. Among other causes which

may lead to leucorrhœa are gonorrhœal vaginitis, and the other rarer forms of vaginitis; venous congestion, the result of heart, lung or liver disease; cancer, fibroids, other new growths from the uterus, and endometritis. Most of these discharges are purulent.

In acute gonorrhœal vaginitis the pus is copious, thick and yellow; in the other more chronic conditions it is thin, watery and less abundant. In mere vaginal catarrh the stains which the discharge leaves are colourless. In cervical endometritis the discharge is thick, and may produce a colourless stain, but as met with clinically it generally either contains pus or is mixed with purulent discharge from the vagina. The leucorrhœal discharge produced by fibroids or endometritis is watery and often tinged with blood. That caused by cancer has in the early stages no peculiar character, but when the cancer begins to break down, the discharge contains fragments of decomposing tissue, and is offensive. But any kind of discharge may cause an offensive smell if the patient neglect cleanliness.

In *old women* who have ceased to menstruate, leucorrhœa may be the result of vaginitis, the discharge being purulent, or of endometritis, the discharge being either watery or purulent.

In *pregnancy* vaginitis and cervical endometritis are frequent, and are especially troublesome to treat.

G. E. HERMAN.

LICHEN.—A generic term now reserved for a well-defined group of inflammatory affections of the skin in which the lesions consist of solid papules throughout the entire course of the disease.

The name was formerly used to designate conditions which are now known to constitute mere phases of other diseases, and much confusion in nomenclature still exists in consequence.

Thus, *L. simplex* and *L. agrius* are now recognized as being the papular stage of eczema; *L. lividus* as severe purpura, in which hæmorrhage occurs into the lesions round the follicles; *L. tropicus* (prickly heat) as constituted by the apparently solid lesions round inflamed sweat glands, and *L. urticatus* by the persistent wheals of chronic urticaria. *L. syphiliticus* is a peculiarly unhappy and misleading designation of the minute papular syphilide. Some doubt still attaches to the true position of *L. circinatus* (vel *circumscriptus*), but the bulk of modern opinion is in favour of

regarding this disease as of sebaceous origin, and its description will be found under the heading of **SEBORRHŒA CORPORIS**.

Lichen ruber is a chronic inflammatory eruption consisting of flat (*L. planus*) or *acuminate*, persistent papules, arranged in groups or lines, or coalescing to form extensive patches.

Lichen planus.—Occasionally, but rarely, the onset of the disease is accompanied by a severe erythematoid outbreak, on the subsidence of which the characteristic lesions may be distinguished. These consist of flat-topped, angular, polyhedral papules, varying in size from a millet-seed to a pea, shiny—especially when viewed by oblique light—and with a central umbilication, when surrounding a sweat duct. Their colour is at first that of the normal skin or a pale pink, but soon they become reddish or purple, and a deep brownish-purple pigmentation is very characteristic and persistent in lesions of old standing, especially when they are situated below the knee and arsenic has been administered freely. The papules are often arranged in lines, bands or groups, suggesting nerve distribution. They do not spread centrifugally like the papulosquames of psoriasis; but extensive plaques or sheets of disease may be built up by the coalescence of numerous papules arising side by side; and over these some thin scale is usually present.

The distribution is almost always bilateral, and usually remarkable symmetry is displayed; the sites of election are the flexor surface of the wrists and forearms, the inner sides of the knees, the legs, ankles and loins; but no region of the body is exempt, except perhaps the face. On the soles and palms the lesions appear as whitish spots scarcely, if at all, elevated. Solid papules are often found on the upper surface of the tongue, generally arranged in two parallel lines along either side of the raphé and on other portions of the buccal mucous membrane, where they resemble the milky-looking patches of syphilis, and are very apt to be macerated and result in troublesome erosions. Much more rarely the glans penis or mucous lining of the vulva is attacked, and in a few cases the lesions of mucous membrane have been known to precede the skin affection by many weeks.

After the subsidence of the papules deep-brown pigmentation and some atrophic pitting are generally left, and the staining is apt to persist for a long time.

In a small proportion of cases the papules and patches become very prominent (*L. hypertrophicus*) and may project from $\frac{1}{4}$ to $\frac{1}{2}$ inch from the surrounding skin, when their surface becomes rough and shaggy—like shagreen—and in such cases the course of recovery is always very tedious.

L. planus is the form usually met with in this country, and is much commoner in women than in men, but there is no line of demarcation to be drawn between it and the next variety.

Lichen acuminatus, the common form on the Continent, assumes a more severe type than *L. planus*, and generally affects men. In many cases acuminate and plane lesions co-exist, the former being on the trunk, the latter on the extremities.

Generally speaking, when the papules are acuminate the disease is very acute and accompanied by grave constitutional symptoms (rigors, pyrexia, sweats, prostration); and itching—usually a troublesome feature of *L. planus*—is intolerably severe.

The constituent papules are minute, firm, conical, capped with scale, very closely aggregated, but can generally be recognized as being around hair follicles. The extent of skin attacked is generally also much greater than in *L. planus*, the whole body surface being frequently involved; deep infiltration and thickening occur, interfering with movements at the joints; the palms and soles become deeply fissured and the nails discoloured, brittle and thinned. Occasionally pityriasis rubra may start from a lichen ruber patch whether plane or acuminate.

In children the disease assumes a somewhat special form; the papules are at first acuminate, but soon become flat and scaly; they develop in groups or circles on either limbs or trunk, and recovery usually occurs spontaneously in a few weeks. In adults, on the other hand, the duration of the disease is indefinite; it is always very chronic, and there is a strong tendency to relapse even after perfect recovery, although not with the same seasonal regularity as in the case of psoriasis.

The *diagnosis* is straightforward in the majority of cases, the characters of the papules being easy of recognition; only when confluent patches are present is diagnosis difficult, and in them outlying papules are always present which exhibit the characteristic appearances. The acute erythematous phase is very rare, and time is necessary to clear up the nature of the case. It is impossible

to enter into the various points of differential diagnosis here; suffice it to say that the distribution, pigmentation, violence of the itching, depth of infiltration with comparatively little scaling, uniformity of type and absence of discharge serve to distinguish it from psoriasis, pityriasis rubra, papular dermatosyphilides and eczema, with which it is most likely to be confounded.

Morbid Anatomy.—There is little that is special in the morbid anatomy, which is that of most chronic dermatites. Copious small-celled infiltration occurs into the superficial layers of the corium; when the process is acute, the rete Malpighii is pushed before the infiltration; when more chronic, the rete cells proliferate, so that the papules are mainly formed by them. There is a special predilection for the lesions to form round the openings of sweat-ducts and hair follicles, surrounding which there is a rich capillary network.

Ætiology.—Little or nothing of a positive nature is known of the ætiology of lichen ruber; it certainly is of common occurrence in persons of neurotic disposition, or in a generally depressed state of health; its subjects are often dyspeptic, and there is good reason to believe that in predisposed subjects a chill may determine an attack. As already mentioned, *L. ruber planus* is commoner in women, *L. ruber acuminatus* in men. Below the age of five years the disease is extremely rare.

Treatment must be both constitutional and local. In acute cases, absolute rest must be enjoined, the food must be nutritious, but easily digestible. Quinine in large doses is very useful, arsenic probably actually harmful. The affected parts may be swathed in rags soaked in lead lotion or calamine liniment, or repeatedly dabbled with lactate of lead lotion (liquor plumbi subac. ʒj ad ʒj of fresh milk). When the acute phase is over, the following lotion may be substituted:—Liq. carbonis deterg. ʒss, glycerini ʒss, liq. plumbi subac. ad Oj.

In chronic cases stimulants, full diet and tonics are indicated, and a change of air and surroundings is often most beneficial. Arsenic is now invaluable, but, to ensure its full effect, must be given in full doses (ʒiv-xv of the liquor thrice daily) with due precautions. Possibly its influence is sooner exerted when given subcutaneously as in Germany, but few English patients will submit to the treatment. In a certain number of cases, in which arsenic is ineffectual, the per-

chloride of mercury appears to be of value.

Locally, the preparations of tar are the most generally valuable; a lotion composed of 1 drachm of liq. carbonis detergens to an ounce or more of water is often useful; or the oil of cade, mixed with oxide of zinc, calamine or subacetate of lead ointments in the strength of 1 drachm to the ounce may be used. Carbolic acid (gr. xx-xxx ad 3j), naphthol or thymol (gr. xx-5j ad 3j), either in lotions or ointments, are also much employed. Prolonged alkaline baths relieve itching perhaps better than anything else, and form a suitable prelude to the use of ointments or lotions.

Lichen scrofulosus (vel scrofulosorum) is not so rare a disease as is usually asserted, but its existence is often ignored, as the eruption is in itself inconspicuous and gives rise to no subjective symptoms; when noticed, its true character is seldom recognized, as Hebra's original description of an exceptionally severe form is still almost universally accepted as that typical of the disease.

Children are, in the great preponderance of cases, its subjects, and in almost all there is a phthisical family history, a strumous physiognomy or physical evidence of tubercular disease of lungs, lymphatic glands or bones.

The eruption is situated on the trunk, especially upon the back, either diffusely or in patches; when diffuse and abundant, the arrangement of the component papules is indiscriminate; when patchy, there is a great tendency to the formation of rings. In either case the papules are very small, pale, conical and surmounted by fine scale; they cause no itching, and, after their subsidence, leave rather persistent yellowish pigmentation. After disappearing from one situation they are apt to crop up in another, and so successively to invade the whole trunk.

In adults the disease is much rarer, but Hebra's description is based upon a study of such cases; the same association with tubercular taint obtains as in children, but the lesions are much less abundant, the papules larger, brighter in colour, more discrete, and with more marked tendency to ringed arrangement.

In children the *differential diagnosis* must be established from papular eczema, and in adults from circinate papular dermatosyphilis, which sometimes closely resembles it.

Pathologically the disease consists of moderate small-celled infiltration into

the upper layers of the corium, especially around sebaceous glands and hair follicles; tubercle bacilli have not been demonstrated.

The *treatment* is mainly that of tubercular affections, prominent among remedies being cod-liver oil; arsenic and the iodides are useful adjuncts. Externally the inunction of vaseline or lanolin probably hastens the disappearance of the rash.

Lichen pilaris (L. spinosus), a rather rare and ill-defined disease, in which inflammatory papules are formed around the hair follicles, the centre of which is occupied by a spiny plug of epidermis. It has affinities on the one hand with so-called keratosis pilaris (vel ichthyosis follicularis), which is, however, a congenital and non-inflammatory affection, and on the other with simple folliculitis—follicular eczema—and with psoriasis pilaris.

It occurs both in children and adults, but especially in early adult life. Very recently Darier has demonstrated the presence of psorospermia in the disease, and they are most probably its immediate cause. Positive evidence in the form of successful inoculation experiments is still, however, wanting (*see PSOROSPERMIA*).

The papules are very prominent, taper to a fine point, and contain a central spine, which, when extracted, leaves a deep pit; at first they are bright red, but afterwards become much paler. They appear suddenly in circular patches, especially about the back of the neck and shoulders, but also on the buttocks, over the trochanters and on the abdomen; they cause a rough nutmeg-grater-like feeling to the touch, as well as some inconvenience to the patient from catching on the underclothing. The amount of itching varies considerably in different cases. - After subsidence some pigmentation is left, and the eruption has a tendency to recur.

The *treatment* consists in the mechanical removal of the plugs by vigorous friction with soft soap, after hot alkaline baths, and the subsequent inunction of some weak tarry ointment—e.g., ol. cadini 5j ad 5j. Internally, cod-liver oil may be used.

J. J. PRINGLE.

LIVER, ABSCESS OF (Hepatic Abscess).—Abscess of the liver is rarely caused by *mechanical injury*, rarely also from irritation set up through *obstruction* of bile passages or *ulceration* of their walls due to calculi or round-worms. A

hydatid cyst may suppurate, and then form an abscess. *Pyæmic* or *metastatic* abscesses occur in connection with surgical suppurations, ulcerative endocarditis, and gangrene of the lung, but the chief cause of abscess of the liver is *ulceration* or *suppuration* occurring in the *area of the portal circulation*.

Among the rarer conditions of this class that have been known to give rise to it are phlegmonous gastritis, ulcer and cancer of the stomach, enteric fever, catarrhal ulceration of the intestine, ulcers of the cæcum and vermiform appendix, pelvic abscesses connected with the uterus or its appendages, and purulent peritonitis.

But by far the most common cause is *dysenteric ulceration* of the large intestine. It is doubtful whether *tropical* abscess ever occurs apart from dysenteric ulceration, but some authorities are of this opinion.

Symptoms.—In the great majority of the secondary forms there are no special symptoms produced by the supervention of this condition; what symptoms there are are constitutional, and are masked by those of the grave disease in the course of which it has occurred.

In tropical abscess there may be no symptoms, several sudden deaths having occurred from rupture of an abscess into one of the neighbouring serous cavities in persons supposed to be in good health. But the most usual symptoms are local pain, feverish attacks resembling ague and often mistaken for that disease, with the appearance of a fluctuating tumour or evidence of enlargement of the liver, and jaundice. If the abscess reaches the peritoneal surface of the liver, it causes local peritonitis. There may be pain at the tip of the right shoulder, furred tongue, gastric catarrh, loss of appetite, wasting, and profuse sweating. The *termination* of such an abscess is by pointing and opening externally or into some neighbouring cavity. The most favourable mode of evacuation next to external pointing is into the colon, but it may open into the pleura, the lung, the stomach, the duodenum, the pericardium, the pelvis of the right kidney, or the peritoneal cavity.

Diagnosis.—When there is a fluctuating tumour the presence of suppuration may be suspected, but is only rendered certain when the swelling is proved to contain pus by puncture with a fine needle. When residence in a tropical climate is followed by local pain, rigors and enlargement of the liver, it is probable that

there is an abscess, but in this case its seat may be difficult to recognize, and the diagnosis is hardly established until, by perhaps repeated punctures with a long fine aspirator needle, the abscess is hit and pus is drawn off.

Morbid Anatomy.—The anatomical appearances vary in the different ætiological forms. In connection with disease of the bile ducts, the abscesses are multiple, and are formed by the suppuration of cavities consisting of dilated and sacculated ducts. In pyæmia and other metastases, abscesses are also multiple, usually of small size, and rounded in shape; the walls of such abscesses are formed of infiltrated and softened liver tissue. In the tropical variety the abscess is generally large, single, and the wall is more organized.

The modern *treatment* of hepatic abscess is exclusively surgical. Wherever it is possible the cavity should be opened, its edges stitched to the abdominal wound, and drained. All other measures are useless.

ROBERT SAUNDY.

LIVER, ALBUMINOID DISEASE OF.—*Symptoms*.—There is *enlargement* of the liver, the organ often

attaining a great size, with a very well-defined edge, easily palpated. There is, as a rule, no ascites, but in the later stages there may be cedema of the lower extremities. The spleen is also enlarged. In many cases the degeneration is not advanced far enough to give rise to distinct enlargement of the liver, and the diagnosis is only made on the post-mortem table. Its existence may often be inferred from the presence of favourable ætiological conditions; but it is a noteworthy fact that, in Birmingham, waxy degeneration occurs with much less frequency in connection with chronic suppurations than it does in London and Edinburgh.

Morbid Anatomy.—The liver is enlarged, smooth and hardened. Its edge is sharp, the normal shape is retained. Its colour is rather pale. On section, it is firm to the knife, like bacon, and on pouring over it a weak solution of liq. iodi (1 part of liq. iodi to 10 of water) a mahogany-brown stain appears; sometimes this reaction can only be obtained by soaking thin sections in the fluid, and examining with the microscope, and this even in organs whose naked-eye appearances leave little doubt as to the nature of the change. Under the microscope, the affected parts are stained rose-violet with methyl-violet while the healthy tissue

is coloured blue-violet. The degeneration commences in the middle zone of the lobules, and attacks the capillaries of the hepatic artery, causing these to swell and compress the cells, which undergo atrophy.

Ætiology.—The various causes of this condition will be found under **ALBUMINOID DISEASE** (*q.v.*).

Treatment.—The removal of the cause is the only measure which is known to have any influence upon this condition. The malarial taint may be treated by quinine and arsenic; syphilis, by mercury and iodide of potassium; phthisis, by quinine and cod-liver oil. Surgical conditions should receive proper local attention, and the presence of evidences of waxy degeneration should not be allowed to bar an operation if it be possible by this means to get rid of the cause. Cases are recorded in which, after removal of a source of suppuration, the liver, although previously much enlarged and extending downwards below the umbilicus, resumed its normal size.

ROBERT SAUNDBY.

LIVER, ACUTE YELLOW ATROPHY OF (Icterus Gravis).—A very rare disease of the liver, characterized clinically by the presence of jaundice, and pathologically by a rapid wasting of the liver. It occurs either as a primary affection or as secondary to chronic hepatic disease.

Symptoms.—In the beginning these cases resemble simple catarrhal jaundice, and in many there is some gastro-duodenal catarrh. But cerebral symptoms soon manifest themselves; headache sets in, followed by delirium, which often amounts to maniacal excitement; later on the patient becomes comatose, and convulsions are common, especially in young subjects. Hæmorrhages may take place from all the mucous surfaces, hæmatemesis being the most common. The temperature is at first sub-normal, normal or slightly raised, and this may persist until the end, but in a considerable proportion of cases during the last hours of life the temperature rises considerably.

The urine is small in amount, of high sp. gr., loaded with bile pigment, and contains very little urea, with much leucin and tyrosin, and is oftentimes albuminous. The jaundice is intense.

Pain in the region of the liver is sometimes complained of, but the area of liver dullness is always reduced or entirely absent. This sign is favoured by the tympanitic distension of the intestines.

The *diagnosis* of the condition may be impossible before the occurrence of cerebral symptoms, but the supervention of acute jaundice in pregnant or puerperal women, or the subjects of cirrhotic liver, should be regarded with watchful misgiving. Later on the disappearance of the liver dullness, and the presence of leucin and tyrosin in the urine, will confirm a diagnosis which the occurrence of the severe cerebral symptoms has suggested.

The *duration* of the disease varies very greatly, from twenty-four hours (?) to two months, but most cases terminate between the fifth and the fourteenth days.

The *prognosis* is said to be not absolutely hopeless; though it is not easy to understand how recovery can take place from an anatomical condition such as we find post mortem, nevertheless a certain number of alleged recoveries have been recorded. Yet the prognosis must be most grave.

Morbid Anatomy.—The liver is much reduced in weight, weighing from 20 to 30 oz. in adults; it is flattened, of very soft consistence, while its capsule is shrunken and wrinkled. The external bile apparatus is generally empty. In the *primary* form, on section, the liver is uniformly yellow, and no definite structure can be recognized. Under the microscope all that can be seen is a mass of granules of fat, bile pigment, blood pigment, and leucin and tyrosin crystals. The liver cells have disappeared. In the *secondary* form the process is commonly partial only; some areas of the liver are bright yellow, while others are bright red, and others again are unaffected by any acute degeneration. Under the microscope the yellow areas are much the same as in the first form, but the red areas show acute infiltration of round cells in the interlobular fissures and spaces. Cornil described a great multiplication of biliary canaliculi in cirrhotic livers undergoing this change, but the process is so common in cirrhosis that it cannot be regarded as specially connected with this degeneration. The liver cells show various stages of acute fatty degeneration, bile and blood-pigment granules and leucin and tyrosin crystals are present. The nature of the pathological process in the yellow form is a most intense acute parenchymatous inflammation; in the red form this is less intense, and is accompanied by interstitial inflammation. A similar parenchymatous inflammation affects the muscular wall of the heart and the parenchyma of the kidneys.

The disease is undoubtedly due to a toxæmia, the nature of which is not known. The best explanation of the jaundice in this disease is that it is due to the absorption of bile secreted in the early stages of the disease, but which is hindered from escaping by the ordinary channels on account of the plugging of the smallest bile ducts by plugs of desquamated and degenerated epithelium (Buhl); but this is not altogether satisfactory.

Etiology.—The influence of previous attacks of jaundice, of syphilis and of alcohol is questionable, except in so far as either may have led to cirrhosis of the liver, for it is especially as a mode of termination of cirrhotic liver that the secondary form occurs.

The primary affection is especially associated with pregnancy and the puerperal state, but the nature of this relation is not understood.

Cases have been observed to occur in enteric fever (Frerichs) and in pneumonia (Liebermeister).

The influence of age is observed in both sexes, it being rare before fifteen and after forty years in both men and women, but females are twice as liable to the disease as males.

In acute phosphorus poisoning the liver may present quite identical appearances to those seen in this disease.

No treatment would seem to be of much use, but, in some of the cases which have recovered, mild purgatives of calomel, jalap, &c., were used, in another aconite, and in still another benzoic acid with musk in large doses.

ROBERT SAUNDBY.

LIVER, CANCER OF.—Cancer of the liver is generally secondary to cancer elsewhere, the primary disease being most commonly situated in the stomach, but primary cancer of the liver is not rare.

Of primary cancers quite a considerable proportion begin in the bile ducts, and the disease is so often associated with gall-stones that the irritation of these has been justly regarded as a cause. In other cases the cancer appears to commence in the liver tissue itself. Like cancer generally, it is rare before middle life, but affects both sexes, though it is more common in women.

Symptoms.—Secondary cancer of the liver often runs a latent course, and is only recognized on the post-mortem table.

In a typical case of cancer of the liver the patient suffers from gradual im-

pairment of health and strength, loss of appetite, gradual appearance of cachexia, wasting and indications of chronic gastro-intestinal catarrh. Ascites and œdema of the legs supervene; jaundice is commonly present, and there may be pain over the liver.

On examination the organ is found to be enlarged, and is often tender; in the nodular form irregularities of the surface may be perceived on palpation. There is necessarily considerable variation in the symptoms, and the *diagnosis* is often beset with difficulty, especially when a primary cancer of the stomach has become adherent to the left lobe of the liver. Perhaps the most important symptom of cancer is an excessive loss of body weight.

The *duration* of the disease is usually from four to five months, but some cases far exceed this limit.

The *prognosis* is necessarily of the worst kind.

Morbid Anatomy.—The cancerous liver is almost invariably greatly enlarged, while the new growth appears under four different forms.

(1) The commonest form is as large, white, hard nodes, which, where they are visible on the surface of the organ, are distinctly umbilicated, and on section their cut surface becomes concave; less commonly the masses are softer. They are sharply marked off from the liver tissue, and their centres are usually undergoing fatty necrosis. Under the microscope they present the usual characters of cancer—epithelial cells lying in an alveolar stroma.

(2) There is diffuse cancerous infiltration of the liver, with much thickening of its capsule and connective tissue.

(3) The liver is beset with small nodules, varying in size from a pin's head to a walnut, which appear to grow in the interlobular connective tissue.

(4) When the primary disease is in the region of the gall-bladder an enormous mass of new growth may be present in the situation with secondary nodules elsewhere in the liver.

Treatment can be only palliative.

The pain can be relieved by morphine hypodermically; if the itching of the skin be very troublesome, sponging with vinegar and water, or pilocarpin (gr. $\frac{1}{2}$) hypodermically may be tried, but these remedies are uncertain. If the ascites be very great it may be quite worth while to draw some of it off by a trocar to relieve the pressure on the diaphragm.

ROBERT SAUNDBY.

LIVER, CIRRHOSIS OF (Interstitial Hepatitis) (κίρρως, yellow).—This disease, or group of diseases, is essentially characterized by the formation of fibrous tissue in the liver, with consecutive atrophy or destruction of the glandular elements.

The following varieties may be distinguished:—

1. Alcoholic cirrhosis.
2. Cardiac or Cyanotic cirrhosis.
3. Biliary cirrhosis.
4. Syphilitic cirrhosis.
5. Tubercular cirrhosis.
6. Malarial cirrhosis.
7. Scarlatinal cirrhosis.
8. Rachitic cirrhosis.

1. Alcoholic cirrhosis is the common form ("hobnail" or "gin-drinker's" liver). The organ is generally small, hard and granular. The disease is frequently met with clinically in association with ascites. It is undoubtedly caused by the abuse of alcohol.

Symptoms.—The ordinary rule is for the cases to come under observation with more or less ascites, associated with various dyspeptic phenomena due to the gastric catarrh, such as morning sickness, loss of appetite, water brash, sour risings, and, later, hæmatemesis.

There is often great flatulence; the skin may have a sub-icteric tinge, and occasionally, though rarely, there is actually jaundice, probably by extension of catarrh from the duodenum to the bile ducts. The urine is generally scanty, high coloured, containing so-called febrile *urobilin*, and loaded with lithates; it often contains a little albumen. Enlargement of the spleen can generally be made out.

On percussion, the liver dulness is notably diminished, especially in the epigastrium, but even in the right vertical mammary line the area of dulness is reduced from $4\frac{1}{2}$ to 2 or $1\frac{1}{2}$ inches, or even less when there is much flatulent distension. Not uncommonly, however, ascites is absent; this occurred, according to Frerichs, in about one-third of his cases; but when there is no ascites it usually happens that the case does not come under medical care until some serious and often fatal accident, such as hæmatemesis or the supervention of acute atrophy (see ACUTE ATROPHY), has taken place.

It is quite possible for this form of cirrhosis to go through its entire evolution without producing any marked disturbance of health. Some years ago the writer examined the body of a foreman

engineer at a colliery, who had died suddenly of hæmatemesis. Although a hard drinker, he was a valued servant and a steady workman, not having lost a day's work for the previous two years. His liver was a most typical example of small "hobnail" cirrhosis, and he died, as these cases often do, from the rupture of a varicose œsophageal vein.

The explanation of the absence of ascites is probably to be found in the venous enlargement taking place more readily and completely in certain cases. But it is not very uncommon to find well-marked chronic peritonitis associated with cirrhosis of the liver, and it is possible that slight degrees of peritoneal inflammation may play a more important part in the production of the ascites of this disease than the prevalent mechanical theory would indicate.

Course and Duration.—The disease is essentially chronic, and usually must have existed for a period of from one to two years before it comes under observation in its developed form. Even after that, such cases may go on for years, but, as a rule, the patients do not give up their drinking habits, and in that case recovery is hopeless.

Morbid Anatomy.—The liver varies in size, but is ordinarily reduced in volume; when it is larger than normal there is usually marked fatty infiltration as well. The atrophy especially affects the right lobe, but there is a general reduction in every diameter. The colour is usually a pale olive-brown. The surface is extremely granular, and the capsule thickened and opaque. The external biliary apparatus contains very little bile.

On section, the organ is very tough, and the cut surface shows bands of fibrous tissue traversing the organ in all directions and encircling groups of acini, which are often stained yellow; hence the name cirrhosis.

Under the microscope the new formation is seen to grow from the pre-existing connective tissue in the portal canals and interlobular fissures and spaces. The branches of the portal vein in the portal canals are dilated and thickened. The branches of the hepatic artery are also thickened, while there is frequently an abundant new formation of capillary bile ducts around the margins of the affected acini. The acini are slowly invaded from their periphery by the encircling growth, their rows of cells undergoing retrogressive changes, losing their protoplasm, and apparently becoming in some places converted into cubical

epithelium which lines the newly formed ducts; in other places they disappear by direct transformation into connective tissue. The hepatic cells can be seen to be enlarged, and their nuclei have divided and proliferated to form groups of round cells, out of which connective tissue is formed (Hamilton).

Ascites is frequently present. There is often great dilatation of the sub-diaphragmatic, gastric, and œsophageal veins, which may be as large as the femoral or iliac veins. The spleen is generally much swollen. The kidneys usually present some degree of chronic inflammatory induration. The mucous membrane of the stomach shows an advanced stage of chronic catarrh, being greyish coloured, covered with thin mucus and mammillated (*état mamelonné*).

Treatment.—The patient should become a total abstainer, and his diet should consist of light meats, fish, fowl, eggs, milk, cream, bread, butter, small quantities of well-cooked vegetables, and some alkaline mineral water or aerated distilled water. The ascites should be tapped and drawn off as often as it re-accumulates. If this be persevered in, the fluid will eventually, in many cases, cease to be poured out, to the patient's great comfort and satisfaction.

If tapping be absolutely objected to, the fluid may be got rid of by purging with bitartrate of potash—*R* Potassii bitartratis \mathfrak{zss} , mellis \mathfrak{zj} ; sig. This may be given as often as required to keep up free purgation—but its use is not unattended with danger, and is not to be recommended in place of tapping. The effect of the cessation of the effusion is to bring the patient into a condition like that of his fellow-sufferers who do not acquire ascites. He is still liable to death from hæmatemesis, due possibly to rupture of a distended œsophageal vein.

2. Cardiac or cyanotic cirrhosis has been described as a consequence of prolonged venous hyperæmia (see LIVER, HYPERÆMIA OF), depending upon pulmonary or cardiac disease.

The liver is at first enlarged, but may atrophy; it is usually hard, with a thickened capsule, and is of a dark colour. The liver cells around the radicles of the hepatic vein in the centres of the acini become destroyed, and are partly replaced by fibrous tissue, mingled with granules of blood and bile pigment. There is often slight jaundice, the liver is tender; the peritoneum contains fluid.

The diagnosis rests upon the recognition of the disease in the thoracic organs.

The treatment must be directed to the cause of the obstruction.

3. Biliary cirrhosis is best seen in cases where there is some permanent or protracted occlusion of the common duct, as by a calculus.

Early jaundice is a leading feature in the clinical history.

The liver is generally enlarged, but may undergo atrophy; its surface is tolerably smooth, its tissue deeply bile-stained and traversed by fibrous trabeculae. Charcot has pointed out that the bands of fibrous tissue embrace single acini (monolobular) instead of groups of acini, as in alcoholic cirrhosis (polylobular). The increase of capillary bile ducts is often very well marked, but not so as to constitute a distinctive feature, as has been asserted (Charcot). Ascites is generally absent.

The course of these cases is chronic, but they are very unfavourable. They terminate sometimes with partial acute atrophy, and often with so-called uræmic (? cholæmic) symptoms—*e.g.*, muttering delirium, dry tongue, and stupor.

The treatment can only be palliative. The diet should consist of light animal and farinaceous food, with no uncooked fruit or vegetables, no pickles, condiments, or strong wines or spirits. Some alkaline water (Kronenquelle or Vichy) should be taken twice a day with lemon-juice or claret. The bowels should be kept open by saline purgatives—Carlsbad salts, Hunyadi water, or Friedrichshall—and if there be any gastric irritability, bismuth (gr. x) should be given before food.

4. Syphilitic cirrhosis.—The disease which most truly deserves this name is only seen in congenital syphilis in children.

Symptoms.—The child usually presents other signs of congenital syphilis—*e.g.*, depressed nasal bones, atrophied incisor teeth, a yellow cachectic skin. The enlargement of the liver is the only local sign of the affection.

Morbid Anatomy.—The liver is enlarged, the capsule opaque, and the surface smooth. On section, it is tough, and in parts the liver tissue has undergone complete fibroid transformation. Under the microscope the growth is seen to invade the lobules, destroying them cell by cell; hence Charcot's designation, "monocellular cirrhosis." In adults, cirrhosis may be combined with gummatous deposit. In the latter case waxy degeneration may also be present. The spleen is always enlarged.

Treatment.—Small doses of mercury, gr. $\frac{1}{2}$ thrice daily, with syrup of the iodide of iron and cod-liver oil, good food and fresh air afford the best chance of arresting the disease and eradicating the constitutional malady.

In **gummatous cirrhosis** the *symptoms* are usually obscure unless the cirrhosis be very well marked. The cases are commonly regarded as examples of alcoholic cirrhosis as the external manifestations of syphilis are often but slight when the effects of the poison on internal organs are very marked. It may give rise to jaundice or ascites or to hæmatemesis. The liver may be enlarged or atrophied or irregular in shape owing to the cicatricial contraction of old gummata.

In many cases the *diagnosis* is only made on the post-mortem table.

The *treatment*, when the nature of the disease is recognized, should be that of constitutional syphilis. Iodide of potassium in full doses, ʒss three times a day, with ʒj doses of liq. hydrargyri perchloridi, or, better, small doses of calomel gr. $\frac{1}{2}$ thrice daily.

5. **Tubercular cirrhosis** occurs in phthisical patients without producing any symptoms.

The liver is enlarged, smooth and of normal consistence; on section, its surface shows a meshwork of fibrous bands running between the lobules, and there is a very great development of capillary bile ducts in the newly formed connective tissue around the lobules.

It is doubtful if it could be diagnosed during life, as enlargement of the liver in phthisis commonly occurs from venous congestion or fatty infiltration or waxy degeneration. It is a very rare disease.

It is probable that the cirrhotic livers described in connection with certain cases of tubercular peritonitis belong to this class.

6. **Malarial cirrhosis.**—The indurated and pigmented liver met with in the subjects of chronic malarial poisoning.

The *symptoms* are indefinite; jaundice is often present, and there is frequently a sense of weight in the hypochondrium, while, on examination, the liver is found to be enlarged. It is usually associated with chronic gastric catarrh. The spleen is also enlarged.

The organ is usually large and dark, tough on section, and under the microscope the new growth is seen in the portal canals, fissures and spaces of the liver, from whence it penetrates the

lobules (Hayem). The connective tissue is loaded with pigment.

The *treatment* consists in the administration of a course of arsenic in small doses combined with nitrohydrochloric acid and a bitter infusion, and the use of mercurial purgatives and saline or alkaline mineral waters—e.g., Carlsbad or Vichy.

7. **Scarlatinal cirrhosis** is a possible explanation of certain examples of cirrhotic liver met with in young children. An interstitial hepatitis seems very commonly to form part of the morbid anatomy of scarlatina, but it is a microscopical fact without any clinical features that are known.

8. **Rachitic cirrhosis** has been recently described as occurring in young children. A very important point in its aetiology is chronic gastro-intestinal catarrh, from which these children have generally suffered.

The *symptoms* are chiefly those of chronic or intermittent gastro-intestinal catarrh, constipation alternating with attacks of diarrhoea. The child's appearance is cachectic and it has a strong superficial resemblance to a case of congenital syphilis, but there is an absence of specific signs and history. In the opinion of the writer, there is no doubt that the two conditions are not identical.

Morbid Anatomy.—The liver is enlarged, smooth, and of normal colour or pale from fatty infiltration. On section it is tough, and on microscopical examination there is an increase of connective tissue in the interlobular fissures and spaces, assuming a "monolobular" distribution, and accompanied by a considerable new formation of biliary canaliculi. The spleen is also enlarged.

The *treatment* which succeeds best is calomel in small doses, from gr. $\frac{1}{2}$ to $\frac{1}{3}$ three times a day, with syrup of the iodide of iron and cod-liver oil, fresh air and good food. Care should be taken to exclude from the diet uncooked fruit and vegetables, and even cooked vegetables which contain much vegetable fibre—e.g., carrots, parsnips, stewed celery, onions. In obstinate cases all vegetable, starchy and saccharine articles of diet must be forbidden.

ROBERT SAUNDBY.

LIVER, HYPERÆMIA OF.—*Symptoms.*—In *mechanical congestion* the main symptom is increased size of the percussion area of the liver, with perhaps a palpable displacement downwards of its anterior border.

In *active congestion* there is often more pain in the right hypochondrium, or at least a sense of weight and fullness there. Jaundice, gastric disturbance, mental depression and ascites may be present.

The urine is generally diminished in amount and loaded with lithates; it often contains albumen, and sometimes bile pigment or febrile urobilin.

Course and Duration.—This will depend upon the causation. When of a temporary nature the liver recovers with the cessation of the cause, but when it is permanent no improvement can be looked for. In congestion from chill recovery is usually rapid and complete, though there is a liability to recurrence.

Diagnosis.—Little need be added on the subject of diagnosis, except that it is necessary to exclude the various organic diseases, which can only be done by a knowledge of their symptoms and relationships.

Morbid Anatomy.—In *mechanical congestion* due to obstruction of the circulation the liver is, at least at first, enlarged and soft, but after a time it becomes reduced in size, of firm consistence and darkened from the deposit of pigment. The central veins of the acini are dilated, and the surrounding cells are more or less destroyed. This is the condition called *cyanotic induration* of the liver. In many cases there is an accumulation of fat in the portal zones of the acini, giving rise to a peculiar mottled appearance called the *nutmeg liver*. There is some increase of connective tissue, the capsule of the liver is thickened, and the surface is more or less finely granular.

In *active hyperæmia* the liver is dark red, soft and vascular.

Etiology.—Mechanical congestion may result from heart or lung disease, pleural effusion, intra-thoracic tumours, or tumours compressing the vena cava just after its junction with the hepatic vein.

Congestion may also result from high living, sedentary habits and abuse of certain articles of diet, especially alcohol.

Chill seems to be a not uncommon cause of active congestion of the liver in predisposed subjects.

There are other conditions which may give rise to hyperæmia of the liver, but they are of minor importance from a clinical point of view.

Treatment.—In all *mechanical congestions* this must take the form of attempting, so far as is possible, to remove the cause. The hyperæmia may be relieved by saline

purgatives, by euonymin, calomel and other cholagogues.

Acute hyperæmia from chill should be treated by hot fomentations and large doses of calomel (5 to 10 grains).

The diet should be as simple as possible, and all substances tending to cause hyperæmia should be avoided—*e.g.*, alcohol, butcher's meat, sugar.

The following pill is a useful one:—

R Euonymini gr. j, extr. aloes gr. ij, extr. belladonnæ gr. ʒ; ft. pil.; sig. One to be taken half an hour before the principal meal of the day. It is especially useful in obesity with hepatic congestion.

ROBERT SAUNDBY.

LIVER, HYDATID OF—For an account of the life-history of the *tænia echinococcus* the reader is referred to the article on HYDATID DISEASE.

Symptoms.—A hydatid tumour produces effects varying with its size and situation in the liver. It may cause displacement of other organs, compression and obstruction of the bile passages and portal vein, leading to jaundice or ascites. It may rupture into the pleura or lung, discharging its contents through the bronchi; or into the bile passages, through the common duct, causing jaundice and pain and simulating the passage of gall-stones. It may rupture into the inferior vena cava or hepatic vein, causing death by embolism of the hepatic artery, or into the abdominal cavity, causing peritonitis.

The *diagnosis* is often difficult, and may be impossible. A slowly growing tumour of the liver unattended by grave constitutional symptoms, especially if it give evidence of fluctuation, is probably an "hydatid." An exploratory puncture with a fine needle will afford positive information if the cyst be not inflamed. Hydatid fluid is clear, free from albumen, of low sp. gr. (1007 to 1015) and contains a large amount of chloride of sodium. It may contain sugar.

Under the microscope, hooklets or even tapeworm heads may be found in the sediment, or pieces of hydatid membrane may be obtained. The latter are recognizable by their characteristic serrated lamination. When the cyst is inflamed, puncture is not so valuable, but hooklets may be found in the pus under the microscope; in this case differential diagnosis is not so important, as operative interference should be undertaken in any case. Multilocular cysts are said to be always accompanied by swelling of the spleen.

The *prognosis* in cases of simple cyst

is good; and of recent years liver surgery has advanced so far that even in suppurating or multilocular cysts a cure may be hoped for.

Treatment.—Simple cysts can be usually cured by merely *withdrawing the fluid by a fine needle or aspirator*. Injection with iodine has been performed, but is not recommended. Electrolysis is not free from danger. Suppurating and multilocular cysts should be treated by free incision, the edges of the cyst being stitched to the abdominal wall and the cavity drained. ROBERT SAUNDBY.

LIVER, PARASITES OF.—The following parasites occasionally localize themselves in the liver:—*Tænia echinococcus*, *distoma hepaticum*, *distoma lanceolatum*, *distoma hæmatobium*, *pentastoma denticulatum*, *psorospermia*, and *cysticercus cellulosa*. Of these the *echinococcus* is the only one which ordinarily gives rise to symptoms (see LIVER, HYDATID OF).

Psorosperms are very rare in man, but are common in the livers of rabbits. They are said to be *gregarina* at rest (*Eimer*). They form small white cysts containing a milky fluid, in which, besides epithelial cells and pus-corpuscles, *psorosperms* can be seen under the microscope (see PSOROSPERMIA).

The *pentastoma denticulatum* is the embryo of the *pentastoma tænioides*, which haunts the nasal cavity of the dog. It has been found chiefly in Egypt, but also in Germany (*Zenker*). It occurs in the liver in the form of rounded nodules, the size of a pin's head, which are composed of a connective-tissue capsule, enclosing the parasite, which is generally infiltrated with salts of lime. If these are dissolved by acids the feet and skin of the parasite can be recognized. The latter is studded with fine thorns alternating with rows of double-contoured stigmata (*Heller*). When a large number of these parasites invade the liver at one time they give rise to grave constitutional disturbances.

ROBERT SAUNDBY.

LOCOMOTOR ATAXIA (*Tabes Dorsalis*).—The variety of the symptoms is so wide, and their grouping so irregular, that it is difficult to give a general definition of the disease. Broadly, it may be said that the affection is characterized clinically by the absence of the knee-jerk, by inco-ordination of movement, by the absence of nutritive changes in the muscles of the affected limbs, by the frequent occurrence of pains and

sensory disorders, and by various nervous symptoms which will be described subsequently. The chief anatomical change is sclerosis of the posterior columns of the spinal cord, and more especially of the posterior-root zones.

Symptoms.—The occurrence of severe pains, especially if they be of short or momentary duration, together with absence of the knee-jerk, strongly suggests the probability of locomotor ataxy. These may be the only indications for months or years, but sooner or later the disease usually justifies its name and symptoms of ataxy or inco-ordination make their appearance. Among other symptoms likely to occur at an early period are diminution of sensibility of the soles of the feet, temporary paralysis of the external ocular muscles, incontinence of the urine or difficulty in passing it, loss of sexual power sometimes preceded by marked increase, and lastly loss of the reflex action of the iris to light.

It will now be necessary to describe the various symptoms of the disease individually.

Pains.—Most commonly they are sudden, so-called "lightning pains," affecting mainly the lower limbs, but sometimes also the arms, head and trunk. Occasionally the pains are described as burning, stabbing, constrictive or rheumatic. The attacks tend to come on in paroxysms, lasting a few hours or a few days. The pains may or may not follow the distribution of a nerve. In rare cases an erythematous, vesicular, herpetic or bullous eruption appears in the track of the pain, especially when this can be referred to the distribution of an individual nerve.

Visceral pains are present in many cases; they are usually paroxysmal and very severe. When referable to the stomach they are accompanied by obstinate vomiting, faintness, and occasionally by slowness or irregularity of the action of the heart. Such attacks are termed "gastric crises." Rectal, nephralgic, vesical, urethral, bronchial and laryngeal crises are also described. Of these the last only demands notice. Most commonly there is severe paroxysmal dyspnoea, due to laryngeal spasm, and resembling an attack of laryngismus stridulus. In some of these cases paralysis of the abductors of the larynx has been found.

Sensory Disorders.—Loss or diminution of sensibility is usually present in an ordinary case. It commonly affects the lower limbs, and more especially the soles, which feel to the patient when standing as though padded. Anæsthesia

may involve the arms, trunk, and rarely the head. All the various forms of sensibility may be affected, but some may be involved more than others. Retardation of perception and impaired localization are common. Anæsthesia may be present in other parts, such as the muscles, joints, or even the viscera. The muscular sense is usually diminished in the advanced stages, so that the patient does not know the position of his limbs when the eyes are closed.

Motor Symptoms.—Inco-ordination is the special motor symptom in locomotor ataxia, and usually supervenes slowly. At first the condition is one simply of clumsiness, as shown by some difficulty in walking in the dark, or in attempting to turn round quickly when walking. If the patient be made to stand with his feet together, his eyes being closed, he sways, and may fall unless supported. Later on the gait becomes affected in a characteristic way. Standing with the trunk bent forwards and the legs apart, his eyes fixed on the ground, the patient proceeds by throwing the limb forwards and outwards, at the same time raising it too high. The foot is brought to the ground violently, the heel touching first. As each limb is brought forwards in progression the trunk is moved from side to side and the arms thrown here and there in order to maintain the equilibrium. After a few steps the gait becomes less irregular, and the patient may walk a considerable distance with comparative ease. At an advanced period walking, or even the upright posture, may be impossible. But as the patient lies in bed the ataxy of his lower limbs is very evident when he tries to touch an object with his foot. Throughout the disease the muscles of the lower limbs, however great the inco-ordination, usually preserve their normal bulk and strength and the electrical reactions are intact. The upper limbs frequently become affected with inco-ordination. Often writing is first noticed to be imperfect, or some difficulty is experienced in picking up fine objects or in buttoning or unbuttoning. Inco-ordination of the hands can be brought out by the observer asking the patient to touch his nose with the index finger when the eyes are closed, or to bring the tips of the forefingers together. In other cases the uncertainty of the movements is very obvious, the patient being unable to feed himself or to perform other necessary duties. In exceptional instances the muscles of the trunk are affected by ataxy. Articula-

tion also occasionally becomes slow and jerky from inco-ordination of the muscles concerned.

Reflexes.—The knee-jerk is almost invariably absent at the earliest period, often long before other symptoms make their appearance. The plantar reflex is usually normal, sometimes diminished or delayed, and occasionally in the early stage increased.

Eye Symptoms.—The pupils are often small (*myosis*), and in the great majority of cases the reflex action of the iris to light is abolished, whilst the contraction on accommodation is preserved (Argyll-Robertson phenomenon). The pupils may be unequal or irregular; occasionally they are of average size, or even large. Erb has pointed out that in many cases the pupils do not dilate on painful stimulation of the skin of the neck. Loss of accommodation sometimes occurs from paralysis of the ciliary muscle.

Temporary paralysis of the external ocular muscles, leading to squint and double vision, has already been described as occurring, usually in the early stages. In the advanced periods persistent paralysis may be present, such as ptosis alone or ptosis together with palsy of the other parts supplied by the third nerve, or convergent squint from paralysis of the sixth nerve. Paralysis of the third and sixth nerves is often present in cases having a syphilitic origin. Ataxic nystagmus occurs rarely, and usually when the disease is advanced. The two following forms of paralysis are comparatively rare:—(1) Impaired power of the internal recti when acting together in convergence, the same muscles acting well when associated with the external recti in lateral movements (paralysis of convergence). (2) Ophthalmoplegia externa or paralysis of most or all of the external ocular muscles.

Atrophy of the optic nerve, often quite an early symptom, is present in a certain proportion of cases. This condition gives rise to colour-blindness, to contraction of the visual field, and, lastly (sometimes soon, sometimes after the lapse of years), to total blindness.

Affections of other Cranial Nerves.—Deafness from atrophy of the auditory nerve occurs as a rare condition, and still more uncommon are disturbances of taste and smell. Hemiatrophy of the tongue from disease of the hypoglossal nerve, paralysis of the facial, and paralysis of the abductor muscles of the vocal cords have been described.

Affections of Joints and Bones.—Tabetic

arthropathy usually occurs early in the disease, and affects mainly the large joints, such as the hips, knees, ankles and shoulders. In many cases the affection commences suddenly, with painless effusion into and around the joint. Later on disorganizing changes may take place, the cartilages becoming eroded, the heads of the bones atrophied, and the ligaments calcified. Bony out-growths are often developed in and around the affected joint after the lapse of time. Dislocations are frequent. The shafts of the bones sometimes become brittle, spontaneous fractures occurring; the union of such fractures is accompanied by an over-abundant callus.

Various Trophic Changes.—Cutaneous eruptions have already been described as occurring after the paroxysmal pains. Perforating ulcer of the foot is not unfrequent. Nutritive changes in the nails, falling out of the teeth, changes in the pigmentation of the skin and hair are of occasional occurrence. Sometimes rapid wasting of muscles supervenes in ataxy, and in such cases there is every reason to believe that the anterior grey matter of the cord has been affected secondarily.

Course of the Disease.—This is subject to considerable variations. Sometimes the affection does not pass beyond the first stage, which is characterized by absence of the knee-jerk, lancinating pains and slight unsteadiness, with perhaps absence of the light reflex of the iris. In a typical case, anæsthesia with marked inco-ordination sooner or later makes its appearance. Not uncommonly, when these symptoms become evident, the lightning pains disappear or become less frequent and severe. At a later period the various symptoms are very irregular in their appearance and development. Sometimes the disease, in whatever stage it may be, remains without material change for months or years; sometimes abrupt exacerbations occur, often dependent on secondary extension in the nervous centres or on affection of the peripheral nerves. Occasionally marked amelioration takes place, and the improvement may be maintained for considerable periods. Death usually proceeds from intercurrent maladies, but occasionally it results from complications occurring in the course of the disease, such as cystitis and pyelitis, or to the formation of bed-sores.

Complications.—Extension of the morbid process to other parts of the cord may take place. When the lateral

columns are invaded, marked muscular weakness without wasting is superadded to the inco-ordination. Muscular atrophy from involvement of the anterior grey matter is not uncommon, and as a rare condition true progressive muscular atrophy may be noted. Symptoms of locomotor ataxy are frequent in general paralysis of the insane, sometimes preceding, sometimes following, the characteristic features of the latter disease. It may be mentioned here that in ataxy, as in general paralysis, acute cerebral symptoms, such as convulsions, may take place, but their occurrence in the former is much rarer than in the latter. Myelitis may come on in the course of ataxy, and its existence will be made clear by the rapid supervention of various spinal symptoms, such as diffuse muscular wasting, with loss of sensation and urinary complications. Ordinary hemiplegia occasionally co-exists with locomotor ataxy, and sometimes symptoms due to independent syphilitic lesions in the brain. Cardiac disease, especially aortic valvular incompetency, is present in a significant proportion of cases of ataxy.

Diagnosis.—The difficulty in diagnosis in the early stage has been already mentioned, and the symptoms which suggest commencing tabes have been described. There will usually be no trouble in differentiating between diphtheritic paralysis and locomotor ataxy. Occasionally, however, the absence of the knee-jerk is the sole indication in the former of any change in the nervous system. In such a case the suspicion of early tabes may arise, but a careful inquiry into the history of the patient will almost invariably clear up the diagnosis. In alcoholic neuritis symptoms resembling locomotor ataxy are sometimes present. The history of alcoholism, the presence of motor weakness as well as of inco-ordination, the existence of muscular wasting with change in the electrical reactions, and the hyperæsthesia on deep pressure are characteristic of alcoholic pseudo-tabes. Disease of the cerebellum is often accompanied by a staggering gait, suggesting locomotor ataxy. In cerebellar disease, however, there are no lightning pains and no impairment of sensation, whereas severe headache, vomiting and optic neuritis are common. The knee-jerk, with few exceptions, is present in cerebellar disease. In general paralysis of the insane, tabetic symptoms are frequent, and not uncommonly play a

prominent part in the symptomatology. In some cases the only indication of the more serious affection may be slight tremor of the face, with some defect of speech and possibly some degree of emotional disturbance. In every case of ataxy having an onset and course more than usually acute the suspicion of general paralysis should be entertained. It occasionally happens that ataxy forms a marked symptom in disseminated sclerosis. Some of the characteristic symptoms, such as nystagmus, vertigo, tremors of the hands and tongue, and the slow, scanning speech, will usually be found even at an early period. The points of difference between locomotor ataxy and other diseases of the spinal cord do not call for special notice.

Prognosis.—The disease, as has already been stated, is subject to many variations. Its course is essentially chronic, but fortunately by no means always progressive. Inco-ordination may never be present, or, if present, may be insignificant. Remarkable improvement frequently occurs independent of treatment, and this is occasionally the case even in the advanced stages of the disease. The lightning pains usually tend to become less severe and frequent in the course of time. Visual defects from disease of the optic nerve as a rule undergo no improvement.

Morbid Anatomy and Pathology.—The spinal pia mater is thickened and adherent, especially on the posterior surface, and the cord itself is reduced in size and flattened from before backwards. The posterior nerve roots are grey and atrophied in the lower part of the cord. On section, the posterior columns in the sacral and lumbar regions show extensive grey, translucent change; higher up the degeneration is less obvious, and is usually limited to the postero-median columns in the cervical region. Sometimes degeneration in the lateral columns can be made out by the naked eye. The precise degree of change in the posterior columns is subject to certain variations.

Not unfrequently the entire extent of the posterior columns is degenerated in the sacral and lumbar regions, the postero-external columns or posterior root-zones becoming less and less affected on passing from the lumbar enlargement upwards. The anterior part of the postero-external column is often only slightly affected. The postero-median columns invariably undergo degeneration throughout their entire

length, the change being traceable to the fasciculi graciles—the continuation of these columns in the medulla. In some cases the posterior root-zones are involved in the dorsal and cervical regions, and in exceptional cases the entire posterior columns may be densely sclerosed throughout all the regions of the cord. A comma-shaped tract of fibres, degenerating from above downwards, and probably commissural, is often found degenerated in the dorsal region, where it occupies the middle of the anterior part of the posterior columns. The fibres of the posterior cornu frequently undergo degeneration, as well as Clarke's posterior vesicular columns and Lissauer's tract. The so-called antero-lateral tract and the direct cerebellar tract are commonly degenerated, and occasionally the pyramidal tracts are invaded. Rarely the cells in the anterior grey matter undergo atrophy from extension of the disease in the posterior columns along the internal radicular fasciculi.

The histological characters of the degeneration call for no special note. It may be stated, however, that the walls of the small vessels are usually much thickened, and that the sclerosis is often most obvious in their neighbourhood. The primary change, however, consists in a degeneration of the nerve fibres in the posterior roots, the sclerosis being secondary. In some cases the peripheral nerves have been found degenerated. Many of the symptoms of *tabes dorsalis* are easily intelligible from the consideration of the morbid anatomy of the disease. The pains are due to irritation of the posterior nerve roots, but it is not so easy to explain the intermittent character of these pains; possibly it may be ascribed to changes in vascular supply or pressure. Anaesthesia is caused by destruction of the posterior roots and the loss of the knee-jerk by disease of the afferent part of the reflex loop. Acute muscular wasting and marked paralysis without atrophy are due respectively to secondary implication of the anterior grey matter and of the lateral columns. Certain symptoms are clearly dependent on affection of the peripheral and cranial nerves. It is believed by many that trophic changes in the skin, bones and joints are caused by degeneration of peripheral nerves, but on this point there is still difference of opinion. No satisfactory explanation of the inco-ordination has yet been adduced. Ataxy may be extreme when cutaneous and

muscular anæsthesia are slight or even absent. There, is, indeed, no necessary relation between the two conditions. Gowers suggests that the ataxy may be caused by disease of the sensory muscle nerves. Ross ascribes inco-ordination to destruction of certain fibres in the posterior root-zones, which co-ordinate afferent impulses. The fact that some of the posterior root-fibres pass by the lateral columns of the cord directly to the cerebellum, as shown by Dr. Sherrington and the writer, strongly suggests that the inco-ordination is due to disease of the cerebello-afferent fibres.

Etiology.—The disease is much more common in males than in females, and the majority of cases occur between the ages of thirty and fifty. Prolonged exposure to cold and wet, great mental and bodily exertion, and injury to the spine have probably some share as predisposing agents. Heredity has some influence, the disease occasionally occurring in subjects in which there is a family history of insanity, epilepsy or other nervous affections. The influence of sexual excess and of alcoholism is doubtful. In a considerable proportion of cases, estimated by some observers as high as 50 per cent., a history of syphilis is obtainable. The precise ætiological share which syphilis holds in the production of tabes is uncertain. It is believed by Gowers and others that syphilis, by lowering the resisting power of the nerve-elements, acts indirectly as a permissive agent. The lesion in tabes, however, is of a "system" nature, and hence it is most improbable that it is directly syphilitic.

Treatment.—It is of great importance that the patient be not subjected to any depressing influences, either bodily or mental. Careful attention to diet, and avoidance of excess in alcohol and tobacco, should be enforced. Rest in bed is often followed by marked improvement. Iodide of potassium and mercury have not the beneficial influence that might be expected on the assumption that the disease is related to syphilis. The former drug may be given in doses up to 30 grains three times daily, and with it bromide of potassium may be combined. Nitrate of silver (in doses of $\frac{1}{4}$ to $\frac{1}{2}$ grain) and arsenic are highly recommended by some authorities. Iron, quinine, nux vomica, ergot, belladonna and cod-liver oil have been frequently employed, but their action for good is doubtful. There is, indeed, no reason to think that any drug has a direct specific action

in tabes. Morphine is often the only efficient agent in relieving the lancinating pains. It should be used with caution. Cannabis indica is sometimes a useful substitute.

Hypodermic injections of cocaine applied locally occasionally relieve pain. Antipyrin has also been used with great benefit, but its action is not constant. For the relief of pain, blisters, chloroform applications and the warm bath may also be used. Blisters or the actual cautery to the spine are occasionally of use in the early periods. Sulphur and saline thermal baths and the cold pack have been recommended. The constant current in an ascending direction applied to the back has been occasionally of some benefit, especially when muscular wasting existed. Faradization over the hypogastrium is useful in vesical weakness. The bladder should be regularly emptied and washed out if there be residual urine and evidence of cystitis. Within the last few years nerve-stretching has been performed, chiefly with the view of relieving pain. Occasionally the operation has been followed by improvement in the inco-ordination. The results of nerve-stretching are not always beneficial, and when improvement has followed it has usually been temporary. The great sciatic nerves have usually been selected for operation.

Quite recently Professor Charcot has warmly advocated a method of treatment which was first advocated by Dr. Motchoukowsky, of Odessa. This treatment consists simply in the suspension of the patient by Sayre's apparatus in the ordinary manner. The duration of suspension is, at the outset, half a minute. At each application the period is increased by half a minute, but the longest time should not exceed three or, at the outside, four minutes. The suspensions should not be carried out oftener than every other day. While the patient is suspended he should be made to raise his arms away from the body, and nearly at right angles to it, at intervals of every fifteen or twenty seconds. Under this treatment it is asserted that in most cases inco-ordination becomes less marked, or may even disappear, the lightning pains diminish, the functions of the bladder are partially or entirely restored, sexual power returns, and that anæsthesia may give place to sensibility; the absence of the knee-jerk and the condition of the pupils are persistent. Experience has since shown that this method of treatment is frequently, but not invariably, of

service. In some cases, at least, the beneficial result has been but temporary.

W. B. HADDEN.

LUNACY LAW.—Many very important changes have been effected in the law of lunacy by the Lunacy Act, 1890.

The scope of this article is for the most part restricted to those points which are of importance to the medical practitioner; officers of asylums and those specially engaged in the care of the insane must be presumed to acquaint themselves directly with the Act of Parliament.

The legal provisions for the care of lunatics may be considered as affecting—
I. Private Lunatics, II. Pauper Lunatics, III. Lunatics wandering at large, IV. Criminal Lunatics.

I. PRIVATE LUNATICS, or lunatics maintained out of their own resources, may be either—(a) Chancery patients, (b) Single patients in unlicensed houses, (c) Patients confined in public or private asylums or in registered hospitals under orders and medical certificates.

(a) *Chancery Patients* are those who, being possessed of property, have been found to be of unsound mind and incapable of managing their affairs, upon a petition to the Lord Chancellor by a person interested, and after inquiry before one of the Masters in Lunacy; a commission having been granted by the Lord Chancellor in the nature of the writ *de Lunatico Inquirendo*. The petition must be supported by the affidavits of two medical men. The alleged lunatic has a notice of the proceedings served upon him, may employ a solicitor, and is entitled to demand a jury, unless the Lord Chancellor or his representative considers him, after personal examination, to be incompetent to express this wish. If the patient be found to be a lunatic, "committees" are appointed of the person and of the estate of the lunatic; these offices may be held separately or united in one individual. Lunatics so found are subject to visitation by the Chancery Visitors, three in number, two being physicians and one a barrister. An inquisition of this nature only takes place when the amount of property is considerable. In the case of persons possessing property not exceeding £2000 in value or £100 yearly income, the Lord Chancellor may, without inquiry under a commission, but after giving notice to the alleged lunatic, make an order for management of his property. The petition has to be supported by affi-

davits or by report of one of the Masters in Lunacy or the Commissioners in Lunacy. A patient found lunatic by inquisition may be admitted to an asylum or to single care on the order of the committee of the person, together with an office copy of the appointment of the committee, and without any medical certificates.

If it be found that the alleged lunatic is of unsound mind, so as to be incapable of managing his affairs, but that he is capable of managing himself and is not dangerous to himself or others, a committee of the estate may be appointed, and provision made for the maintenance of the lunatic, although his personal liberty is not interfered with.

If a Chancery patient completely recovers, it is necessary to apply for a "supersedeas" to set aside the finding of the inquisition; but if he become capable of managing himself, although he remains incapable of managing his affairs, the Judge in Lunacy may, if he think it desirable that the ordinary proceedings for a supersedeas should not be insisted upon, make an order superseding the inquisition, and restore the patient to his liberty.

b. Single Patients in Unlicensed Houses.

—A person of unsound mind may be taken care of privately in the house of a relation or friend, without "order" and certificates, the Commissioners having power to visit; but if in the care of a person deriving profit from the charge, the patient must be under an "order" and medical certificates (unless a Chancery patient), and comes directly under the notice of the Commissioners in Lunacy, to whom copies of the above-mentioned documents have to be sent within twenty-four hours of the date of reception. The law relating to the petition and reception order and certificates is the same for single patients as for those in asylums. (See under following section.) The patient must be visited at least once in every two weeks by a medical man not deriving, and not connected with those deriving, profit from the charge of him, who must keep notes of the patient's condition in a medical journal and "Medical Visitation Book," and must forward to the Commissioners at the expiration of one month from his reception a statement of the bodily and mental condition. He must not have signed either of the certificates for the patient's reception. Notice has also to be sent of the death, removal, discharge, escape or recapture of the patient. A pa-

tient can be transferred from single care to the charge of another person, or to a licensed house or registered hospital, with the consent of the Commissioners, upon the original certificates. Not more than one patient may be detained in this way without a licence, unless the Commissioners are satisfied that it is desirable, under special circumstances, and for the interest of the patient, that one or more additional patients should reside in the same house.

c. Patients (other than those found lunatic by inquisition) in Licensed Houses (Private Asylums) or Registered Hospitals.

It is provided by the Act of 1890, that with certain exceptions :—

No person, not being a pauper or a criminal lunatic, and not being found a lunatic by inquisition, shall be received and detained as a lunatic in any asylum, hospital, or licensed house, or as a single patient, unless under a reception order made by a county court judge or magistrate, or by a justice of the peace, specially appointed, and having jurisdiction in the place where the lunatic is. No relative of the person applying for an order, or of the lunatic, or of the husband or wife of the lunatic, can make such an order.

The *Order* (Form 3) is to be obtained upon a private application by a *Petition* (Form 1) accompanied by a *Statement of the Particulars* (Form 2) and by two *Medical Certificates* (Form 8) on separate sheets of paper under the hands of two medical practitioners (*vide infra*).

The Petition.—The petition is to be presented, if possible, by the husband or wife, or by a relative of the patient. If not, it must contain a statement of the reasons why the petition is not so presented, and of the connection of the petitioner with the patient, and the circumstances under which he presents the petition.

No person can present a petition unless he be at least twenty-one years old, and has seen the patient within fourteen days.

The petitioner must undertake that he will visit the patient once at least in every six months, but he may appoint a deputy.

The Medical Certificates.—One of the medical certificates accompanying the petition, must, whenever practicable, be given by the usual medical attendant of the patient. If for any reason it is not practicable to obtain a certificate from him, the reason must be stated in

writing to the presiding magistrate, by the petitioner.

No order can be made upon a petition unless each of the persons who sign the medical certificates accompanying the petition, separately from the other, has personally examined the patient not more than seven clear days previously to the date of the presentation of the petition.

The medical men signing must not be partners, nor one the assistant of the other, nor be nearly related to each other, or to the person who signs the petition or urgency order, and they must be duly registered and in actual practice. Further, they must have no connection with the Institution into which the patient is to be received.

Proceedings on Presentation of the Petition.—Upon the presentation of the petition and certificates, the presiding magistrate considers the statements they contain, and decides whether it is necessary for him to see and examine the patient personally; and may either make an order at once, or appoint a time, not being more than seven days after the presentation of the petition, for its consideration: and may make any further inquiries concerning the patient which he may consider necessary. Notice of the time and place appointed for the consideration of the petition (unless personally given to the petitioner) must be sent to him by post in a registered letter.

The presiding magistrate if not satisfied with the evidence of lunacy appearing in the medical certificates, may visit the patient wherever he may happen to be. In carrying out these duties, the magistrate is invested with the same powers as he has when sitting in his court.

Consideration of the Petition.—The petition is considered in private, and no one except the petitioner, the patient (unless the magistrate order otherwise), one person appointed by the patient, and the persons signing the medical certificates are allowed to be present without the leave of the magistrate.

The magistrate may make an order or may dismiss the petition, or adjourn the consideration of it for a period of not more than a fortnight for further evidence, and may give notice to any one he pleases of the adjournment, and may summon any one to attend before him.

Every one present at the consideration of a petition for a reception order (including the presiding magistrate), or who has official knowledge of the fact that a petition has been presented except the

patient and the person appointed by him already referred to, is bound to keep his knowledge secret.

If the petition be dismissed, the magistrate must give the petitioner a statement in writing of his reasons for dismissing it, and must send a copy of the statement to the Commissioners in Lunacy, and when the patient is detained under an Urgency Order, he must send notice to the person in whose charge the patient is, that the petition has been dismissed.

The magistrate, if requested by the Commissioners in Lunacy, must give them all information they may require as to the circumstances under which an order was made or refused, and they may communicate the information to the patient or to any one who satisfies them that he is a proper person to receive it.

If, after a petition has been dismissed, another petition be presented about the same patient, the petitioner, should he have any knowledge with regard to the previous petition and its dismissal, must state it in his petition, and must obtain from the Commissioners, and present with his petition, a copy of the statement sent to them of the reasons for dismissing the previous petition, and, if he wilfully omit to comply with this regulation, he is declared guilty of a misdemeanour.

The Reception Order.—A reception order, if in conformity with the Act, is a sufficient authority for the petitioner or any person authorized by him to take the patient to the place mentioned in the order and for his reception and detention there.

The order, with the petition, statement of particulars, and medical certificates, must be delivered or sent by post to the person on whose petition it was made, and he or his agent must deliver it to the superintendent or proprietor of the asylum or hospital, or licensed house in which the lunatic is to be received and to the person who is to receive him.

Unless a reception order be acted upon within seven clear days from its date, it becomes invalid.

A person upon whose petition a reception order is made, has the same powers and liabilities as, by the Lunacy Acts, formerly belonged to a person signing an order for the reception of a lunatic not a pauper.

A reception order expires at the end of one year from its date, and any order dated three months or more before the commencement of the Act expires at the end of one year after the commencement of the Act, unless such orders are continued.

If the patient has not been personally seen by the magistrate who made the order, he has the right to be taken before or visited by a judge or a magistrate, unless the medical superintendent of the asylum, or the medical proprietor or attendant of the house, or in the case of a single patient, the medical attendant, within twenty-four hours after the patient's reception, in a certificate signed and sent to the Commissioners, states that the exercise of the right would be prejudicial to the patient.

In all other cases the responsible person must, within twenty-four hours after his reception, give to the patient a notice in writing of this right, and must ascertain whether he desires to exercise it; and if within seven days after his reception he expresses his desire to exercise this right, then the superintendent or person in charge must get him to sign a notice to that effect, and he must immediately send the notice by post in a registered letter to the magistrate who is appointed to exercise this jurisdiction or to the clerk of the justices of the petty sessional division or borough, where the lunatic is, to be forwarded to the magistrate, who must thereupon arrange, as soon as possible, either to visit the patient or to have him brought before him by the superintendent, or person in whose charge he is. Any one omitting to perform this duty is guilty of a misdemeanour.

Urgency Orders.—Important provision is made for the immediate care of the insane in exceptional cases by means of these orders (see Form 4).

When it is expedient, either for the welfare of the patient (not being a pauper) or for the public safety, that he should be forthwith confined, he may be received and detained upon an urgency order, made (if possible) by the husband or wife or by a relative, accompanied by one medical certificate (see Form 4).

The medical practitioner who signs the certificate must have personally examined the patient not more than two clear days previously to the reception of the patient, and the date of the examination must be stated in the certificate.

An urgency order may be signed before or after the medical certificate.

If an urgency order be not signed by the husband or wife or by a relative of the patient, the reasons why it is not so signed and the connection of the person signing it with the patient, and the circumstances under which he signs it, must be stated in the order.

No one can sign an urgency order unless he be at least twenty-one years old, and he must have seen the patient within two days before the date of the order.

An urgency order may be made either before or after a petition for a reception order has been presented (or an application made to the Judge in Lunacy, in cases where the reception order is to be made by the Judge in Lunacy). If an urgency order be made before a petition has been presented, it must be referred to in the petition, and if made after the petition has been presented, the petitioner must immediately send a copy of it to the magistrate to whom the petition has been presented.

An urgency order only remains in force for seven days from its date; but if a petition for a reception order or an application to the Judge in Lunacy be pending, then it is good until the petition or application is finally disposed of.

A statement of particulars must be annexed to an urgency order.

Discharge of Patients.—The Commissioners may visit a patient detained in any hospital or licensed house, or as a single patient, and may, within seven days after their visit, if the patient appear to them to be detained without sufficient cause, make an order for his discharge.

An order for the examination by two medical practitioners, of any patient, may be obtained from the Commissioners upon the application of any one, whether a relative or friend or not, who shall satisfy them that it is proper for them to grant such an order; and on production of the certificates of the medical practitioners so authorized, certifying that after two separate examinations with at least seven days interval, they are of opinion that the patient may, without risk or injury to himself or to the public, be discharged, the Commissioners may order the patient to be discharged at the expiration of ten days from the date of the order.

Voluntary Boarders.—The superintendent or proprietor of a licensed house may, with the previous consent of two of the Commissioners, or, where the house is licensed by the justices, of two of the justices, receive and lodge as a boarder for the time specified in the consent, any one who is desirous of voluntarily submitting to treatment. After the expiration of the stated time (unless consent be given for its extension) he must be discharged.

Protection to Persons signing Certificates, &c.—The following provisions are of great importance to medical men:—

“A person who before the passing of this Act has signed or carried out or done any act with a view to sign or carry out an order purporting to be a reception order, or a medical certificate that a person is of unsound mind, and a person who after the passing of this Act presents a petition for any such order, or signs or carries out or does any act with a view to sign or carry out an order purporting to be a reception order, or any report or certificate purporting to be a report or certificate under this Act, or does anything in pursuance of this Act, shall not be liable to any civil or criminal proceedings, whether on the ground of want of jurisdiction, or any other ground, if such person has acted in good faith and with reasonable care.”

“If any proceedings are taken against any person for signing or carrying out or doing any act with a view to sign or carry out any such order, report, or certificate, or presenting any such petition as in the last preceding sub-section mentioned, or doing anything in pursuance of this Act, such proceedings may, upon summary application to the High Court of Justice or a Judge thereof, be stayed upon such terms as to costs and otherwise as the Court or Judge may think fit, if the Court or Judge is satisfied that there is no reasonable ground for alleging want of good faith or reasonable care.”

II. PAUPER LUNATICS.—Lunatics who were paupers before becoming insane, or who become paupers as a result of lunacy, must be relieved by the guardians or other local authorities charged with the relief of the poor. They may, according to circumstances, be kept in the workhouse, or be lodged with friends or relatives, or be boarded out, or be sent to the county or borough asylum, being in all cases under the supervision of the Lunacy Commissioners. For admission to a county asylum it is necessary that the “reception order” should be signed (after examination) by a justice of the peace. One medical certificate only is required, usually signed by the medical officer of the parish. If certificates are signed by a medical man called in specially, and also by the medical officer of the parish, the justice has no alternative but to sign the necessary reception order. The latter differs somewhat in form from that for private patients, but the form of certificate is the same.

FORM 2.

Statement of Particulars.

STATEMENT of particulars referred to in the annexed petition [or in the above or annexed order].

The following is a statement of particulars relating to the said *A.B.* [1]:—

Name of patient, with Christian name at length.

Sex and age.

†Married, single, or widowed.

†Rank, profession, or previous occupation (if any).

†Religious persuasion.

Residence at or immediately previous to the date hereof.

†Whether first attack.

Age on first attack.

When and where previously under care and treatment as a lunatic, idiot, or person of unsound mind.

†Duration of existing attack.

Supposed cause.

Whether subject to epilepsy.

Whether suicidal.

Whether dangerous to others, and in what way.

Whether any near relative has been afflicted with insanity.

Names, Christian names, and full postal addresses of one or more relatives of the patient.

Name of the person to whom notice of death to be sent, and full postal address if not already given.

Name and full postal address of the usual medical attendant of the patient.

(Signed)

When the petitioner or person signing an urgency order is not the person who signs the statement, add the following particulars concerning the person who signs the statement.

{	<p>Name, with Christian name at length.</p> <p>Rank, profession, or occupation (if any).</p> <p>How related to or otherwise connected with the patient.</p>
---	---

[1] If any particulars are not known, the fact is to be so stated.
[Where the patient is in the petition or order described as an idiot omit the particulars marked †].

FORM 3.

Order for reception of a private patient to be made by a Judge of County Courts, Stipendiary Magistrate, or Justice appointed under the Lunacy Acts Amendment Act, 1889.

I, the undersigned *E.F.*, being the Judge of the County Court of [or the Stipendiary Magistrate for,

Justice for specially appointed under the Lunacy Act 1890] upon the petition of *C.D.*, of [1] in the matter of *A.B.* a lunatic, [2] accompanied by the medical certificates of *G.H.* and *I.J.* hereto annexed, and upon the undertaking of the said *C.D.* to visit the said *A.B.* personally or by some one specially appointed by the said *C.D.* once at least in every six months while under care and treatment under this order, hereby authorize you to receive the said *A.B.* as a patient into your asylum [3]. And I declare that I have [or have not] personally seen the said *A.B.* before making this order.

Dated

(Signed) *E.F.*

The Judge of the County Court of

[or a Stipendiary Magistrate, or a Justice for

appointed under the above-mentioned Act.]

To [4]

[1] Address and description.
[2] Or an idiot or person of unsound mind
[3] Or hospital or house or as a single patient.
[4] To be addressed to the medical superintendent of the asylum or hospital, or to the proprietor or superintendent of the house in which the patient is to be placed.

FORM 4.

Form of Urgency Order for the reception of a private patient.

I, the undersigned, being a person twenty-one years of age, hereby authorize you to receive as a patient into your house [1] *A.B.*, as a lunatic [2], whom I last saw at _____ on the [3] _____ day of 18 ____ . I am not related to or connected with the person signing the certificate which accompanies this order in any of the ways mentioned in the margin [4]. Subjoined [or annexed] hereto [5] is a statement of particulars relating to the said *A.B.*

[1] Or hospital or asylum or as a single patient.

[2] Or an idiot or a person of unsound mind.

[3] Some day within two days before the date of the order.

[4] Husband, wife, father, father-in-law, mother, mother-in-law, son, son-in-law, daughter, daughter-in-law, brother, brother-in-law, sister, sister-in-law, partner, or assistant.

[5] See Form II.

[6] Describing house or hospital or asylum by situation and name.

(Signed)

Name and Christian name at length
Rank, profession, or occupation (if any)
Full postal address

How related to or connected with the patient.

[If not the husband or wife or a relative of the patient, the person signing to state as briefly as possible :—1. Why the order is not signed by the husband or wife or a relative of the patient. 2. His or her connexion with the patient, and the circumstances under which he or she signs.]

Dated this _____

day of _____

18 ____ .

To _____
house [6] [or hospital or asylum].

FORM 8.

Certificate of Medical Practitioner.

[1] Insert residence of patient.

[2] City or borough, as the case may be.

[3] Insert profession or occupation, if any.

[4] Insert the place of examination, giving the name of the street, with number or name of house, or should there be no number, the Christian and surname of occupier.

[5] City or borough, as the case may be.

[6] Omit this where only one certificate is required.

[7] If the same or other facts were observed previous to the time of

In the matter of *A.B.* of [1] _____ in the county [2] of _____
[3], an alleged lunatic.

I, the undersigned *C.D.*, do hereby certify as follows :—

1. I am a person registered under the Medical Act, 1858, and I am in the actual practice of the medical profession.

2. On the _____ day of _____ 18 ____, at [4] in the county of [5] _____ [separately from any other practitioner] [6], I personally examined the said *A.B.*, and came to the conclusion that he is a [lunatic, an idiot, or a person of unsound mind] and a proper person to be taken charge of and detained under care and treatment.

3. I formed this conclusion on the following grounds, viz. :—

(a) Facts indicating insanity observed by myself at the time of examination [7], viz. :—

(b) Facts communicated by others, viz. :—[8]

[If an urgency certificate is required it must be added here. See Form 9.]

If the lunatic is to be received as a single patient in a house belonging to or kept by a medical practitioner under the order of a county court judge, magistrate, or justice, add the following paragraph :—

4. The said *A.B.* appeared to me to be [or not to be] in a fit condition of bodily health to be removed to an asylum, hospital, or licensed house.[9]

5. I give this certificate having first read the section of the Act of Parliament printed below.

Dated (Signed) C.D. of [10]

Extract from Section 317 of the Lunacy Act, 1890.

Any person who makes a wilful misstatement of any material fact in any medical or other certificate or in any statement or report of bodily or mental condition under this Act, shall be guilty of misdemeanour.

FORM 9.

Statement accompanying Urgency Order.

I certify that it is expedient for the welfare of the said *A.B.*, [or for the public safety, as the case may be] that the said *A.B.* should be forthwith placed under care and treatment.

My reasons for this conclusion are as follows: [*State them.*]

LUNGS, CIRRHOSIS OF. —

Chronic pneumonia, chronic interstitial pneumonia, indurative pneumonia, ulcerative pneumonia, fibroid induration of the lung, fibroid phthisis, are other names used to designate the same affection, but the term cirrhosis is preferred, as it implies no theory.

The pathological changes included in this condition are so varied that a consideration of them is a necessary preliminary to an account of the clinical features which it presents.

Pathology.—Cirrhosis of the lung is a condition characterized by consolidation of the pulmonary texture consequent upon an overgrowth of connective tissue. Contraction and excavation of the lung, bronchial dilatation, thickening and adhesion of the pleura are generally, but not necessarily, associated with cirrhosis. The pulmonary induration may remain stationary for a long period of time, but more often a tendency to extension is manifested. Fibrous changes in the lung may be the result of several different causes, of which tuberculosis is, without question, the commonest and most important. Few cases of tubercular phthisis run their course without inducing some degree of fibrous induration. Tubercular cirrhosis represents a late stage of phthisis pulmonalis, a chronic infective disease, which is described elsewhere, and cannot be further noticed here.

Non-tubercular indurative lesions of the lung—that is to say, affections which are not the result of constitutional disease, and in which there is no ten-

dency to specific infection of other organs—are therefore alone included in the scope of the present article.

Cirrhosis may be *massive, insular or reticular*. In pronounced instances of the *massive* form, one or more lobes of the lung are converted into a tough, greyish, airless substance, which commonly shows irregular pigmentation or marbling on section. In the early stages the consolidation closely resembles red hepatization, from which it is only distinguished by its greater toughness. The consolidation may be uniform, or small islets of partially spongy tissue may be scattered through the solid lung.

The disease is generally confined to one lung, and the lower lobe, as a rule, is mainly or exclusively affected, though the whole lung may be more or less involved. In rare cases cirrhosis may attack the upper lobe in the first instance.

Except in the early stages, some degree of shrinking of the affected lung is an invariable occurrence. The bronchi commonly show a diffuse cylindrical dilatation, saccular expansions being less frequently observed. Sacculated bronchiectasis is very apt to be complicated by ulceration of the bronchial wall, giving rise to irregular cavities; but ulcerative excavation of the lung may develop without the intervention of bronchial dilatation. It is important, however, to recognize that bronchiectasis and the formation of vomicae are not essential accompaniments of the cirrhotic process.

The *insular* type of cirrhosis is sometimes met with in the less diseased por-

the examination, the certifier is at liberty to subjoin them in a separate paragraph. [8] The names and Christian names (if known) of informants to be given, with their addresses and descriptions. [9] Strike out this clause in case of a private patient whose removal is not proposed. [10] Insert full postal address.

tions of lungs affected with massive induration, but in other cases it constitutes the prevailing character of the lesion. Saccular dilatation of the bronchi is more generally combined with this variety of cirrhosis than with any other, but at the same time cylindrical bronchiectasis is also very common. The lung tissue separating the indurated patches may be unaltered, or it may be marked by fibrous strands extending from the larger cirrhotic foci. Varying degrees of emphysema are also very common.

In the *reticular* form of cirrhosis the lung is traversed by pigmented, tough, fibrous bands, which cross one another at various points, forming a sort of trellis-work. This change may be confined to the base, or to special parts of the organ, and in exceptional cases may be uniformly distributed throughout both lungs. The intervening tissue is often more or less emphysematous, and sometimes presents a condition of brown induration.

Emphysema has been a prominent feature in the few cases that the present writer has met with. Bronchial dilatation is either slight or absent.

Caseous nodules are absent in all forms of this affection, but tuberculosis occasionally develops as a secondary disease in cases of advanced non-tubercular cirrhosis.

Small aneurysms sometimes develop in the cavities, as in cases of chronic tubercular phthisis, and give rise to fatal hæmorrhage. Slight hæmoptysis may be produced by erosion of small vessels in the cavity walls, and possibly also by rupture of the dilated capillaries in the diseased bronchioles. In all forms of cirrhosis some degree of thickening and adhesion of the pleura is almost invariably present, and this condition is most pronounced where the induration of the lung is greatest. The pleura may be comparatively little affected in reticular cirrhosis.

As regards the relation between bronchiectasis and cirrhosis, it may be shortly stated that bronchial dilatation in the great majority of cases is secondary to pulmonary induration. Shrinking of the lung tissue by its traction on the tubes, coupled with the greater influence of inspiratory pressure on the elastic bronchial walls than on the unyielding thoracic parietes, the expiratory pressure of cough, diminished power of resistance on the part of the altered bronchial tissues, and accumulation of secretions

in the tubes surrounded by rigid lung, are probably all concerned in different degrees in the production of bronchiectasis. Bronchial dilatation occasionally leads to gangrene of the lung.

The *microscopical appearances* consist in a growth of connective tissue replacing the vesicular structure of the lung. In some cases a small-celled infiltration is found irregularly distributed about the margins of the cirrhotic masses. At other times sharply defined, rounded collections of small cells, possibly distended lymphatic vessels, are seen in various parts. Collapsed alveoli with thickened walls, and irregular spaces lined with short, cubical epithelium suggesting an adenomatous structure, and due to compression of groups of air sacs and alveolar passages, are also common appearances. Bunches of dilated capillaries may often be seen in large numbers, especially in the walls of the smaller bronchi.

The changes just described refer more especially to cirrhosis of long standing. In the earlier stages the disease may often be seen to consist essentially of a fibro-cellular thickening of the alveolar walls, causing compression and collapse of the pulmonary vesicles. A similar growth is almost invariably witnessed in the interlobular and peri-bronchial spaces. The alveoli in many places contain collections of large epithelial cells and leucocytes, but in some instances they are filled with an opaque fibrinous material, and no distinct epithelial lining is visible. In such cases it is not unusual to find evidence of a process of intra-alveolar cirrhosis, depending on the ingrowth of granulation tissue from the alveolar walls into the substance of the fibrinous plug. This process has with much reason been likened to the organization of a thrombus.

The development of connective tissue cannot always be traced to the alveolar walls, even in the early stages, and the fibrous growth seems to start from the peri-bronchial and peri-vascular sheaths. The framework of the lung consists of the sub-pleural, interlobular, peri-bronchial and inter-alveolar connective tissue, which is continuous throughout, and is brought into the closest relationship through the lymphatic and bronchial blood-vessels which ramify along these lines. Hence it is easy to understand how any irritant acting upon one part of the pulmonary connective tissue may affect other sections of the same system.

In comparatively rare cases the cirrhotic process commences at the pleural surface, and spreads inwards along the interlobular septa.

The smaller bronchi always show some alteration, being usually more or less dilated and distended with secretion. The epithelium, as a rule, has undergone irregular desquamation, groups of columnar, ciliated or short cubical cells being separated by gaps where no epithelial lining remains. The basement membrane is sometimes thickened and glassy-looking; at other times no trace of this structure is visible, the bronchial wall being lined by an irregular granulating surface. A cellular infiltration and a varying amount of fibrous growth commonly exist in the coats of the bronchi, the fibrous change reaching its highest development in the external layer. The cartilages may disappear or may undergo a fibrous or calcareous transformation. The mucous glands are commonly atrophied, owing to implication in the indurative process, and the orifices of the ducts are dilated. The larger bronchiectases and the pulmonary cavities are lined by granulation tissue, small scattered islets of mucous membrane being traceable at times in the bronchiectatic spaces. These morbid conditions are more pronounced in the medium and smaller bronchi, the larger tubes presenting generally the appearances of chronic bronchitis.

The bronchial lesions just described seem to be the starting-point of some examples of the insular and reticular forms of cirrhosis, and the term "peri-bronchitis fibrosa" fitly describes this condition, which, however, is not to be confounded with the small pigmented nodules met with in cases of chronic tubercular phthisis, which are sometimes spoken of as peri-bronchitis, but which in most cases are merely old fibrous tubercles.

Having now given an account of the naked-eye and microscopical appearances of cirrhosis, it remains to discuss the ætiology of the affection.

Ætiology.—If we exclude the circumscribed fibrous lesions due to infarction and perhaps to syphilis, it may be said that pulmonary cirrhosis is the result of the following causes:—

1. *Inflammatory Affections of the Lung.*
—Acute croupous pneumonia may probably, in very exceptional instances, terminate in cirrhosis, though this event is denied by good authorities. Cases have been observed in which an apparently typical

pneumonia has lapsed into a condition of chronic pneumonia or cirrhosis. On the other hand, it is urged that these forms of indurative pneumonia differ from the classical type in certain points, and sometimes present a resemblance to typhoid fever (Wagner). Our knowledge of pneumonia is still very incomplete, and it is not improbable that acute fibrinous exudation into the air sacs may be a consequence of different diseases. In the absence of a decisive test, whether bacteriological or otherwise, the analysis of the various forms of pneumonia is at present beset with difficulties. A sub-acute type of pneumonia has been lately described by Heitler, Talma and others, which may end fatally in a few months or may pass into cirrhosis. The inflammatory changes in this variety are mainly interstitial. The onset of the disease is less acute, and constitutional symptoms are less pronounced than in the true croupous pneumonia.

Broncho-pneumonia, especially when it ensues on measles, whooping-cough, and possibly typhoid fever and diphtheria, is a more frequent source of cirrhosis, particularly in children.

Certain affections of the mediastinal structures may also lead to pulmonary induration, probably through transmission of inflammatory processes along the peri-bronchial sheaths which are continuous with the mediastinal connective tissue. Disease of the sub-tracheal glands, especially suppuration, spinal abscesses, suppuration around the œsophagus, and aneurysm of the aorta, may occasionally in this manner give rise to pulmonary cirrhosis. It is possible that cirrhosis is sometimes the outcome of a primary chronic interstitial pneumonia.

2. *Certain Diseases of the Bronchial Tubes.*—Bronchial dilatation or stenosis, chronic bronchitis resulting from inhalation of finely divided particles, and foreign bodies in the bronchi may occasion fibrous induration of the lung as the result of extension of the inflammatory process.

It is true that bronchiectasis in most cases is a consequence of cirrhosis, but there is no reason to doubt the truth of Laennec's view that bronchial dilatation may be the primary change in some instances.

The rare cases in which stenosis of the main bronchus leads to bronchiectasis, cirrhosis and ulcerative excavation of the lung are also examples of the bronchial origin of pulmonary induration. (Cf. Cases by Pearson Irvine, *Path. Soc.*

Trans., vols. xxviii., xxix., xxx., and by the writer, *ibid.*, vol. xxxvi.) In all these cases, and in those instances where cirrhosis seems to have developed out of a simple chronic bronchitis, the occurrence of broncho-pneumonia, whether sub-acute or chronic, is probably intimately connected with the indurative process.

The inhalation of irritant particles causes chronic bronchitis and peri-bronchitis, and secondary cirrhosis of the lung (pneumo-coniosis). In many cases this affection is so indissolubly associated with chronic phthisis—*e.g.*, miners', steel grinders', potters' phthisis—that the part played by the inhaled dust is difficult to estimate. But there appears to be no doubt that in some instances fibrous changes in the lungs may be produced by dust (Zenker, Traube, and others).

3. *Pulmonary collapse* is another cause of cirrhosis, especially when it is due to bronchitis. Induration is probably the result of extension of the bronchial inflammation to the alveolar walls. This process is therefore closely related to broncho-pneumonia and affection of the bronchial tubes.

4. *Pleurisy* is an occasional cause of cirrhosis, more particularly when the lung has been long collapsed. In this case the induration mainly consists in a patchy or reticular fibrous growth in the peripheral part of the lung, which seldom attains to important dimensions.

Symptoms and Course.—The onset of symptoms may date from an acute pulmonary attack, or more commonly the history is that of chronic bronchitis.

In the first case the constitutional and local symptoms of pneumonia may continue for weeks or months without intermission, the patient ultimately making a gradual and imperfect recovery. Or, again, the acute illness may be succeeded by a sub-acute or chronic stage, which ends fatally in the course of a few months. An interval of apparent good health may separate the initial attack from the onset of symptoms of chronic disease of the lung. In the second case the illness commences insidiously, and appears to be chronic throughout, but attacks of sub-acute bronchitis are very liable to arise from time to time, and these probably lead to the development of broncho-pneumonic processes.

Patients suffering from this condition complain of cough, expectoration, dyspnoea and pains in the chest—in fact, the

symptoms of bronchitis. The severity of the symptoms depends on the extent of lung involved, on the stationary or progressive character of the lesion, and on the presence or absence of bronchitis, bronchiectasis and excavation of the lung. The supervention of constitutional symptoms, like wasting, fever, night sweats, debility and loss of appetite, is determined partly by a tendency to extension on the part of the pulmonary induration, but still more by the development of bronchial dilatation and excavation of the lung, which are apt to give rise to a low septic condition depending upon absorption of the products of suppuration.

The clinical course of the disease under these circumstances can hardly be distinguished from that of chronic phthisis, the same irregular type of pyrexia being observed in both affections. It is commonly said that the progress of non-tubercular cirrhosis is more gradual, nutrition is longer preserved, and constitutional symptoms are less pronounced, but these differences are not to be relied on generally. Laryngeal ulceration, so common in phthisis, is almost unknown in cirrhosis.*

Diarrhoea is not uncommon in the present affection, and sometimes depends on accidental swallowing of the putrid sputa or on amyloid disease of the intestine. Ulceration of the intestine does not occur. In cases uncomplicated by bronchiectasis or by ulcerative changes in the lung, the fatal termination is commonly due to bronchitis with dilatation of the right heart, visceral stasis and dropsy, or to intercurrent pneumonia or œdema of the sound lung.

Where bronchial dilatation or excavation is a prominent feature, the sputum becomes profuse and puriform, and generally acquires a terribly putrid character. The paroxysmal expectoration of large quantities of foul-smelling purulent fluid is very characteristic of bronchiectasis or excavation affecting the lower part of the lung. When these changes are limited to the upper lobe, the secretions gradually drain away by force of gravity, and in such cases cough and expectoration are more continuous. In basic cavities or bronchiectases the

* In a few cases of non-tubercular cirrhosis associated with bronchial dilatation or pulmonary excavation, the writer found laryngeal ulceration, not depending on tuberculosis, and apparently due to the local action of the foul sputum derived from the cavities in the lung.

secretion slowly accumulates, and, until it overflows the margins of the inert cavity walls or bronchial expansion, no cough is induced. But when the acrid fluid trickles over the less diseased bronchial mucous membrane in the neighbourhood of the morbid area, it excites reflex cough and evacuation of the contents of the cavity or dilated tubes.

A tendency to general bronchitis is always very marked in these cases, owing to contamination of the bronchi by the foul fluid passing over them, and to inhalation of noxious materials into the air tubes of the healthy lung.

Bronchitis is very apt to assume a putrid character, and death commonly results from the development of septic broncho-pneumonia or pleurisy. The fatal termination may also be due to abscess of the brain, multiple pyæmic abscesses, phlegmonous erysipelas, exhaustion, amyloid disease of the kidney produced by the long-continued suppuration, nephritis, pulmonary gangrene and hæmoptysis.

The subjects of this disease at times complain of rheumatoid articular pains, which Gerhardt regards as a pyæmic manifestation.

The subjects of pulmonary cirrhosis are generally more or less anæmic and cachectic, though nutrition may be fairly preserved for some time. Clubbing of the fingers is very marked in most instances.

Physical examination discovers signs of consolidation of the lung associated with contraction of the chest walls and displacement of neighbouring organs.

In the ordinary form of cirrhosis the lower part of one side of the thorax is flattened, the respiratory movements are restricted and the heart is displaced to the affected side. Percussion elicits a varying degree of dullness, combined, as a rule, with a marked sense of resistance. At times a somewhat tubular or tympanitic quality of resonance may be associated with the dullness. When the stomach or intestine is drawn up from contraction of the lung, a tympanitic note is produced on percussion over the lower part of the chest. The vocal fremitus and resonance are increased, and the breath sounds acquire a bronchial or tubular character. At times the most cavernous breathing and pectoriloquy may be heard, especially where large bronchi or cavities approach the surface of the lung. Bubbling or metallic râles, of medium or large size, are commonly audible, and, when bronchial dilatation

or excavation exists, a peculiar croaking or sucking rhonchus can often be detected. A succussion or splash sound on cough may sometimes be recognized in such cases. Various rhonchi and râles are frequently heard over the upper part of the same side, or over the healthy lung, pointing to diffuse bronchitis. The resonance of the sound lung commonly extends across the middle line of the sternum. The amount of dullness on the affected side may undergo some diminution in the course of the disease when much emphysema is developed.

The breath sounds and vocal phenomena are liable to great variations, typical cavernous breathing and pectoriloquy alternating with weak indistinct breath sounds and vocal resonance. These differences depend on the amount of fluid contained in the cavities and dilated bronchi.

In some cases the respiratory murmur and vocal phenomena are persistently obscured over the dull area. The presence of dense pleuritic adhesions may contribute to mask the signs of consolidation and excavation.

The expectoration in uncomplicated cirrhosis does not differ from that of bronchitis. The sputum of bronchiectasis has a curious tendency to separate into three layers on standing, a description of which will be found in the article devoted to that subject. When ulcerative changes are proceeding in the lung, elastic fibres may be detected in the expectoration, but tubercle bacilli are absent.

Diagnosis.—Contractile disease limited to the lower part of one lung, combined with signs of excavation or bronchial dilatation, and with marked fœtor of the breath and sputum, is rarely tuberculous. But the same group of physical signs, excluding putridity of the sputum, which is no essential part of simple cirrhosis, may be presented by certain rare cases of chronic basic phthisis.

A failure to detect tubercle bacilli in the sputum after repeated examination would almost negative the idea of pulmonary tuberculosis. It must be remembered, however, that secondary tuberculosis may become grafted upon a simple cirrhosis. The following affections have to be excluded :—

Chronic Pleurisy.—The breath sounds and vocal fremitus are always weakened, there is no evidence of bronchial dilatation or excavation, and the symptoms, both local and constitutional, are less pronounced.

Empyema perforating the lung may closely simulate cirrhosis and bronchial dilatation, but the fœtor has not the special characters of bronchiectasis, and the purulent fluid expectorated does not separate into the characteristic layers. In some cases, an exploratory puncture will alone decide the point.

Chronic abscess of the lung may give rise to contraction and to physical signs hardly distinguishable from those of cirrhosis, but the history of the case and the character of the sputum will usually prevent mistakes.

Hydatid cysts of the lung and liver do not cause contraction, and pulmonary symptoms are slight or absent.

Abscess of the liver perforating the lung is often associated with persistent blood-stained expectoration, and enlargement of the liver can usually be recognized. The history may also throw light on the case.

New growths are mainly distinguished by the absence of contraction and by the existence of symptoms of mediastinal pressure. When external tumours exist the diagnosis presents little difficulty.

Prognosis.—The area of lung involved, the presence or absence of bronchitis, bronchial dilatation and excavation of the lung, and the condition of general nutrition and digestion, are the main elements on which prognosis must rest. Except in those cases where cirrhosis is very limited, the prognosis is always more or less unfavourable, owing to the progressive nature of the disease. At the same time the duration of life is likely to be protracted.

Treatment.—The treatment of cirrhosis of the lung is practically included in that of chronic phthisis, bronchitis and bronchiectasis, and therefore requires but brief notice here. The patient should wear flannel next the skin, he should live in a light airy room, and avoid smoky or dusty atmospheres. A temperate and moderately bracing climate is generally to be preferred. Nutritious food, including cream, milk and cod-liver oil, is of much importance. Iron, quinine and other tonic remedies may be prescribed from time to time. The patient must especially avoid all possible causes of bronchitis, and catarrhal attacks must be promptly met by suitable treatment. Where bronchiectasis or excavation of the lung exists, the patient should endeavour to promote periodical evacuation of the cavities by resorting to certain postures which experience will often suggest—*e.g.*, stooping down, partial inversion, &c.

Drugs like turpentine, terebene, pix liquida and creasote may be administered internally for the purpose of diminishing the fœtor of the breath and expectoration. The same result is sometimes more successfully obtained by the inhalation of creasote, carbolic acid, eucalyptus, iodine and other remedies diluted with chloric ether or rectified spirits in some form of oro-nasal respirator. Cough as a rule should not be treated directly, but this symptom may sometimes be relieved by counter-irritation and expectorants which promote the removal of bronchial secretions. When the cough is so severe and incessant as to prevent sleep, the inhalation of a few drops of oil of peppermint or eucalyptus in the oro-nasal respirator may be attended with marked relief. Opium should only be exhibited in exceptional cases. The question of surgical interference is considered in the article on BRONCHIECTASIS. Diarrhœa, dyspepsia, albuminuria and other complications must be dealt with on general principles. Patients should be specially cautioned against the practice of swallowing their sputa, as diarrhœa and digestive disorders are often produced in this way.

PERCY KIDD.

LUNGS, GANGRENE OF.—Necrosis of a more or less extensive area of the lung following arrest of the circulation, with putrefaction of the sphacelated mass, and the subsequent formation of a cavity or cavities. Gangrene of the lung is produced by a variety of conditions, the majority of which are related to the inhalation of septic material; it is also occasionally a sequel of acute pneumonia.

Symptoms and Physical Signs.—Unless the gangrenous mass be in open communication with a bronchus, its presence may not be detectable. It thus sometimes happens that a gangrenous focus, unsuspected during life, is revealed at the post-mortem examination. The supervention of gangrene is, however, generally denoted by the accession of dyspnoea, the continued irregular hectic fever, and a marked degree of prostration. The patient often presents a pinched and livid appearance. If there be bronchial communication, the extremely foul and penetrating odour of the breath and sputum is characteristic, but not absolutely pathognomonic, as it may be present in putrid bronchitis and bronchiectasis without gangrene. The appearance of the sputum, apart from its odour, is also fairly characteristic. It

consists of greenish or greyish-black matter, and a thin dirty grey or slate-coloured fluid in which muco-purulent masses and the other more solid elements are suspended. Traube considered it to form characteristically three layers, the upper frothy, turbid and brownish-green in colour, the middle layer liquid and serous, the lower thin, brownish and in masses (v. Jaksch).

Microscopically, the sediment and solid masses are found to consist of a quantity of granular debris, oil globules and fat crystals, many bacteria, especially leptothrix, and according to some writers monads are also present. The rarity, or even entire absence, of elastic fibres has been explained by the presence of a ferment which dissolves them (v. Jaksch).

When the gangrenous cavity is in communication with a bronchus, then the physical signs of excavation are present, including cavernous breathing and metallic râles. It must, however, be borne in mind that all the signs of a cavity may be yielded by a congeries of closely aggregated small cavities or even by consolidated lung, and also that there is hardly any safe criterion for determining the size of such a cavity.

Pleurisy may also be present, and in some cases the supervention of pneumothorax is indicated by its special signs. When gangrene supervenes upon chronic lung disease or any of the concomitant conditions mentioned below, there will perhaps be no other indication of its presence beyond the fetor of the breath. Occasionally the occurrence of hæmoptysis denotes that the gangrenous process has eroded a pulmonary vessel. As the disease progresses it is not uncommon for diarrhœa to occur; this is obviously due in the main to the entrance into the alimentary tract of the foul ichorous material discharged from the lung.

The ordinary termination of pulmonary gangrene is by death from exhaustion and septic poisoning. The existence of a gangrenous cavity is likely to lead to the formation of foci of septic bronchopneumonia in other parts of the lung by the inhalation into them of the ichorous matter proceeding from the original focus. In this way it is possible for the opposite lung to become affected, and the chances of recovery are thereby greatly diminished. It would be wrong, however, to say that recovery does not sometimes take place, the conditions for such a favourable issue being a limitation

of the affected area and the maintenance of the patient's strength.

The *diagnosis* has to be made between gangrene and abscess of the lung, and also from putrid bronchitis and bronchiectasis. From abscess the diagnosis is not always possible, for this, like gangrene, may ensue upon pneumonia, and the pus expectorated may have undergone putrefaction. The presence of putrid bronchitis is denoted by an abundant bronchorrhœal secretion of a fetid character, and the diffusion of bronchitic signs throughout the lungs. In the case of bronchiectatic cavities the expectoration is often fetid, and the distinction from gangrene is the more difficult, since the latter condition may supervene on the former.

Prognosis.—From what has already been stated, it is obvious that the prognosis in cases of pulmonary gangrene is very grave.

Morbid Anatomy.—The area of lung involved in gangrene varies considerably in extent. There may be a small limited focus, or the greater part of a lobe may be sphacelated. Or, again, the lobe may be pervaded by numerous areas of "lobular gangrene." As a rule, there is a single cavity of most irregular outline, with blackish discoloured shreds of tissue depending into it on all sides containing a foul grumous material of most penetrating odour. When its contents have been washed away, the ragged cavity remains, in which it is possible to detect the relics of disintegrated bronchi and blood-vessels. In the latter, thrombi may be seen, sometimes extending into branches of large size. The gangrenous focus is mostly surrounded by a more or less wide zone of hepatized or carnified lung.

Laennec, who was the first to describe the clinical and anatomical features of the condition, classed all its forms into the two groups of *diffuse* and *circumscribed*. The distinction is practically unimportant, since in all cases circumscription tends to occur (as in gangrene elsewhere) by reactive inflammation, provided life be sufficiently prolonged. Such definite demarcation and encapsulation of the gangrenous focus is, however, seldom found.

Besides pneumonia, there are several pulmonary lesions which may be associated with gangrene, phthisis, bronchiectasis and cancer being perhaps the most frequent of these. If, as often happens, the focus be situated near the periphery, there is a concomitant pleu-

ritis of intense severity. Pyo-pneumothorax may be set up by the rupture of a gangrenous cavity.

As regards the exact site of the disease, it may be stated that of 20 cases in which pneumonic hepatization or chronic consolidation co-existed with gangrenous cavities, the latter occurred in the right upper lobe in 11, in the right lower lobe in 3, in the left lower lobe in 4. In 2 cases gangrenous foci were found in both lungs—viz., in the right lower lobe and left upper lobe in one, and in the converse lobes in the other.

Pathogeny.—The precise mode of production of pulmonary gangrene is by no means easy to elucidate. As stated above, it must, in accordance with what is known of the general pathology of gangrene, be primarily due to vascular obliteration. Yet the number of cases in which the lesion is clearly traceable to thrombosis or embolism of the pulmonary or bronchial arteries is very small. Simple obstruction from such causes is certainly not productive of gangrene, but of the form of necrosis known as "hæmorrhagic infarction." For gangrene to occur it would seem that there must be an additional factor, viz., sepsis, and it will be seen that this may be the essential element in determining the lesion. At the same time there may, in certain cases, be no proof of the intervention of septic agencies, but only evidence of depraved nutrition, which *per se* may favour the passage of a condition of inflammation into one of gangrene. This may explain the greater liability of post-pneumonic gangrene in typhus, tuberculosis, in the habitual drunkard, and the insane, as well as in diabetes and chronic Bright's disease, constitutional states which are prone to favour similar low forms of inflammation elsewhere than in the lung. It is a moot point whether the nervous system may so control the nutrition of the lung as to determine pneumonia and gangrene. This view, once held, seems no longer tenable. So far, then, as present knowledge permits a classification of the antecedents of gangrene of the lung, they may be divided into the following:—

A. Thrombosis and embolism (mostly septic).

B. Inflammation.

1. Acute lobar pneumonia.
2. Chronic lobar pneumonia.
3. Lobular (septic) pneumonia.

A. Out of a series of 38 cases of gangrene of lung analysed by the writer, there were only 3 in which pulmonary

embolism could be traced, and but 1 with pulmonary thrombosis as an antecedent. In all there was evidence of the septic nature of the process, whilst in 1 another explanation than that of mere thrombosis was possible. It is certainly remarkable that, as regards the lung, the supervention of gangrene upon vascular obstruction alone should be practically unknown.

B. To deal first with *acute pneumonia*. In the series mentioned (38 cases) hepatization was found associated with the gangrene in 14 cases. But in only 8 of these could it be said that the gangrene was dependent on the pneumonia. Laennec thought that pneumonia was always secondary, but he attributed gangrene to a special constitutional tendency, and seems to have regarded it as a disease *sui generis*. It is important to note that in the majority of cases of gangrene following pneumonia there is to be found one or other of the predisposing conditions above alluded to. The same remark applies to *chronic pneumonia*, which is singularly common in association with gangrene (in 6 out of 38 cases). But by far the most frequent antecedent of gangrene is *septic pneumonia*, which is *lobular* in form. This condition may be excited in various ways, all of which are referable to the inhalation into the lung of decomposing or putrescent material. The sources of such products may be thus classified:—

(1) Retained bronchial secretion, as in bronchiectasis, or compression of bronchus by aneurysm, cancer, &c.

(2) Putrid material from extra-pulmonary sources, as the products of ulceration in the mouth, fauces and larynx (noma, diphtheria, cancer), cancerous ulceration of œsophagus ulcerating into air passages or lung (a common cause of gangrene), discharge of a suppurating bronchial gland into a bronchus, especially if it also perforate the gullet.

(3) Foreign bodies in the lung, causing ulceration of a bronchus, and the consequent inhalation of the discharges into the lung, the inhalation of food particles (*Schluck-pneumonie*), or of vomited matters, or of foul water. The latter circumstances may explain the frequency of gangrene in the insane and the paralysed.

Doubtless there are other ways in which putrid or septic material may gain access into the lung and excite a form of lobular pneumonia, which, owing to the presence of putrefactive organisms, passes into gangrene. At the same time

it is highly probable that the process thus initiated is accompanied by blood stasis.

Treatment is general and local. As regards the first, the object is to support the vital powers in the hope that the pulmonary sphacelus may become encapsulated and detached, the cavity then cicatrizing. In all cases it is necessary to administer restoratives, a free amount of stimulant, and as nourishing a diet as possible. Cinchona, with ammonia and ether, or with the mineral acids, is clearly indicated.

Local Treatment.—The inhalation of antiseptic vapours, such as of turpentine, benzoin, eucalyptus, &c., is essential, and it is generally necessary to use disinfectants freely around the bedside and in the sputum.

The propriety of surgical interference for the drainage of gangrenous cavities may be regarded as established, as several cases have been successfully treated. The chances of success depend on the limitation and circumscribed character of the cavity, and also on the existence of pleural adhesions over the affected area. But there are some cases where the cause of the gangrene is of a nature precluding any hope of treatment being other than palliative; but even then an operation may be justifiable, as affording a vent to the fetid products, and thus diminishing the harassing cough, the fetor of the breath and the risk of secondary broncho-pneumonia. The most fortunate results have been obtained where the gangrene occurred in consequence of the impaction of a foreign body in a small bronchus, the operation causing the detachment of this body as well as the drainage of the cavity. The precise localization of the gangrenous area is, however, often a matter of great difficulty. The very nature of the morbid process precludes an invariably successful issue to surgical intervention: but, on the other hand, the rarity of spontaneous cure on expectant treatment would seem to demand such intervention.

SIDNEY COUPLAND.

LUPUS (Lupus Vulgaris).—A chronic disease of the skin and some mucous membranes, characterized by the formation in the connective tissue of nodules of granulation tissue.

The name Lupus was formerly applied to a heterogeneous assemblage of destructive lesions of the skin, but since Willan's time it has been used to denote a disease of a definite clinical type.

Lupus vulgaris, as it is termed in distinction to lupus erythematosus, assumes very many clinical phases, to denote which a multitude of distinguishing appellations have been from time to time used.

Lupus maculosus is a term applied to an affection characterized by the eruption of very soft, smooth, brownish red, semi-translucent (apple-jelly-like) miliary nodules, which develop without subjective sensations in the connective tissue of otherwise healthy skin. This eruption constitutes the earliest sign of lupus, and may also be seen at the periphery of a spreading area, or recurring in scars where the disease has pre-existed. The nodules increase in size, others arise between and around them, and join together to form a more or less circular patch of a special reddish-brown colour. The centre undergoes retrogressive changes beneath the unbroken epidermis and cicatrizes, whilst new miliary nodules may be seen beyond the extending raised border. The inter-papillary processes are flattened out, and hence the patch is smooth and glistening. When the surface desquamates the name *lupus exfoliatus* is by some used to designate the condition.

The term *lupus exulcerans* is used when the destruction of lupus tissue is rapid or intense, or when the epidermis is lost and a secreting ulcerating surface is disclosed. The ulceration may be deep and rapid or phagedænic, and cause great destruction and mutilation. On the removal of the crust, a readily bleeding irregular, granulating surface is seen, composed of a soft, friable neoplasm. Sometimes the connective tissue proliferates very freely, and large granulations form and give the growth a framboesoid aspect.

The term *lupus hypertrophicus* is applied to a condition in which new connective tissue formation predominates over the destructive process, and markedly raised, thick patches result. Sometimes again sclerosed patches are formed by the organization of the new inflammatory tissues.

If, without any breach of surface, the papillæ are irritated and undergo much hypertrophy, a warty-looking patch results, often completely masking the original lupus formation, a phase which is called *lupus verrucosus*.

Further, as a lupus patch spreads or creeps on peripherally it cicatrizes centrally, or at one part of its border, and hence the term *lupus serpiginosus* has arisen.

Lupus is generally stopped by the deep fascia and bones, but necrosis of the latter may result if the periosteum be destroyed. Cartilage is, however, frequently invaded by lupus, as may constantly be seen in the nose and ears, where great destruction and deformity result.

The disease may exist as a single patch or less often as several patches, but it only becomes symmetrical by accident. Sometimes a limb, or the face, neck, and much of the trunk, may be extensively invaded.

The exposed parts of the body, such as the face and hands and feet are by far most frequently attacked.

Primary lupus of the mucous membranes of the nose, mouth, pharynx, larynx, eye and external genitals of the female is far less common than a secondary affection, by extension or infection from the skin. On mucous membranes the little nodules are generally covered by papillary overgrowths and whitish collections of epithelium, and the patches thus formed soon break down into shallow intractable ulcers, with an irregular granulated base.

Course.—Lupus is usually a very chronic disease, persisting over many years, or a lifetime, but the rate of evolution of the nodules and their destruction varies widely, according to the resistance offered by the tissues and to the intensity of the process. A patch may be almost stationary for years, and very limited in extent, or it may spread actively, and break down with surprising rapidity, and be accompanied by the formation of other patches.

Diagnosis.—Mistakes can rarely occur if due attention be given to the presence of the characteristic brownish-red, jelly-like nodules, and the more diffused friable neoplasm, the usually scanty number of patches and the symmetry, the peculiar method of spread, the chronicity, the production of spontaneous scarring, the frequent concomitance of tuberculosis, and the age at onset. It is only when some of these characters are masked that difficulties arise in the diagnosis of lupus vulgaris from lupus erythematosus, or from a chronic localized patch of eczema or psoriasis.

Fungating forms may stimulate epithelioma, and the latter occasionally arises from a lupus patch.

Rodent ulcer is usually situated on the upper two-thirds of the face, and generally affects old people. There is also a history of a continuous spread from a

simple nodule, and the rolled cartilaginous-looking border can be always distinguished. Tuberculated and serpiginous syphilides, whether ulcerating or not, may be almost indistinguishable in aspect, and the age at onset, the far more rapid spread of syphilis, &c., have to be taken into account.

Pathological Histology.—Lupus belongs to the class of infective granulomata. The newly formed tissue consists of a small-celled granulation growth situated about the vessels in the connective tissue, and forming little rounded nodules. In the periphery of the latter, collections of lymphoid cells, larger epithelial and giant cells form, whilst the central parts gradually undergo caseation, a process which overtakes the peripheral portions also. The lupus patch results from the repeated formation of these nodules, which coalesce, and thus the growth extends along the vessels. The connective tissue lying between and about the nodules becomes infiltrated with inflammatory cells, which may become part of the lupus growth, or undergo organization into fibrous tissue. Tubercle bacilli are present in the new growths, but only sparsely.

Ætiology.—The view which is now generally held is that lupus is essentially a tubercular affection of the skin, but this is still opposed by some distinguished observers.

As already stated, it histologically resembles tuberculosis, but the process in this affection is less acute and less intense. Caseation is a less-marked feature, the epithelial cells are fewer, and the giant cells more numerous, the miliary nodules are less distinctly isolated and circumscribed than in pulmonary tuberculosis.

Clinically, also, the evidence is very strong. It is undoubtedly an infective process. The disease is frequently associated with tuberculosis or so-called scrofulosis of glands, joints and bones, and it may result from the extension to the skin of a tuberculous gland or cold abscess. Evidence is also forthcoming that, though purely a local process in the skin, the subject is not without danger of acquiring general tuberculosis, and inoculation experiments on animals point in the same direction.

Those who hold that it is not a phase of tuberculosis consider it a disease *sui generis*.

Lupus is not hereditary; it but rarely attacks two or more members of a family simultaneously, and is far more frequent

in females than males. It mostly commences in childhood, between the third and tenth years, and after puberty its onset becomes rarer, but it may appear at any age, even in advanced life.

Treatment.—Whether lupus be a phase of tuberculosis or not it is necessary that the disease should be removed, and at an early stage, especially when situated about the face, so that the distressing disfigurements which it entails may be avoided. Lupus very seldom dies out spontaneously, and then only after having committed ravages. No specific is known; indeed, lupus is absolutely refractory to internal treatment, though some, and often considerable advantage is obtained by improving the general health by the judicious administration of cod-liver oil, iodine preparations (iodine, the iodides of starch or potassium or iron, iodoform), arsenic and other tonics, proper hygienic and dietetic precautions, and a sojourn at suitable sea-side or other localities, or at some ferruginous, sulphur, arsenical, or salt spa.

Local treatment alone promises a radical cure, and this can usually be effected. The infective nature of the disease must be borne in mind, because after the larger areas of infiltration have been removed or destroyed there may still remain in the surrounding tissues centres where the virus is active, and hence relapses are the rule.

Caustics.—The majority of these agents are very difficult to regulate and effect either too much destruction or too little. Caustic potash (Potassa fusa, Vienna paste), arsenical paste, lactic acid, carbolic acid, and acid nitrate of mercury may be tried, but the one most recently in request is a 10 per cent. ointment of pyrogalllic acid spread on linen and renewed twice daily for three days. This is said to have a selective action on the lupus tissue.

Nitrate of silver or chloride of zinc pencils can be used to bore out the lupus nodules, and their destructive action is mainly mechanical. This method of treatment is now but little employed.

Extirpation or excision is only applicable in certain sites where the lupus is very limited in extent, and even then is not a certain means, and leaves bad scars. The same may be said for the *thermo*—or *electro*—or *actual cautery*, except that these agents are exceedingly useful when the disease is situated upon a mucous membrane.

The injection of fluids, such as iodized glycerin lactic acid, iodoform &c., into

the nodules has been practised with some success.

Scraping and Scarification.—The nodules may be scraped away or removed by the use of spoons of various sizes and shapes, or by double-threaded screws. By this method only the friable lupus tissue is removed and good scars are produced. Still better results are attainable by the destruction of the neoplasm by multiple stabbings or linear scarifications, operations which should be repeated in various directions at different sittings till a scar forms. In any case it is essential to destroy every vestige of the disease. Sometimes it is advisable to supplement this treatment by the application after each operation of a caustic, such as one composed of equal parts of chloride of zinc and alcohol. The wounds may be dressed on ordinary surgical principles, but iodoform is believed by some to have a special action upon lupus tissue.

Unna has introduced *plaster mulls* which contain various definite proportions of salicylic acid and creosote. These are applied night and morning till the neoplasm is destroyed.

Besnier strongly recommends a fragmentary punctiform or linear cauterization with a thermo—or galvano—apparatus, with which he claims to have obtained excellent results (for his method and apparatus see *Ann. de Derm. et de Syph.*, Nos. 7 and 8, 1883).

T. COLCOTT FOX.

LUPUS ERYTHEMATOSUS.—

An affection of the skin, probably of an inflammatory nature, usually limited to the superficial portion of the cutis, and characterized by the evolution on certain definite elective sites of symmetrical erythematous-like macules, which tend to persist, spread peripherally, and leave, without antecedent ulceration, smooth superficial cicatrices.

There are two views with regard to the nature of this disorder—the one, that it is allied to ordinary lupus, that typical cases of each are connected by a series of intermediate links, and that the former may pass into the latter; the other view, which is more generally held, being that *L. erythematosus* has no relation to ordinary lupus beyond an occasional close resemblance in aspect.

Symptoms.—The eruption ordinarily commences by the appearance of smooth, slightly elevated macules, from a pin's head to a lentil in size, which disappear on pressure, and resemble a patch of

erythema, seborrhœa or psoriasis. They spread peripherally, with a distinctly limited border, are usually very persistent, feel a little thickened, and undergo atrophic changes in the older central parts, which result in the formation of a delicate scar.

The surface is sometimes dotted with dilated sebaceous follicles, which may contain comedones. There is no tendency to suppuration or ulceration, though the patches may now and again show signs of secondary inflammation.

The course of the disease may be very chronic or more or less acute, and is marked by the increase of the "primary eruptive spots" to the size of a shilling or half-a-crown, and the evolution of fresh macules, which tend to coalesce, especially over the nose and cheeks, where they form the so-called "butterfly" configuration.

The sites chiefly affected are the nose, cheeks, ears, scalp, fingers, eyelids and lips. On the scalp and ears the atrophic feature is very prominent, and in hairy regions there is a total destruction of hairs. Sir Erasmus Wilson first pointed out that chilblains are prone to form on the nose, fingers and ears, and that, though for a time apparently simple in nature, they may acquire the characters of *L. erythematosus*. The disease tends to symmetry, though it may remain asymmetrical for many months, or years. Such is the phase known as *L. erythematosus discoides*.

Kaposi has also described another variety, which is very rare in this country, and is only known here in its milder forms, the lupus-psoriasis of Hutchinson.

This form, *L. erythematosus disseminatus v. aggregatus*, is characterized by a wider diffusion of the eruptions, an extension by repeated outbreaks, and by the fact that the patches never coalesce. In some cases the whole surface may be dotted over. Its spread is usually chronic, but Kaposi describes an acute febrile and very grave form, accompanied by a typhoid condition. The eruptions may be vesicular or pustular, and the subcutaneous tissue may be involved, giving rise to doughy swellings.

Diagnosis.—At an early period of the evolution of the disease a patch may look very innocent, and simulate erythema, seborrhœa or tinea circinata. Its persistence, and any implication of the sebaceous glands, will, however, excite suspicion, which subsequent observation, and the formation of scarring, will confirm. On the face, old-standing patches

where the deeper layers of the cutis are involved, will simulate exfoliating lupus vulgaris. The diagnosis will be sometimes very difficult unless the mode of development or extension of a patch can be watched, but in lupus erythematosus there will be no small stellate, semi-translucent, brownish-red, soft granules and nodules. On the scalp the atrophic scarring is very characteristic, but it is seen to be associated with an erythematosus condition. On the fingers and the tip of the nose chilblains are simulated, but attentive examination will ultimately disclose the scarring and scaling. The disseminated form, in this country, may closely simulate psoriasis, but is distinguished from it by the presence of scarring.

Pathology.—The diseased condition commences in the corium, generally in the papillary layer (rarely in the deeper or subcutaneous connective tissue), by dilatation of the blood-vessels, and stasis of the blood, changes which are followed by considerable cell infiltration and fluid exudation into the periphery, forming the circumscribed morbid product. Fatty and hyaloid degeneration ensue in the cells, and a cicatrix is formed. The process is very prone to pick out the vascular plexuses about the follicles. It is to be observed that there is not the same tendency as in lupus vulgaris to the formation of cell-nests and giant cells, and no micro-organisms have been found.

Etiology.—This is very obscure. It is not contagious, and not hereditary. *L. erythematosus* is much less frequently met with than ordinary lupus. Females are much more often affected than males, and the age at which it occurs is somewhere between twenty and forty years. It has no effect on the general health except in the malignant cases. Many sufferers are anæmic or debilitated, or belong to tuberculous families. All congestive conditions of the skin appear to predispose to it.

Treatment.—Internal treatment cannot be relied on to cure the disease, but success has been reported from the use of arsenic, phosphorus, iodide of potassium and iodide of starch. No effort, however, should be spared to place the general health on as satisfactory a footing as possible.

All local exposure to extremes of heat and cold should be avoided. In the selection of local treatment minute regard must be had to the condition of the patches, whether actively congested and inclined to spread, or chronic and

quiescent, the depth to which the skin is affected, and the site of the lesion.

If active and angry-looking, soothing measures, such as calamine or weak lead lotion or zinc ointments, are called for; if chronic and quiescent, the following plans of treatment may be tried:—Constriction by contractile collodion, and the application of strong astringents, such as nitrate-of-silver solution or liquor plumbi by means of a camel's-hair brush. Stimulants of various degrees of strength, up to those verging on caustics, are much in vogue. For superficial forms, Dühring recommends sulphide-of-zinc lotion (sulphate of zinc, sulphuret of potassium, aa gr. xxx , alcohol ʒij , rose-water ʒiijss), increasing the strength if well borne. Weak tarry ointments, if used, should be long continued. Liveing advises the use of a 3 to 5 per cent. oleate of mercury. Daily frictions with flannel dipped in Hebra's spiritus saponatus kalinus (2 parts of soft soap in 1 of methylated spirit), to which tar may be added, is often very beneficial, especially if soothing applications, such as ung. plumbi vaselinum, be used in the daytime. There are also various kinds of absorbent and stimulating plasters in use, such as emplastrum hydrargyri, the French sparadrap rouge (diachylon plaster 26 parts, red oxide of lead $2\frac{1}{2}$ parts, cinnabar $1\frac{1}{2}$ part). To do good they must be persisted in, but the length of time over which they should be continuously used must be carefully determined by observation. The pyrogallic and iodoform plaster mulls (Unna's) are stronger, and require only an application of several days. As caustics, collodion of mercurial sublimate, ethylate of sodium, caustic potash (equal parts, or 1 to 2 of distilled water), the strong iodine preparations, and the still more powerful chloracetic acid and the acid nitrate of mercury, are all of service in suitable cases. Before scarification was introduced, Veiel obtained the best results from blistering, with subsequent removal of the thick coating, then painting with equal parts of chloride of zinc and alcohol, removal of the crusts on the third or fourth day, and the application of progressively weaker solutions of the chloride of zinc. This treatment may be repeated if necessary. Lassar lightly brushes over the surface with a Paquelin's cautery at a dull heat. In recent years the best results have been obtained from linear scarification of the skin. The part having been rendered anæsthetic, the skin is lined superficially with parallel cuts, and

these are crossed. This is best done with Pick's instrument. When the crusts have fallen off, the process is repeated until a delicate scar forms. This operation is specially suitable for patches on the face where the least possible scar is desirable.

T. COLCOTT FOX.

LYMPHADENOMA (Hodgkin's Disease; Lymphadenosis; Malignant Lymphoma; Adenie; Pseudo-leukhæmia; Anæmia Lymphatica).—An affection characterized by a progressive enlargement of lymphatic glands and other lymphoid tissues, with new formation or hyperplasia of such tissue in various viscera, notably the spleen, and with anæmia and emaciation. The first examples of this disease were recorded by Dr. Hodgkin in 1832.

The diversity of opinion respecting its nature and affinities is shown in the numerous synonyms it has received, some of which are given above. Indeed, it seems to bear, on the one hand, relations to malignant growths, and, on the other, to such blood diseases as leucocythæmia and pernicious anæmia, whilst its precise cause is unknown. In aspect and mode of extension it resembles new growths—hence the term "malignant lymphoma;" but there are many cases of lympho-sarcoma, especially those originating in the mediastinal glands, which neither clinically nor pathologically run the course or exhibit the characters of this affection. To signify its more general condition and its analogy with scrofula and tubercle, the term "lymphadenosis" was suggested by Dr. Gowers. Trousseau on similar grounds applied to it the name of "adenie." To differentiate it from leucocythæmia, and especially from "lymphatic leukhæmia," the unfortunate term "pseudo-leukhæmia" has been employed in Germany. But in this country most, if not all, cases of so-called lymphatic leukhæmia are considered to be examples of the disease first described by Hodgkin. A less debatable term is "anæmia lymphatica," which, however, does not wholly express the condition, and it is highly probable that it may be differentiated into more than one variety or type.

Symptoms.—In a disease which presents so many variations the symptomatology is necessarily varied. At the onset the subject may be in comparatively good health, until the appearance of glandular enlargement. Or the earliest symptoms may be those of anæmia—viz., lassitude, debility and emaciation, to-

gether with pyrexia. In such cases the starting-point of the gland affection may be in the internal groups rather than the external. The commonest cases are those where the cervical glands are primarily involved.

In the pronounced disease the symptoms are referable to (1) the mechanical interference due to the enlarged glands, (2) the accompanying anæmia, and (3) the pyrexia.

Thus (1) the cervical tumour may compress the carotid and jugular, leading to cerebral symptoms or to congestion of that side of the head and face. Or the axillary may produce pain and œdema of the upper limb; the mediastinal, by pressure on the trachea or œsophagus, may produce cyanosis, dyspnoea, bronchopneumonia or dysphagia; whilst involvement of the mesenteric and lumbarglands may seriously impair nutrition and produce great emaciation. Or, again, hydrothorax may be caused by pressure on the azygos and bronchial veins; ascites, by pressure on the portal vein in the hilus of the liver; jaundice may accompany the ascites.

(2) The anæmia in some cases is very pronounced, in others by no means marked. An examination of the blood shows manifest diminution in the number of red corpuscles, and often many small, red, spherical corpuscles or microcytes. The relative number of white corpuscles varies; the proportion may be normal, or there may be such an excess as to justify the name "lymphatic leukæmia;" but, as already stated, it is doubtful if this can justify the establishment of a distinct disease. The usual symptoms of anæmia may be present, and a cardiac hæmic bruit is often to be heard. Edema of the feet may sometimes be due to the anæmia present; at other times to pressure of enlarged glands on the iliac veins or vena cava.

(3) The pyrexia forms a marked feature of the affection, and is often of the remittent type, as in tuberculosis. No doubt it accounts for some of the wasting observed in this disease.

There are but few symptoms attributable to the presence of lymphomatous growths or infiltrations of organs. Vomiting may be due to this cause, or more indirectly to pressure on the vagus nerve. Diarrhœa is sometimes marked. Albuminuria is very rare; indeed, the urine is not notably altered. There is some liability to cutaneous eruptions, especially furuncles, and occasionally to lymphomatous growths in the skin.

Pigmentation of the skin simulating the browning of Addison's disease, and attributed to pressure of a glandular mass upon the sympathetic plexuses in the abdomen, has been noted in a case of Sir W. Jenner's and one of Sir G. Paget's. In neither case were the suprarenals involved, although they are sometimes the seat of lymphomatous infiltration, like other organs; but in such cases none of the characteristic symptoms of Addison's disease are present.

Certain intercurrent affections, as pneumonia, pleurisy and pericarditis, may occur in the course of the disease; and a few cases are on record where acute tuberculosis has supervened. The disease terminates by asthenia, or by the involvement of the respiratory passages, or by coma from cerebral congestion; but hæmorrhages are less common than in leucocythæmia or pernicious anæmia.

The *diagnosis* of the disease has to be made from (1) chronic lymphadenitis, (2) tubercular lymphadenitis, (3) lymphosarcoma, and it rests upon the diversity of the seat of the affected glands, the absence of any tubercular history or evidence of tubercular disease elsewhere, the association with an enlarged spleen, anæmia and pyrexia.

Morbid Anatomy.—The essential anatomical change in this disease consists in a hyperplasia of lymphatic glands, which seems to assume infective or malignant qualities. The change at first, and for a long time, may remain localized to one group of glands—more often the cervical—but the axillary, inguinal, mediastinal or abdominal glands may be the starting-point of the affection. In other cases several groups of glands enlarge almost simultaneously.

There are differences also in the type of the glandular lesion. Thus, and this obtains in the majority, the enlarged glands may be smooth, hard, discrete and mobile, the enlargement gradually involving one gland after another. They may remain so throughout the course of the affection, or after a time may become fused into a lobulated mass from adhesion to one another and to surrounding tissues. The cases in which the glands remain firm and discrete run a more chronic course than those in which they are softer and more nearly confluent.

The histological characters of the two types of enlarged glands depend on the greater amount of trabecular and fibroid tissue in the firm variety, which, on section, are of potato-like consistence and aspect and the more abundant cell

formation in the other type, which may infiltrate through the capsules, and present a soft, pinkish, medullary appearance resembling the soft sarcomata.

Other lymphatic tissues are prone to a similar hyperplasia—*e.g.*, the tonsils and adenoid tissue of the pharynx, and the abundant lymphoid tissue in the gastro-intestinal sub-mucosa—leading either to a diffuse infiltration and thickening of the wall of the stomach and intestines, or to marked enlargement of the solitary and agminate follicles, or even to vascular growths which readily ulcerate. The thymus, in some cases, has been observed to be enlarged.

The spleen is, in typical cases, somewhat enlarged, firm, of dark-red colour, but studded throughout with pale-yellowish masses (variously compared to lumps of suet and to hardbake) which consist of the altered (fibrous) Malpighian bodies or of masses of new-formed lymphoid tissue. The trabeculae of the organ are greatly thickened. In some cases, however, the spleen is barely altered from the normal; and in at least one case—marked by leucocythæmia—the spleen had all the characters met with in that disease.

Lymphomatous nodules, firm and yellowish, may be also met with in the kidneys, liver, lungs and other organs. They have been mistaken for tubercle. But it is unusual for either the lymphatic glands or these nodular formations to caseate.

Course.—The disease runs a variable course, often being local, limited and almost stationary for months, and having a duration of three to five years, but there are cases of much more acute nature. The majority have a duration of from one to two years. Sometimes a distinct regression occurs apart from the effects of treatment, and in some there may be considerable subsidence of the gland before death.

Ætiology.—The disease, which in some cases appears to be initiated by irritation—*e.g.*, a lymphadenitis from otorrhœa, eczema or chancre—is more common in early life, although a fair proportion of cases are recorded beyond the age of fifty. It is more frequent in males than in females. Beyond the alleged connection of some cases with local irritation, the causes of the affection are mostly unknown.

Treatment.—Attempts have been made to effect a radical cure of the disease by removal of the glands first implicated, in the hope that further extension may

be checked. Apart from the fact that there are few cases where the affection is so local and limited as to warrant a surgical operation for their removal, the failure of such a measure is often due to the existence of the glandular swelling in internal regions. Indeed, the disease, although often localized at the onset, is eminently a generalized affection, and theoretically as well as practically it is hardly to be arrested by such a measure.

Some good results have been recorded from the administration of arsenic, and also from the injection of liq. arsenicalis into the substance of the enlarged glands, a procedure not entirely free from the risk of setting up severe inflammation. Under the use of arsenic the glandular swellings have been known to almost entirely disappear. The same has been said of phosphorus. But the disease is known to occasionally retrogress spontaneously and then again to develop, so that some caution is necessary in accepting these statements. Arsenic, which is the only drug known to have any pronounced effect in pernicious anæmia, and has also been used with advantage in leucocythæmia, does, however, seem to exert in some cases of Hodgkin's disease almost a specific influence. Iodide of potassium, iron, cod-liver oil, strychnine and other tonics may be given.

SIDNEY COUPLAND.

LYMPHATIC DISEASES OF THE SKIN.—Under this title certain rare forms of skin disease may be considered which are essentially of lymphatic origin and are not known by familiar clinical names, as in the case of ELEPHANTIASIS (*q.v.*).

Lymphangioma Circumscriptum (Lymphangiectodes, Lupus lymphaticus of Hutchinson) was first described by Sydney Jones in 1874, subsequently by Tilbury and Colcott Fox in 1879, and, of the remaining ten cases on record, all but two have been described by Englishmen.

The disease is always first observed in early life, although it is not proved ever to be congenital. The lesions consist of vesicles, connected with lymphatics from which albuminous fluid containing a few lymph-cells exudes on puncture, closely aggregated together to form patches. These vesicles are of straw-yellow colour, deeply situated in the skin, their walls thick and tense; sometimes they are intimately intermingled with dilated capillaries and papillary hypertrophy, so that the composite

patches assume a very vascular and warty appearance, which may mask the nature of the fundamental lesion. There may be one or numerous clustered patches, and their commonest seats are the shoulders, trunk, face, neck, back, thighs and arms. The disease causes no subjective symptoms; it tends to spread gradually by the formation of fresh vesicles at the periphery, and to recur after destruction by caustics or removal with the knife. Nothing positive is known of its etiology. Its lymphatic nature is proved by the microscopic researches of Sangster, who describes flask-shaped spaces in the papillary layer, and smaller, more regular spaces in the deeper layers of the corium, the former being due to rupture, the latter to dilatation of lymphatic channels.

Treatment.—Electrolysis applied in a manner similar to that for the destruction of superfluous hairs seems the method of treatment most likely to be useful, and one good result is reported by Crocker.

Lymphangioma Tuberosum Multiplex is a still rarer condition, of which but three cases are on record, the first by Kaposi. The disease is probably congenital. The lesions consist of large, brownish-red papules or tubercles, the size of a lentil, not in groups or clusters, but scattered indiscriminately over the trunk. They dip down into the subcutaneous tissue, and both feel and look solid, but on section they prove to be made up of much dilated lymphatics.

A diffuse general lymphatic dilatation, causing *erythrodermia*, and accompanied by swellings of lymphatic glands, may be the precursor or represent the first stage of some cases of **GRANULOMA FUNGIFORME** (*q.v.*), and a localized ectasia of lymphatics, generally unsuspected, enters into the constitution of many *naevoid*, telangiectatic and warty growths.

J. J. PRINGLE.

LYMPHATIC SYSTEM, DISEASES OF.—Although the above heading should include all diseases of the absorbent system, yet it has been found more convenient to describe several of the affections under distinct titles, owing to their having more or less sharply defined characters. The most important of these are: Erysipelas, gangrene, elephantiasis, leucocythæmia, lymphadenoma, phlegmasia dolens, lymphangioma of the skin, scrofula, tubercle, glanders, and syphilis.

The absorbent system is divided into three parts:—(1) Absorbent surfaces, which include the serous surfaces of the different cavities of the body, the skin and mucous membranes, and intercellular interstices, particularly of the connective tissues; (2) the whole of the lacteal and lymphatic vessels; (3) the lymphatic glands and other masses of lymphoid tissue.

In consequence of the universal distribution of the system throughout the body, it is liable to be affected by a very large number of morbid conditions, and, though any one part may be alone involved, there is a tendency for two or all to be so.

Most of the diseases of the lymphatic system commence locally, but they are liable to spread to a greater or less extent throughout the whole.

ACUTE INFLAMMATION presents itself under three forms—(1) of the vessels alone; (2) of the glands alone; (3) where both are involved.

(1) **Lymphangitis.**—If only the smallest vessels near the point of irritation be affected, the part is red, and the small lymphatics appear as fine wavy red lines, and the condition is spoken of as Reticular Lymphangitis. If the larger trunk be inflamed, the condition is spoken of as Lymphangitis simply.

Symptoms.—There is tenderness of the affected part and along the course of the vessels, often accompanied by pain, which has usually a throbbing character. The position of the vessels, if superficial, is often marked by red lines in the skin, and they can occasionally be felt as fine cords just beneath the skin. There is some swelling of the surrounding tissues, and, if the vessels be obstructed, œdema of the part supervenes, which becomes, in consequence, peculiarly tense and swollen, and the pitting usually produced by pressure on œdematous parts is difficult to obtain (lymphatic œdema).

Pathology and Morbid Anatomy.—The larger vessels, when exposed, are seen to be swollen, often irregularly so, and red, with, perhaps, some thickening of the connective tissues around. If a vessel in this condition be laid open, the contained lymph will be found coagulated and adherent to the lining endothelium, which is irregular, proliferated in some parts and destroyed in others. The rest of the wall is thickened with an increased number of round cells. Under the microscope, micro-organisms can frequently be demonstrated in the coagulated lymph and in the endothelial cells.

The inflammation may either subside or the vessel may become occluded by organization of the clot, or the clot may suppurate and the pus escape into the system, either along the lymphatic vessels and so into the general circulation, or inflammation may occur in the tissues surrounding the vessel, leading to local suppuration, and in either of these ways general septic infection may result.

(2) **Acute Inflammation of the Glands (Adenitis).**—An irritant may traverse the vessels without injuring them and become lodged in a gland, which is generally the first one met with.

The first evidence of inflammation of a gland is its enlargement and induration; it is usually tender. The gland is at first freely movable beneath the skin, and may continue so. The enlargement is due to blocking of the sieve-channels by leucocytes, followed by multiplication of the parenchymatous and connective tissues of the gland. If the inflammation continue the surrounding tissues become adherent, so that the gland is no longer movable. From this point subsidence may occur and the gland return to its natural size; it will contain, however, an increased quantity of connective tissue; or suppuration may supervene. This commences in the centre of the gland, where an abscess forms; the overlying skin becomes red and œdematous, and finally the abscess discharges, unless the pus has been liberated by operative interference.

As the distance of the gland from the original point of irritation is in many instances considerable, as, for instance, when a femoral gland becomes enlarged from suppuration under a toenail, it is customary to speak of the inflammation of the gland as sympathetic, and as the term "*bubo*" (*βυβών*, the groin) has been inaccurately applied to any acutely inflamed or suppurating gland, such a swelling is sometimes termed a "*sympathetic bubo*." Suppuration of the parotid gland is thus termed "*parotid bubo*." The word *bubo*, when unqualified, signifies a swelling of an inguinal gland secondary to venereal disease.

Although the gland nearest to the source of irritation is the most liable to be affected, yet not uncommonly several, even a whole chain of glands, may become inflamed.

When a gland has been enlarged by irritation, but has not suppurated, the enlargement, as soon as the irritant is

removed, generally quickly subsides, but occasionally it continues for a long time. This is due to the inflammatory products having become organized from a formation of fibroid tissue. Contraction slowly ensues, and the size of the gland is reduced, occasionally to less than its normal dimensions.

Ætiology.—Acute inflammation of lymphatic vessels and of glands originates from some source of irritation within or without the body.

From within—from inflammation of internal absorbent surfaces, as mucous or serous membranes, joints, bones; from without—from wounds, burns, scalds and friction.

The immediate cause, however, is the entrance into the vessels of an irritant such as micro-organisms or cells from malignant growths.

In the vessels, micro-organisms, and particularly micrococci, can often be demonstrated in the clotted lymph or in the endothelial cells. It is very rare to find bacilli in the vessels, though tubercular deposits, containing tubercle bacilli, have been found in the thoracic duct.

In the glands, micro-organisms, both micrococci and bacilli, are frequently found, as also are cells derived from a malignant growth. If micrococci be present they are nearly always of the staphylococcus forms, and, as a rule, suppuration follows. The bacilli found in glands are generally those of the specific diseases, *e.g.*, tubercle, syphilis or glanders. Malignant cells also correspond to those of the original disease, whether carcinoma or sarcoma.

Treatment.—The first point is if possible, to remove the exciting cause. The affected part must be kept at rest, and poultices or fomentations, with or without belladonna, opium or other anodyne, should be assiduously applied.

If suppuration have occurred, the pus should be let out by free incision, and in the case of glands, the ragged glandular wall of the abscess should be scraped out. During the pyrexial stage, some febrifuge drug, as citrate of potash, should be given, and free action of the bowels maintained. After the occurrence of suppuration, cod-liver oil, quinine, and port wine are of great use. Residence in a dry, bracing air, is an essential adjunct to the treatment of glandular diseases.

CHRONIC INFLAMMATION.—The lymphatic glands are liable to various forms of chronic inflammatory change, and

such lesions constitute a prominent feature in the morbid anatomy of the various diseases mentioned at the begin-

ning of this article. Reference may be made to those headings for further information.
F. G. PENROSE.

M

MADURA FOOT (Fungus Foot of India; Mycetoma).—A rare affection of the foot, or more seldom of the hand, endemic in certain parts of India.

Symptoms.—The disease first shows itself in the form of small erythematous patches, or of pustules or tubercles, the exact nature of which cannot be accurately diagnosed. Soon more diffuse swelling and induration occur, and boil-like lesions, either superficial or deep, ensue. These suppurate, rupture and discharge ordinary pus, which, in the majority of cases, soon becomes blackish in colour from the presence in it of dark, granular matter, like poppy seed ("black fungus foot"). As the disease progresses in extent and depth, the affected part becomes studded with wart-like mammillary projections, at the bottom of each of which there is a discharging orifice, enormously swollen and disfigured, riddled with sinuses in all directions and totally disorganized, bones and fibrous tissue being generally absorbed, and soft parts thickened and infiltrated. The sinuses are lined by distinct membrane, and contain characteristic "fish-rope-like" particles of a white, yellowish, reddish, or blackish colour.

The disease is much commoner in men than in women, and almost always occurs in adults. It attacks only natives, and preferably those who work with bare feet. Very rarely, the shoulders and scrotum are affected, similarly to the hands and feet. The rate of progress of the disease is very variable, cases lasting from three to thirty years. The result is always lethal, unless the patient die from intercurrent disease.

Nothing definite is known of its *etiology*, although there is every probability of its being of microbic, parasitic origin. The "fish-rope" bodies are mainly composed of fatty and caseous matters, the results of decomposition, encrusted with salts and blood pigment. The fungus (*Chionomyces Carteri*) found in the black, poppy-seed-like bodies is now universally considered to be accidental, not essential.

Treatment.—In the earlier stages the growth may be removed by scraping or excision. In the later stages, when the

limb has become a burden to the patient, amputation, wide of the disease, is the only resource.
J. J. PRINGLE.

MALARIA.—A term applied to the miasm which produces the malarial fevers.

Malaria is most frequently observed as an emanation from marshes, and has hence been called marsh-miasm, and the fevers which it produces paludal fevers. Low, moist, warm localities, and the late summer or autumn produce the miasm in its most virulent form. This is explained by the observation that the miasm only develops when the mean air temperature has been 59° or 60° F. for about three weeks, and by the fact that the flooding of a marsh by heavy rains diminishes malaria. Marshes which are regularly covered by the sea, or which consist chiefly of peat, are seldom malarious. Malaria may be carried for considerable distances by winds, but an expanse of water tends to limit this extension, and even a river may afford considerable protection. A belt of trees also has a similar effect, while the planting of quick growing trees, such as the *Eucalyptus globulus*, exercises a beneficial influence, partly by drying the soil, and partly by regulating the rainfall and distributing it more evenly through the year. Except under peculiarly favourable topographical conditions, malaria does not extend far into a hilly country; even a few feet sometimes make all the difference between a healthy and an unhealthy site. The early morning and late evening hours are especially dangerous, as is sleeping in tents or on the level ground in a malarious locality.

The conditions of soil under which malaria arises may be thus summarized: (1) alluvial soils in deltas, or old estuaries which are silting up, especially if occasionally overflowed by the sea; (2) old water-courses and partially drained lakes, and sandy plains with a clay or marl subsoil—a condition often found in old river beds; (3) at the foot of hills in the Tropics where the soil is full of vegetable matter, and is imperfectly cultivated; (4) in the lower chalk formations, especially if the subsoil be

clay or marl; (5) weathered granitic or trap rocks containing much vegetable matter (fungi, &c.). Rocks in this condition absorb and retain much moisture. To these main conditions are to be added (6) soils recently cleared of forest or brush and not completely brought under cultivation, and also when soils have been deeply turned up, as in making canals or railways; (7) where tracts of rich land have been allowed to fall out of cultivation. Finally, it must be observed that on board ship outbreaks have occurred which could not be traced either to previous infection ashore or to the drinking of water obtained in malarious localities, and must be attributed to the development of the miasm from the foul bilge-water in an ill-ventilated ship.

On the other hand, malaria tends to disappear as a country is drained and brought under systematic cultivation; it has thus disappeared within the last century from Scotland, almost disappeared from England and Ireland, and has greatly decreased in the New England States.

As may be inferred from the above statements, the diseases produced by malaria are, as a rule, endemic; occasionally a great prevalence in an endemic area is followed or accompanied by an epidemic prevalence in neighbouring tracts of country; more rarely pandemics occur, four such having been noted during the present century.

A consideration of all the circumstances have led the majority of observers to the conclusion that the malarial poison is a living organism. Various attempts have been made to identify this organism, and at the present time two diverse views are entertained. This subject is further dealt with in discussing the pathology of the intermittent form of malarial fever.

DAWSON WILLIAMS.

MALARIAL FEVER (Ague; Intermittent Fever; Remittent Fever).—An acute, non-contagious, specific disorder, produced by a miasm, generally air-borne, originating under certain conditions of soil and climate (*see* MALARIA).

The symptoms of malarial fever vary very greatly, and many subdivisions have been made; in a well-marked case of intermittent fever, or ague, a febrile paroxysm occurs daily, or at longer intervals, the temperature in the intervals being normal and the patient free from any symptoms. In other types (remittent)

the pyrexia is continuous, but presents more or less marked remissions.

Intermittent Fever (Ague).—*Prodromal Symptoms.*—Lassitude, pains in the limbs, and anorexia, or nausea, are sometimes present.

Phenomena of the Ague Fit.—The actual ague fit, whether preceded by these symptoms or not, sets in abruptly; weariness, epigastric discomfort, headache and giddiness are quickly succeeded by severe shivering.

Cold Stage.—The surface is cold, the features pinched, the tongue pale and dry, nausea may be distressing and accompanied by vomiting; the pulse and respiration are quick and often irregular.

Hot Stage.—This, after a varying period succeeds; the surface becomes gradually red and warm, the face flushed, the eyes injected, the pulse full and bounding, the respiration deep and frequent. The headache, which was complained of at the commencement of the cold stage, acquires a throbbing character, and is more distressing.

Sweating Stage.—This gradually replaces the hot stage. The flushed skin is now moist, and perspiration quickly becomes very profuse; coincidentally all the general symptoms subside, and the patient is left free from pain or fever, but probably somewhat exhausted.

The body temperature (as ascertained by a thermometer placed in the mouth or rectum) begins to rise before the cold stage, and as the rigor becomes well developed the temperature rises as much as 4° F. or 5° F. in the course of an hour. It continues to rise all through the hot stage, eventually reaching 105° F. to 107° F. or even higher, but when the sweating stage has set in, or a little later, it begins to fall as rapidly as it rose, finally dropping 1° F. or 2° F. below the normal.

The duration of each paroxysm varies from two to twelve hours; as a rule the more severe the disease, the longer the paroxysm; the cold stage may last for several hours, for a few minutes, or may be so short and slight as to pass unnoticed by the patient; the hot stage lasts from three to eight hours, but may be much shorter and is occasionally not to be observed, the sweating immediately, or almost immediately, succeeding the cold stage.

The urine undergoes a parallel series of changes; the amount of urea and water is increased from the time the temperature begins to rise, that is, a little before the cold stage develops, and re-

mains in excess until the temperature falls at the commencement of the sweating stage. During the sweating stage the quantity of urates and of chloride of sodium is increased, and albumen or blood may be occasionally found.

The period which elapses between the end of one paroxysm and the beginning of another is termed the *intermission*; that between the beginning of one paroxysm and the beginning of another, the *interval*. In any given case the intervals are generally about equal, often exactly so. The commonest interval is one day, the paroxysm commencing at the same hour daily; this is the *Quotidian* type, which generally has a short cold stage and a relatively long hot stage, the whole paroxysm lasting eight to ten hours. The next most usual type, and that which is perhaps oftenest seen in temperate climates, is the *Tertian*, in which the paroxysms occur every other day; it has a long cold stage, and a relatively short hot stage, the whole lasting six to eight hours. Occasionally cases are met with—generally in patients who have contracted the disease in the autumn in a temperate climate—in which there are two entire days between the paroxysms, which begin on the fourth day; this is the *Quartan* type, which generally has a short paroxysm with a relatively long cold stage, and is reputed to be very obstinate.

A somewhat complicated terminology has survived from the writings of the Roman physicians, to describe cases in which the paroxysms occur at other intervals; thus, in a "double tertian," there is a paroxysm daily, but the hour of onset and other characters of the paroxysms on alternate days correspond. There may be a double quartan, the two series being thus combined:—Days 1. 2. 4. 5. 7. 8. Celsus described a "semi-tertian" which would really appear to be a combination of the quotidian and tertian, the patient having two paroxysms on one day and one on the next. In practice, however, it is neither easy nor necessary to employ these terms in a large proportion of cases, and it appears certain that many slight cases occur in which the intervals seem to be much longer, either because the intermission is really prolonged, or because some of the paroxysms are very slight. In fact, as a case grows milder the interval lengthens, the disease being said to "postpone;" thus a postponing quotidian becomes a tertian. Conversely, if the case becomes more severe the parox-

ysms occur at shorter intervals, and the fever is said to "anticipate;" thus an anticipating tertian becomes a quotidian. After apparent recovery *relapses* are very frequent, and in time a condition of malarial cachexia may become established.

The most frequent and important *complication* of intermittent fever is pneumonia; consolidation occurs very rapidly, frequently affects both lungs, and seems to be determined by a sudden transference to a cold climate. In persons who have previously suffered from bronchitis, dysentery, diarrhoea, asthma, or epilepsy, these diseases may reappear. It has, however, sometimes been observed that epilepsy has disappeared on the onset of ague.

The *diagnosis* of well-marked intermittent fever is generally easy, the regular sequence of the three stages, the sudden rise and fall of the temperature, the urinary changes, the enlargement of the spleen, the history of exposure, and the effect of quinine, combining to form a very characteristic group of phenomena. In relapses, the history of previous attacks will serve as a guide. Hectic fever, due to phthisis or other chronic suppuration, has been confounded with ague, as have also pyæmia and ulcerative endocarditis; careful physical examination ought to prevent such errors.

The *prognosis* is generally good, the direct mortality being very low. During the Civil War in the United States over seven hundred thousand cases of intermittent fever were treated, the mortality being in quotidian, 1.047 per mille; in tertian, 1.007 per mille, and in quartan, 2.245 per mille. In making a prognosis, the influence of complications has chiefly to be considered, and the special liability to pneumonia must be borne in mind.

Some points in the *pathology* of intermittent fever have already been considered in the article on *MALARIA*. The chief morbid changes are those observed in the blood and spleen. The spleen is enlarged, soft, and easily ruptured; the liver is congested, pigmented, and in cases of some standing enlarged from overgrowth of connective tissue. The myocardium is soft, and pale or yellowish. The blood is profoundly affected: the red corpuscles are diminished in number, and do not run so readily into rouleaux, the white corpuscles are increased, the serum is stained a brown colour, and the coagulum is loose, friable, and dirty red; the blood, as a whole, has a dark colour. The *bacillus malarie*,

found by Klebs and Crudeli in the air and mud of the Pontine Marshes, is said by them to produce remittent fever in dogs and rabbits with enlargement of the spleen, the organism being discoverable in the spleen and medulla of bones. The bacillus is said to be present in the blood of human patients, but only during the period of invasion. A minute hæmatozoon, provisionally named *hæmatomonas malarie*, has been found (Laveran, Richard, Osler) associated with malaria in a large proportion of the cases examined. In a case which has not been treated, if the blood be examined before the paroxysms, a large proportion of the red blood-corpuscles are seen to contain minute hyaline bodies in which pigment granules are included; these pigmented bodies increase in size until the cell is filled; a process of segmentation then occurs, and the cell wall breaks down leaving the segments free. Each segment or spore is oval and contains a pigment granule or granules. It is believed that the adult form, which is always free, is derived directly from these spores; it is a rounded or oval body, a little smaller than a red corpuscle, containing pigment granules, and possessing one, two, or three mobile flagella. The process of segmentation appears to coincide with the onset and course of the paroxysm; at its conclusion the segmentary bodies within corpuscles are no longer seen, though abundant at its commencement. The administration of quinine is followed by the immediate disappearance of the intra-cellular forms above described. In their place are found, in many cases, crescent-shaped bodies, consisting of a hyaline material, including granular pigment. The length of these bodies is about double the diameter of a red blood corpuscle. They are believed to be the resting form of the organism, and are met with in cases which have been under treatment and in chronic cases. Whichever of these series of observations may eventually turn out to be the more correct—and the evidence with regard to the *hæmatomonas* appears to be by far stronger than that advanced by the discoverers of the bacillus—the important clinical fact is that the malarial poison is capable of producing with extraordinary rapidity the most profound anæmia, inasmuch that severe dropsy may quickly supervene, and the patient may even succumb to an attack of œdema of the larynx.

Treatment during the paroxysm must, in the main, be limited to relieving the more distressing symptoms. During the

cold stage the patient's desire for warm covering should be gratified, and if this stage be prolonged the onset of the hot stage may be favoured by warm drinks (e.g., tea). The emptying of the stomach by emesis, which is generally considered advantageous, is thereby facilitated. Severe neuralgia is an indication for a small dose of morphine administered hypodermically. The routine use of purgatives during the prodromal or early paroxysmal stages is generally condemned, but the great traveller, Dr. Livingstone, whose experience was very large, strongly recommended their use in the prodromal stage. (His "rousters" were thus compounded:—*Jalapæ resinæ*, pulv. *rhei*, āā gr. vj , *hydrargyri subchloridi*, *quininæ sulph.*, āā gr. iv .)

If the tongue be furred, the skin sallow, and the bowels constipated, mild purgatives should be administered during the hot stage, as otherwise the quinine to be subsequently given may be rejected. Special caution must be used when the patient is much debilitated, or there is a previous history of diarrhœa or dysentery.

Advantage must be taken of the intermission to administer quinine. Not less than 20 grains should be given during the interval. This quantity may be given in two equal doses, one at the end of the sweating stage, and the other about five hours later; others prefer to give 3 or 4 grains every hour until the desired quantity is exhibited, believing that thus absorption is better assured. If there be purgation or much irritability, laudanum in doses of 7 or 8 minims may be combined with the quinine. If there be obstinate vomiting, the quinine must be administered by enema, or, in very urgent cases, by hypodermic injection; but if an irritating solution be used, ulceration may be produced, and in a few cases tetanus has been observed to follow. The best salt for the purpose is that known as the acid hydrobromate; gr. j dissolves in ℥vj water. The acid hydrochlorate is soluble in the same proportion; the dose of each is gr. $\frac{1}{2}$ – ij .

The temperature ought to be watched systematically for several weeks, and as long as any periodic elevations are to be detected quinine should be taken daily to the amount of about 10 grains. On the appearance of prodromal symptoms, 10 or 15 grains should be taken in a single dose. The remaining anæmia should be combated by arsenic and iron. In cases where quinine in doses sufficiently large to produce toxic symptoms fails to prevent the re-

currence of modified paroxysms, arsenic, either alone or in combination with the quinine, is sometimes found to succeed. The following prescription is recommended by Dr. Bemiss:—*Ferri redacti gr. xl, acidi arseniosi gr. j, quiniæ sulph. gr. xl, ol. pip. nigr. gr. x; M., ft. pil. No. xx.* Sig. One pill three times a day. Warburg's tincture, which contains quinine in combination with numerous aromatic drugs, is a powerful remedy. The bowels having been opened, half an ounce is given, all other fluids being withheld; the dose is repeated in three hours. It is a powerful sudorific, and this action, beneficial as a rule, renders it a somewhat dangerous remedy in patients exhausted by disease. Chloroform in large doses, as much as 1 drachm, given at the commencement of the paroxysm, either alone and immediately followed by water or suspended in mucilage, sometimes arrests it and produces refreshing sleep. Small doses (mʒij to ℥x) of nitric acid four or six times a day are also said to be of great use in some cases, and may be easily combined with quinine. Other alkaloids of cinchona, and "cinchona alkaloid," prepared by a cheap process and containing all the alkaloids, were formerly recommended as substitutes for quinine on the score of economy, but the price of quinine is now very moderate.

The administration of pilocarpine at or shortly before the beginning of the paroxysm has been observed to prevent or arrest the attack, and in some cases no recurrence has taken place. The salt used has been the hydrochlorate; the dose by the mouth is gr. $\frac{1}{4}$, but the drug is better given hypodermically, the dose being gr. $\frac{1}{4}$ dissolved in water ℥x. The alkaline sulphites, carbonic acid, biberine, various preparations of eucalyptus and numerous other drugs have been praised by some, but when tested by others have not yielded satisfactory results.

Remittent Fever.—A severe type of malarial fever exhibiting periodic oscillations of temperature of the same character as those observed in intermittent fever, but without complete deferrescence.

The factors determining the occurrence of malarial fever of this severe type are—(1) a virulent form of malaria; (2) new arrival in a malarious district, especially if combined with exposure to a hot sun, or with alcoholic excesses; (3) personal idiosyncrasy or dyscrasia; (4) want of early treatment of intermit-

tent attacks, and continued exposure to malaria. For the reasons mentioned under (1) and (2), remittent fever is most often observed in the tropics: in India it is commonly known as "jungle fever"; it is peculiarly virulent on the West Coast and tropical interior of Africa; it is frequently seen in Algeria, Italy, and the Southern States of North America.

The *symptoms* bear a general resemblance to those of intermittent fever, but the onset is generally more abrupt, prodromal symptoms may be absent, and the cold stage short and often but slightly marked. As the temperature begins to rise, the patient feels chilly and ill. The hot stage is quickly developed; the face becomes flushed and anxious, and the skin pungently hot to the touch. The tongue is large, with white or yellowish fur and indented edges. There is great epigastric oppression and usually free vomiting, the vomited matters being at first clear, then bile-stained (hence the term "bilious fever" is applied). Hiccough is often distressing. The bowels are, as a rule, constipated, and the motions passed are bile-stained. Jaundice is rare, but a sallow tint, often due to blood degeneration, is generally observed. The urine is acid, scanty, high-coloured, and often bile-stained, and, occasionally during the height of the febrile paroxysms, contains albumen; during the hot stage the urea is increased. The pulse is rapid (120 or more), full and tense. Epistaxis is not infrequent. The nervous system is less profoundly affected than in enteric fever, but there is severe headache with pain in the back and limbs at the onset of the illness, and delirium is frequent at a later stage.

The temperature begins to rise with extreme rapidity during the cold stage, and in the hot stage may reach 105°–107° F., or even to 110° F. The high temperature and the other acute symptoms above described continue unabated for six or twelve hours; then the *remission* occurs. The temperature falls from two to four degrees, the skin becomes moist, the epigastric discomfort and vomiting cease or greatly diminish, and the headache is less severe. After a remission of from two to twelve hours, varying according to the severity of the case, the patient again becomes chilly, and quickly passes into the hot stage; the remission almost invariably occurs in the early morning, the exacerbation at noon or in the afternoon. If the paroxysm be short, there may be a second less well-marked remission in the evening, a second exacerba-

tion before night, and the chief remission in the morning. In severe cases the exacerbations, roughly speaking, last from noon to midnight, the remissions occurring during the early morning hours. The duration of remittent fever is very uncertain; in mild cases it may end in from five to seven days, and in severe cases it may end in death in from seven to ten days. In average cases exacerbation succeeds exacerbation for from twenty to forty days. As improvement occurs, the remissions may be observed to become more marked, until the temperature finally falls to or beyond the normal, the case being in fact converted into one of intermittent fever.

The *diagnosis* of remittent fever is often difficult. It is especially liable to be confounded with enteric fever, and there is no doubt that the belief long entertained, that the latter disease did not occur in India, was due to such confusion. The mode of onset, however, of the two diseases is, as a rule, different, that of enteric being gradual, that of remittent sudden, a difference well evidenced by the characters of the temperature curves. The eruption, iliac gurgling, and peculiar stools of enteric fever are absent in remittent. There seems to be, however, some reason to believe that the course of enteric fever may be materially modified by the co-existence of the malarial poison, and that some at least of the cases described as Typho-malarial Fever (*vide infra*) are to be thus accounted for.

From yellow fever the diagnosis may sometimes be difficult in latitudes where both are met with. It must be borne in mind that yellow fever is a continued fever, without morning remission, and is liable to cause death in three or four days. It tends to spread as an epidemic, and has a very high rate of mortality. In yellow fever hæmorrhage from the mouth, nose, eyes, ears, bowels and kidneys (all or some) is the rule, whereas in remittent fever epistaxis and blood-stained vomit or stools are rare, and hæmaturia is very rare.

The *prognosis* is more serious than in intermittent fever. In the United States army during the War of Secession the mortality among the cases of remittent fever under treatment was 13.45 per thousand. The unfavourable elements in prognosis are a history of alcoholism, marked typhoid symptoms, collapse during remission, a tendency to hæmorrhage, severe offensive diarrhoea, hiccough, or slight and short remissions. The favourable signs are long and distinct remis-

sions, free action of the skin, a tendency for the exacerbation to be less severe, and for the temperature during remission to reach nearer to the normal.

The *morbid anatomy* of remittent fever is greatly modified by the co-existence of the consequences of malarial cachexia. The blood presents to a very marked degree the changes already mentioned under Intermittent Fever; the spleen is always large, congested and pigmented; the liver commonly presents similar changes. Congestion of the gastric and intestinal mucous membrane is present to a greater or less degree.

In the *treatment* of remittent fever the two main indications are to bring the system under the influence of quinine, and to prevent the temperature from reaching a dangerous height. At the onset it will probably be necessary to combine a purgative with the quinine; for this purpose Livingstone's pills (see above), or a combination of calomel, ext. colocynth co. and scammony, about 3 grains of each with a few drops of oil of black pepper, may be given. This may be supplemented or, in cases where purgatives have to be avoided, replaced by lemonade containing bitartrate of potassium. Some physicians wait until the remission occurs before giving quinine in large doses, but with this partial exception all are agreed that there is no contra-indication to its use; scruple doses are given every four hours until three doses at least have been taken; if vomiting prevents retention of the quinine, it must be given by enema, a half-drachm dose repeated once; if this also fails, by hypodermic injection (see above, under Intermittent Fever). Warburg's tincture is highly valued by many physicians, and may be given in the manner described above (*see* Intermittent Fever). During the hot stage, with a view of quieting the pulse and diminishing restlessness, drop doses of tincture of aconite may be given every quarter of an hour until πxij have been taken. Vomiting is best met by a small dose of morphia given with dilute hydrocyanic acid, alone or by hypodermic injection; sucking lumps of ice is a useful adjuvant and is grateful to the patient. At the same time a cold damp towel, sprinkled with chloroform may be placed over the epigastrium. Drop doses of liq. arsenicalis have been recommended. High temperature is best treated by the cold bath. Maclean recommends a bath at 90° F. cooled down to about 85° F., or sponging of the skin with water, the temperature of which is

gradually reduced, as in the case of the bath. Collapse, which is most apt to come on at the beginning of the remission, must be treated with stimulants, of which the best are champagne, brandy with aerated water, and white wine whey.

Pernicious Malarial Fever is a convenient term under which to classify cases of malarial fever, chiefly remittent, presenting aberrant symptoms of a serious character.

In the *Algide*, or *Congestive* form, the patient passes, sometimes quite suddenly, into a condition of stupor from which it is difficult or impossible to arouse him. The surface is cold, livid and often moist, the face pinched, the pulse slow, small and irregular, and the pupils dilated; diarrhoea may be present. This form is extremely fatal. The statistics of the United States Army previously quoted show a mortality among such cases of 239.1 per mille. The treatment of a paroxysm of this type may be commenced by the application of warmth to the surface, or of cold or iced water followed by vigorous rubbing; one-sixth of a grain of morphine combined with one-fiftieth of a grain of atropine should be given by hypodermic injection, or one-fifth of a grain of pilocarpine administered in the same manner. Either morphine or opium may be given by the mouth combined with large doses (ḡi to 3j) of chloroform suspended in mucilage; chloral hydrate is also recommended, especially for rectal injection. Quinine ought also to be given at once—a scruple of the sulphate by the mouth, or half a drachm by the rectum, or 5 grains of the neutral sulphate, by hypodermic injection. The administration of quinine should be continued in doses of 10 to 20 grains (by the mouth) after the paroxysm has passed away, in the hope of arresting the onset of another. Warburg's tincture is also highly recommended in these cases. If the probable length of the intermission be known, the patient should go to bed before the next paroxysm is due, should take hot stimulating drinks, and an extra dose of quinine combined with an opiate. After the first paroxysm, the object should be to induce mild cinchonism and to maintain it until one or more paroxysms have passed.

The *Syncopal* form described by French writers appears to be a variety of the above. The onset is so sudden that the patient may fall while going about his business. As the syncopal condition continues, the faint evidences of organic

life may be overlooked by careless observers, and cases are on record where persons thus affected have been prepared for burial.

In the *Comatose* form the onset of the symptoms is less sudden, the patient complains of throbbing headache, and a sensation of heat and general discomfort, he then becomes drowsy, and finally unconscious, lying motionless with stertorous breathing, a hot turgid yellowish skin, and full bounding pulse. In the treatment the main indication is to give quinine in full doses at once in one or other of the ways above mentioned; a mercurial purge is also generally required, followed by lemonade containing bitartrate of potassium (3j to Oj).

The *Asthenic* or *Adynamic* form occurs in persons debilitated by privation or excesses; vomiting early becomes serious, and the rejected matters are deeply stained (by bile or altered blood). A large proportion of the cases formerly classed under this head are now believed to be examples of enteric fever, perhaps complicated by malaria (Typho-malarial Fever; *vide infra*), or of Mediterranean fever (*q.v.*).

The *Hæmorrhagic* form is comparatively rare and is not a distinct variety. A liability to ecchymosis or to hæmorrhages from the mucous surfaces appears to be developed in some persons long exposed to malaria; the hæmorrhages occur during the chills. As has been already stated, hæmaturia occurs in a certain small proportion of cases. Two varieties of malarial hæmaturia have been described—(a) A mild form following or accompanying intermittent fever, in which the urine sometimes contains hæmoglobin but no corpuscles. It is doubtful whether these cases ought to be distinguished from paroxysmal hæmoglobinuria (*q.v.*). (b) A malignant form characterized by the ordinary symptoms of severe remittent fever; the urine is of a dark red or porter colour, and jaundice is present. The urine contains blood pigment but few blood-corpuscles, and the jaundice is undoubtedly hæmatogenous. In these cases, which form the most typical examples of the hæmorrhagic type, bleeding may also occur from the nose, bowels, or uterus, and the vomited matters contain altered blood. In the treatment of these cases, the administration of quinine must be accompanied by the use of stimulants and easily assimilable foods. The administration of ergot, combined with gallic and sulphuric acids, has been

recommended in the hope of controlling hæmorrhage.

Typho-malarial Fever is a term which has led to much controversy. It does not denote a specific form of disease; the majority of cases are instances of enteric fever occurring in persons who have also been exposed to malaria; others are probably examples of remittent fever with diarrhoea, in which asthenic symptoms are early and severe; others again are probably examples of the fever commonly known as Mediterranean fever (*q.v.*).

Malarial Cachexia is the condition of ill-health produced by continued exposure to malaria. The paroxysms of malarial fever may continue for many weeks or months if untreated. In any case relapses very frequently occur, and this even after removal from the malarial district. Persons residing in such districts, either after suffering from the disease in a well-marked form, or without such an attack, are liable to become subject to latent intermittent fever, the so-called "dumb-ague." The paroxysms are not well developed, but the patient periodically suffers from malaria, loss of appetite, furred tongue and nausea. The temperature rises during the period of indisposition, which is often described by the patient as a bilious attack. The enlargement of the spleen is at first present only during the paroxysms, and is due to congestion, and the organ may then be ruptured by a blow, may rupture spontaneously, or may become the seat of infarcts, leading to suppuraction or even to gangrene. When the disease has become chronic the spleen is permanently enlarged, owing to fibroid overgrowth, producing the typical "ague-cake"; its capsule is thickened, and may be adherent to other organs. The liver undergoes similar changes, though to a less extent. Whether malaria also produces fibroid kidney is doubtful, but in the cases in which the spleen is much enlarged, and there is anasarca, albuminuria is not uncommon.

Anæmia is an early symptom, and may after a few paroxysms of intermittent fever be sufficiently severe to produce extensive anasarca; the skin has a sallow or yellow tint, and the patient has an aged appearance. Patients who are already suffering from malarial anæmia are peculiarly susceptible to scurvy if exposed to causes tending to produce that disease. During the acute attacks also, the serum of the blood may become pigmented from destruction of red cor-

puscles. This probably plays some part in the deep pigmentation of the brain, liver, spleen, and other organs, observed in persons who have died while suffering from malarial cachexia, but to a large extent it is due to the presence of particulate pigment, probably indirectly derived from hæmoglobin, through the intervention of the *hæmatomonas malarie* (*see vide supra*). When melanæmia is well established, the pigment granules may be seen in the white and red corpuscles of the blood, and in the parenchyma of the spleen, liver, osseous medulla, lymphatic glands, and central nervous system, giving these organs a slaty or slaty-brown colour. The existence of the malarial cachexia, or it would seem the mere fact of having at one time suffered from malarial fever, tends to impress a periodic character on many disorders; this has been observed in bronchitis, pneumonia, and many other diseases. Neuralgia, especially of the first division of the fifth nerve, is so common an accompaniment of the malarial cachexia, that the term "brow-ague" is in popular use. The malarial cachexia may be congenital.

In the *treatment* of malarial cachexia, the first indication is to remove the patient from the malarial district; if this involves a journey from a tropical or sub-tropical to a temperate climate, great care is called for, especially as to clothing. The systematic use of Carlsbad and Friedrichshall waters combined, with careful employment of Turkish baths, is to be recommended, but is considered to be less useful than taking the baths and drinking the waters of Carlsbad and Homburg. The anæmia must be combated by iron or arsenic or both combined, as in the pill mentioned in the section on Intermittent Fever. The phosphates of iron, quinine and strychnine are conveniently combined in the *syrupus ferri, quininæ et strychninæ phosphatis* (Easton's syrup), which is a useful remedy. The following prescription is a substitute for this syrup:—Take of phosphate of iron 16 grains, of quinine 12 grains (=sulphate 16 grains), of strychnine $\frac{1}{2}$ grain, of syrupy phosphoric acid 20 drops or q.s. Triturate the strychnine with the phosphate, mix all the ingredients quickly, and divide into sixteen pills (Martindale). In the treatment of enlarged spleen, Maclean recommends the ointment of the biniodide of mercury, a piece the size of a walnut to be rubbed into the skin of the hypochondriac region, and the part exposed to the heat of a

fire until the smarting becomes too severe to be borne; the process should be repeated the same day, and again in a fortnight if necessary. The ointment should contain 13 grains of the biniodide to the ounce of lard—i.e., a little less than the ung. hydrarg. iod. rubr. (B.P.).

DAWSON WILLIAMS.

MALINGERING.—Deliberate shamming is more common amongst prisoners, soldiers and schoolboys than in the community at large. Even where there are good grounds for suspecting that an illness is feigned, great caution should be exercised in giving expression to such suspicion. The best way to detect the malingerer is to appear to believe all his statements, but to keep him under very close observation, when he will probably betray himself, because he does not think that he is being watched. It is often very difficult to distinguish between hysteria and malinger-ing, or to say where the one begins or the other ends.

MANIA.—A form of insanity broadly characterized by exaltation of nervous action, the symptoms being in many respects the direct antipodes of those which obtain in melancholia.

Thus, whilst in melancholia the cardinal characteristics are nervous depression and mental pain, in mania we observe exalted self-feeling, and general nervous excitement. At times but little noticeable, at others strikingly predominant, these are the features which most attract the attention of the onlooker, and appear to be the essential elements of the disease.

A closer examination will, however, show that this excitement is the result, not of excess of nerve force, but of defect of inhibitory power—that the excess of nerve-action in one direction connotes a corresponding failure in another.

The real pathognomonic element, then, in mania—the factor which alone can be said to be common to all cases alike—is *defective inhibition*, in other words *loss of control*.

Symptoms.—An attack of acute mania may begin with considerable abruptness, but it is more usually ushered in by a period of incubation, in which the individual becomes dull, depressed, and apparently self absorbed; this constitutes the so-called “stage of melancholia” which is such a frequent prelude to an attack of mania, and which may last a

variable time—from a few days to a week or two, or more.

The fully developed attack presents considerable variety as regards the grouping and intensity of the symptoms. The patient appears gay and happy, sanguine and confident, and his exuberance of feeling finds expression in general muscular activity. He is ever on the move, pacing up and down the room, dancing about and performing all kinds of antics; his arms are thrown about in various positions, and he assumes all sorts of attitudes.

The facial expression is continually changing, the tongue may be thrust out, the eyeballs rolled about, and grimaces of all kinds indulged in. The fantastic and the scornful, the sublime and the ridiculous, follow one another in quick succession, and are grouped in the most incongruous ways. Loquacity is usually pronounced, and the patient may be singing, shouting and talking, almost incessantly; though there are sometimes interludes of quietude, the chatter is not unfrequently kept up from morning to night with scarcely any intermission, and the patient may be as noisy and talkative at night as he is by day.

His talk, too, presents some interesting features. There is almost always some want of connection between the sentences—in other words, *incoherence* is exhibited; this may be very slight, and evidenced merely by a too rapid transition from one subject to another, or so extreme that even the individual words seem to stand by themselves without apparent connection. It is not, however, to be understood that there is no association of ideas in mania; on the contrary, such association can often be clearly traced, but from the suppression of intermediate links it very generally happens that two sentences are placed in juxtaposition, which are apparently in no way related to each other.

There is not unfrequently a tendency to rhythm in the speech, and actual rhyming is often observed. This may be exhibited merely in the terminations of sentences; or a string of words or syllables, resembling one another in sound, may be repeated in quick succession. It is frequently the case that a word spoken by a bystander is taken up by the patient, and acts as the starting-point of a series of verbal associations of this kind.

The conversation is at times foul and obscene, even in the case of those who, when well, are perfectly correct in the matter of morals.

The behaviour is similarly at times indecent; or it may be aggressive and blustering, and the patient may indulge in coarse and insolent personal remarks at the expense of the bystanders.

The faculty of attention is almost always more or less impaired. In mild cases, indeed, the impairment may be but slight; the patient may readily be got to answer questions, and even to give some account of himself; but in the severe forms he is with difficulty recalled to himself for however short a period, and even if got to answer a question he immediately afterwards resumes his stream of talk without paying any regard to his questioner.

Memory is usually impaired in proportion to the severity of the attack. It is not that no cognizance is taken of surrounding things, but the degree of attention paid to any one object or occurrence is usually so slight that sufficient time is not afforded for a permanent impression to be made. Events are, however, sometimes remembered by patients in a most unexpected manner. Some patients, indeed, recollect clearly all they have gone through, whilst to others the past is as a dream.

The senses are usually active and may be over-acute.

Hallucinations and illusions of the different senses are frequently met with. Hallucinations of sight and hearing are the most common, the patients hearing voices and seeing visions which have no objective existence. It is exceedingly common for patients to mistake the identity of those around them, and to address strangers as familiar acquaintances.

Ideation is active although irregular. Ideas, more or less vague and ill-formed, seem to arise in great numbers in the patient's mind, either simultaneously or in quick succession; his rapid talk is, as it were, a reflex of this, and his very incoherence may in part be due to this cause, one idea being supplanted by another before there is time for the full expression of the first. It is, however, scarcely correct to say that, in an ordinary case of this kind a patient labours under delusions, for his ideas are of too random and fleeting a character to come with strictness under this designation.

Frequently, though by no means constantly, the patient exhibits strong destructive propensities, and will tear his clothes, or his bedding, or destroy any articles of furniture within reach.

As mentioned at the outset, the patient is usually exhilarated and appears in a

general good humour—especially is this the case in the milder forms of the disease; but it is by no means always so; on the contrary, annoyance and anger may predominate, or a state of happiness and contentment may be disturbed by fitful gusts of passion. When this is the case the patient is often violent and dangerous to those around him, especially if, as is generally necessary, his disorderly actions have to be restrained.

In a mild case a patient may be correct in his habits, and conduct himself with a certain amount of propriety, but in proportion as the case becomes severe it is usual for the calls of nature to be unattended to, and for urine and feces to be passed without regard to locality; especially is this the case at night, when it is very common to find the linen wet or soiled unless special precautions are taken.

There is a great tendency in most cases to untidiness and slovenliness of person, and it is very common for patients to remove their clothing and strip themselves naked, if permitted to do so; this practice is resorted to by night as well as by day.

The physical condition of a maniacal patient varies according to the intensity of the attack.

Insomnia is usually marked even in mild cases, whilst in severe cases sleep may be almost totally wanting.

The general sensibility of patients is often much diminished, so that they take no notice of changes of temperature, and appear not to feel injuries or sores of which they would be acutely conscious in health.

The pulse is usually accelerated, and its rapidity is generally proportionate to the degree of muscular activity and the severity of the attack.

The temperature in mild cases may not be raised, but if the case be at all severe it is common to find a rise of one or two degrees, or even more.

The digestive functions are usually disturbed. In a case of any severity the tongue gets thickly loaded with fur, and tends at times to become dry; whilst, if there be much loquacity, ropy saliva accumulates about the corners of the mouth and sordes collect on the teeth. When this condition prevails, the appetite is usually interfered with, and there may be much difficulty in administering food; but in mild cases the patient often takes his food well, at times, indeed, in excess, whilst in the more chronic forms a ravenous appetite is common. The bowels are usually constipated.

In women menstruation is generally arrested—at any rate for a time.

A patient who is actively maniacal always loses flesh, often to a great extent. The nutrition, indeed, of the whole body suffers, as evidenced by harshness of skin, dryness of hair, and the like.

The foregoing symptoms may last a variable time—a few days, or weeks, or months—but sooner or later, if recovery is to take place, the restlessness gradually subsides, the loquacity ceases, and the patient instead of being lively and talkative becomes dull and taciturn. In some cases, indeed, the patient may pass almost directly into his normal sane condition, but it is more usual for a longer or shorter period of mental depression, or dulness to be passed through, before the mind is restored to its previous state.

Even, however, when recovery takes place convalescence is not always uninterrupted, but the process of amendment may be interfered with by a relapse, and this may occur on more than one occasion and yet the patient may ultimately be restored to vigour.

The above described symptoms in various degrees of combination form a picture of the ordinary forms of mania, as most usually presented to us. But individual cases vary considerably from this type, either in the direction of mildness or severity. The muscular over-activity may be so slight as merely to be evidenced by a little aimless restlessness, and fidgetiness, and incapacity to settle to anything, and the patient in ordinary conversation may appear rational and coherent. There is often also a semblance of wilfulness about a patient's acts and language, which conveys to the clinical observer the impression that he could control his vagaries if he liked. Or such a simple form of mania may declare itself by unusual liveliness, humour and gaiety, and a person may even present a certain mental brilliancy impossible to him at ordinary times.

There are yet other cases in which the morbid change is almost entirely on the moral side of the patient's nature, the intellectual being scarcely affected; as for example, when a man who has hitherto led a quiet, moral, sedate, business-like life, becomes restless, boastful, extravagant, inattentive to his affairs, and putting no check upon his appetites.

The proof that such cases belong to the class we are now considering, lies partly in the fact that all this is the expression of a *change in the character* coming on, it may be without obvious

cause, and partly by the observation that such a condition often occurs as a stage in a typical attack of mania, all these manifestations simply being precursors of an acute outbreak.

At the opposite end of the scale a class of very severe cases is met with which has been described as a special disease under the name **Acute Delirious Mania**. In this form the physical symptoms are so severe as to rank co-ordinately with the mental. The muscular restlessness and excitement is extreme, the patient pours forth a volume of incoherent talk, and his attention is so much in abeyance that he usually takes no notice of surrounding things and cannot be got to answer questions; he appears, in fact, to be almost unconscious of his environment.

There is combined with all this excitement much physical prostration. The temperature rises, often considerably; the pulse is small and rapid, the tongue gets dry and brown, and sordes forms on the teeth and lips. There is often great difficulty in administering food. Sleep is absent, or nearly so. The patient, in fact, often passes quickly into a typhoid condition, and death frequently ensues. These cases form one of the varieties of so-called "brain fever."

Pathology and Morbid Anatomy.—That the brain of a maniacal patient is in a hyperæmic condition is a legitimate conclusion from clinical facts, seeing that an excess of nervous action cannot go on, unless an excessive supply of nutrient material is furnished by the blood. And this conclusion is also borne out by the facts of morbid anatomy, for when death occurs in the acute forms of the affection, evidence of hyperæmia, both of the brain and its membranes, is constantly found.

On stripping the membranes the surface of the cortex is found to present a pink staining, which is either uniformly diffused or occurs in irregular patches. The cortex, too, on section exhibits congestion of its deeper layers—those adjoining the white matter. In some cases also the puncta cruenta of the white matter are numerous, and there are signs of excess of blood in the basal ganglia.

Microscopically, in addition to the evidences of vascular engorgement, there may be some swelling of the nerve cells of the cortex, but this is not constant, and the cells may appear quite healthy.

The excess of blood is, however, at least in the majority of cases, secondary,

being the result of an increased demand upon the part of the brain cells.

The question then arises, whence comes this increased demand? The view taken by the writer, is, that mania is an affection of the highest controlling plexuses of the brain, which results in the loss of the inhibitory action of these centres, in consequence of which the lower centres escape from their control, and acting over-vehemently and discordantly, attract to themselves an inordinate supply of blood.

On this view the maniacal manifestations are the result of over-activity of certain healthy portions of the brain, this over-activity being permitted by abeyance, or loss of function on the part of other portions. There would therefore be a negative and a positive condition in the brain of a maniacal patient—negative as regards the higher centres, positive as regards the lower. The primary affection would thus be located in the highest controlling and co-ordinating plexuses, and their tendency to implication is explained by the fact that they are the latest developed in the course of evolution, and are consequently the most unstable, and the most liable to give way.

Ætiology.—Mania may occur at all periods of life from youth to old age, but it is probably most common in young adult life.

The most powerful predisposing cause is undoubtedly hereditary taint, by virtue of which people come into the world with unstable brains, ready to fall into abnormal lines of action on meeting with adverse conditions in the environment.

The exciting causes are various, and are not peculiar to this special form of insanity. Anxieties and worries, domestic bereavements and mental shocks of all kinds, may precipitate an attack. Intemperance in drink is probably the most common exciting cause in men, and acts largely in women also. Injuries, especially cranial injuries, form a not infrequent cause, especially in the male sex. In women parturition and the puerperal state account for a large number of cases.

Terminations.—(1) *Recovery.*—This is the most frequent termination, the majority of cases recovering from a first attack. It is not however always complete, even when the patient is apparently well, a change of disposition being sometimes noted.

(2) *Death.*—This seldom occurs in the ordinary forms of the affection, but may

happen if the patient be old, or much debilitated at the outset, or the subject of organic visceral disease. It is, however, frequent in the acute delirious form.

(3) *Chronic Mania.*—This is a chronic form of the acute affection. The limit between the two is an arbitrary one, but if a case last more than a year it is usually included under this head. The noisy, dirty, destructive, patients who fill asylum wards are of this class. Chronic mania is, however, almost always associated with a certain amount of dementia.

(4) *Monomania.*—Not unfrequently after an attack of acute mania has subsided a delusional state is left—that is, the patient may appear rational on ordinary topics, and his memory may be good, but he nevertheless exhibits perverted judgment or actual delusion on one or many subjects.

(5) *Dementia.*—There are all degrees of this. An attack of mania may pass off and leave a person apparently well with the exception that the fine edge of his faculties is taken off, and he can no longer face the world as before. Or it may leave the mind a wreck, and the patient may henceforth live a vegetative existence, unconscious of his surroundings and entirely dependent upon the ministrations of others for his continued existence. And between these two extremes every variety is met with. The dementia which is consecutive to mania is as a rule more profound than that which is sequential to other forms of mental disease.

Prognosis.—This is good in proportion as the onset has been rapid and dependent upon a definite cause, and according as the patient is young and the reserve of nerve force good. It is unfavourable when the patient is old and debilitated, or when the disease assumes the acute delirious form. It is a good sign if in the acute forms the patient takes nourishment freely. Probably more than half the cases recover perfectly. The prognosis becomes bad if the disease lasts over a year.

Hereditary tendency is not unfavourable as regards recovery, but connotes a greater liability to the recurrence of the disease.

Treatment.—It might appear at first sight a simple matter to quiet the excitement of a maniacal patient by means of sedative drugs, and undoubtedly the most violent mania can thus be subdued for a time. But experience has not

endorsed the value of this treatment, for the effect of the drugs soon passes away, and continued persistence in their use appears to have a deteriorating effect on the nervous centres.

This statement is general and is not intended to imply that sedative drugs are never to be given in mania; the occasional use of them in selected cases may, indeed, be of benefit, but their routine use is certainly to be condemned.

Nor is it advisable to restrain the patient's disorderly actions by mechanical means, such measures having in most cases a decidedly injurious effect upon the brain.

The best measure to adopt in an ordinary case of acute mania is to get the patient out in the fresh air as much as possible and allow him to work off his excitement by muscular exercise. Walking a patient about all day long between two attendants in the open air will often prove the best possible hypnotic, and sleep obtained in this way is of much more value to the patient than that got by the administration of chloral or other sedative drugs.

But, if the temperature be much elevated and the patient too debilitated for outside muscular exercise, as when the disease approximates to the acute delirious form, he should be placed in a bed on the floor of a room which has been well covered with mattresses so that he may not injure himself. A padded room is preferable, though not always essential. In cases of this kind, much benefit is sometimes obtained from a prolonged warm bath with cold affusion to the head; this requires, however, to be used with caution. The wet pack has also its advocates, and may be tried in similar cases. It must be admitted, however, that these measures are often utterly futile.

The question of food administration is important. In the acute forms a patient will sometimes refuse food altogether, and, if so, there need be no hesitation in at once feeding him with the stomach-pump, as it is very important that abundance of nutriment should be introduced into the system or fatal collapse may ensue. Strong soups, beef essences and liquid custards may thus be given.

Stimulants are undoubtedly often useful, and should as a rule be given with food. Sometimes a glass of port or at night will act as a genuine hypnotic. A dry tongue is as a rule an indication for pushing the administration of food and stimulants, but, if the latter increase the

excitement, as they sometimes do, their use should be interdicted.

Cases of acute mania are with difficulty treated at home, and early removal to an asylum is as a rule called for. Even in the milder cases where the excitement is not great it is generally advisable to take the patient away from his home surroundings, the subjection to discipline and the moral control exercised in an asylum often acting as distinct aids to recovery.

JOSEPH WIGLESWORTH.

MARASMUS (Atrophy; Wasting), including **INFANT FEEDING.**—The term *marasmus* is usually reserved for the wasting of infants, though strictly it may be used for such a condition at any period of life.

As regards adults, such a degree of wasting as to merit special notice may be met with in organic disease of any of the viscera, in diabetes, and in the voluntary starvation of hypochondriasis, hysteria, or madness.

The late M. Parrot endeavoured to create out of *marasmus* a disease special to infants, which he named "*atlempsia*," but his views have not been generally accepted, and several different conditions are included under the term *marasmus*.

Congenital syphilis is usually associated with wasting, and organic disease of the lungs or other viscera may also lead to wasting. Catarrh of the stomach or intestines, apart from any dietetic error, may produce it, otherwise the cause must be sought in some defect in the feeding of the child, either as to the quantity or the quality of its nourishment. *Marasmus* is much more frequently encountered in those brought up by hand than in breast-fed infants.

The concomitants of wasting in young infants are constipation, with flatulence and griping pains, or sometimes diarrhoea and vomiting, the vomited matters consisting mainly of curdled milk. When these conditions or any of them are present, it is clear that the feeding is at fault; if the child is being suckled by its mother it is more than probable that it is put to the breast too often, as this is the universal panacea for a crying babe; it is not good for an infant any more than for an adult to be fed too often or to take too much at a time.

The health of the mother must be inquired into, as this will have a most important influence over the quality of her milk, which, as is well known, may vary, not only at such times as the menstrual

periods, but may be affected by purely emotional disturbances. If the mother be in good health and the child is not put too frequently put to the breast, a chemical and microscopical examination of the milk should be made to see in what particular it departs from the normal. Where a wet nurse is employed, the infant may waste from the fact that the date of her lactation is in advance of that which is necessary for the child, since changes in the character of the milk take place during the whole period of lactation.

In children who are brought up with the bottle, the malnutrition is very frequently chiefly due to the kind of bottle used, a long india-rubber tube and a sour cork are not calculated to make the milk which passes through them agree with the infant, and they are conditions which largely prevail; even when the tube and cork have been successfully kept sweet, the child is often allowed to go on sucking at the tube after the bottle is empty, a procedure which must lead to indigestion. Not unfrequently all possible trouble has been taken with the milk that is placed in the bottle to make it agree with the child, but finding that the infant did not thrive, its diet has been supplemented by the addition of sop or boiled bread, and yet to the surprise of the mother the infant continues to waste even more than before. In such cases even a return to a most approved dietary or the procuring a wet nurse does not always suffice to avert a fatal result. It seems as if the child's digestive powers had been so completely and permanently deranged as to be beyond the reach of improvement.

In the majority of cases, however, the prognosis is good, no matter how late the patient comes under observation.

The order to wean an infant because it does not thrive is one that ought very rarely to be given, unless it be obvious that the mother's state of health renders it imperative. Careful treatment of the mother and attention to her diet will materially alter and improve the quality of her milk, whilst, if it seem too rich for the infant, weak barley-water may be given alternately with the breast, or a few teaspoonfuls immediately before being put to the breast. The subject of infant feeding is dealt with more fully in the following section.

JOHN ABERCROMBIE.

Infant Feeding.—The best food for babies is, of course, their mother's milk. The child should be put to the breast

three times in the first twenty-four hours, and afterwards every two hours for ten minutes at a time. During the first twenty-four hours the secretion of milk is scanty, but a healthy child does not suffer from this. The only proof that the mother's milk is healthy and sufficient for the child, is its well-being and steady increase in weight. If it be fretful and cease to gain weight, it is possibly because the mother's milk is poor in quality and insufficient in quantity, and in that case breast-milk must be supplemented or replaced by other food. The milk supply may be deficient from the first, so that the child has to be brought up entirely "by hand" as it is called. It is better, if possible, to secure a wet nurse, but this cannot always be done.

The most easily obtainable substitute for human milk is cow's milk. This differs from human milk chiefly in containing much more casein. The casein is coagulated by the gastric juice into lumps or curds much larger than those formed by the casein of human milk. These large lumps are digested slowly and with difficulty. Hence cow's milk must be diluted. In the first month one part of milk should be mixed with two of water and sweetened. Of this the child should have from 1 pint to 1½ pint in the twenty-four hours. As the child gets older the proportion of milk to water must be gradually increased, and the quantity taken also increased. Pure cow's milk should not be given till the child is at least six months old. The best milk is that which is last expressed from the teat, and known by dairymen as "strippings" or "afterings;" it contains more cream than the rest of the milk.

This is the simplest diet on which to bring up a child that cannot be suckled. But there are many children who cannot digest this; they vomit, pass undigested curds in the fæces, and do not thrive. In such a case the diet must be altered so as to increase the digestibility and the nutritive value of the food.

To prevent the coagulation of the casein into large masses, the milk may be boiled (a measure which has the further advantage of preventing it from carrying infection), or it may be diluted with barley water or with lime water, or it may be peptonized by means of Fairchild's or Benger's peptonizing powders.

To increase its nutritive value, it may be diluted with whey (milk from which the casein has been separated) as in the

so-called "artificial human milk;" and cream and raw meat juice may be added. If milk continue to disagree, however administered, the child may for a day or two be fed upon cream, diluted and sweetened, and raw meat juice.

The latter is made by finely mincing fresh rumpsteak, and stirring it up with water, one part of water to four of meat. It should soak for half an hour. Then the meat is put between folds of muslin, and the juice expressed by twisting.

Condensed milk is often used, and has the advantages that it keeps perfectly, and that its casein coagulates in smaller masses. The objection to most forms is that to preserve the milk much sugar is added, which is apt to undergo acid fermentation after being taken. Therefore *unsweetened condensed milk* is the best kind. It must be remembered that for young infants condensed milk must be diluted much more than the instructions given with the package direct.

Milk may be given with the addition of farinaceous foods. It is common for ill-informed mothers to thicken the milk with corn-flour, bread, arrowroot, or biscuits. Such food disagrees with young infants, because they cannot digest starch. Farinaceous foods are made in which the starch is more or less perfectly converted into sugar. These may be divided into three chief classes.

(1) *Malted Foods*.—In these malt is mixed with wheat meal, and by the action of the diastase in the malt upon the starch in the meal, the starch is changed, first into dextrine, then into maltose, then into grape sugar. In some this process is only commenced, and is set going again when the food is mixed with water, being then completed in 10 or 15 minutes, and in some the process is complete. Among the malted foods may be mentioned Mellin's, Allen and Hanbury's, Savory and Moore's.

(2) *Baked Flour*.—In these preparations the starch is by heat partly converted into sugar. This is excellent for older children, but not good for very young ones. Of this kind are Ridge's and Neave's foods.

(3) *Pancreatized Foods*.—These are made of wheat meal with pancreatic ferment. This ferment converts starch into dextrine and grape-sugar, and proteids into peptones, and emulsifies fat. This is the most easily digested food of any, but some think that it relieves the stomach from too much of its work, and thus may retard the development of

digestive power. Benger's is a food of this kind.

Meat juices, meat essences, jellics, &c., are often recommended, and are useful, but none of them so good as the raw meat juice described above.

G. E. HERMAN.

MASSAGE (including the **Weir Mitchell Treatment**).—It is not easy to give in a very few words a clear and comprehensive definition of massage, but it may be said that massage, properly so called, is more than mere rubbing or shampooing. It includes systematic, skilled manipulation and scientific rubbing.

To properly carry out this mode of treatment, the operator (*masseur* or *masseuse*, as the case may be) must have had a thorough training under one skilled in the different methods, and should have at least a good general notion of the surface anatomy of the body, and the position of the chief organs.

Massage has been at different times brought into discredit by patients being allowed to fall into the hands of ignorant persons, calling themselves medical rubbers, who are possessed by the one idea, that rubbing will cure everything. Serious harm has in this way often resulted, and it need hardly be insisted upon here that massage should be carried out only under the direction of a medical man, who has taken the trouble to make himself practically acquainted with its processes and methods.

Several different forms of manipulation are included under the general term massage. One form consists of a kneading and pressing or squeezing of the muscles, with a certain amount of rotatory movement. If, for example, it is wished to act upon the muscles of a limb the operator begins at the lower part and works steadily and uniformly towards the trunk, taking up one muscle or group of muscles at a time, firmly grasping and rolling them. In dealing with the smaller muscles one hand will suffice, but in the case of the limbs both hands are used, and they should follow each other with such regularity that no part is missed.

In another form, the palm of the hand is made to pass over the part that is being operated upon, in a direction towards the body. It may consist of a mere gentle stroking of the surface, or pressure intended to affect the deeper structures, may be employed. One hand

follows the other in a regular rhythmic manner, so that when the stroke of one is finished the other is in position ready to commence.

A third method, known as *friction*, consists in stroking or sliding one hand over the muscles, combined with pressure of the tips of the fingers of the other hand in a somewhat rotatory manner. This is frequently of use in dealing with affections of the tissues in the neighbourhood of joints. In another form different kinds of percussion are made by means of the finger tips, or by the palm of the hand, or by its edges.

The foregoing is a mere outline of the different processes, but the art of massage cannot be learned from any description. The different procedures may be employed in some instances singly, or two or more may be suitable in combination, according to the circumstances of the particular case.

General massage, that is, when the manipulations are applied to the whole body, is useful when it is desired to stimulate the nutritive functions generally, to promote tissue change in the different organs, and to increase the excretion of waste products. Hence, when for any reason the patients cannot take sufficient exercise, general massage is an excellent substitute, for under its use, not only are the muscles passively exercised, but the internal organs also are stimulated and rendered functionally more active. Improved appetite, better assimilation and increased weight are the results.

By local massage the circulation in the blood-vessels and lymphatics is accelerated, probably both on account of the increased contractions of the muscles, and by the effects of direct pressure. The nutrition of the part acted upon is greatly increased, waste and effete matters are more speedily and effectually removed, the muscles become firmer, and there is a marked increase of muscular power.

Of the local uses of massage, a few examples only need be given.

Marked benefit is obtained in many cases of infantile paralysis, from a well-regulated course of massage, commenced gradually and carried out systematically. Again, in cases where splints or supports have been in use for a long time, the resulting attenuation and weakening of the muscles, rapidly disappear under its use. In hysterical affections of joints and limbs, massage has been found of the greatest value, and it is often helpful

in cases of long-standing paralysis, even when due to some organic lesion.

Massage applied to the abdomen, in patients suffering from atonic dyspepsia with flatulent distension, and from constipation, is often attended with good results. In constipation, a course of systematic kneading and rubbing over the colon, commencing at the cæcum, and carried along its course to the left iliac region, is followed by gradual relief of the symptoms and usually leads to the establishment of regularity in action, although the time taken to accomplish this desirable end varies considerably. In some cases the bowels begin to act regularly at the end of the first week, but in others not until several weeks have elapsed. The result is to be attributed mainly to the stimulating effect of massage upon the intestine, by which peristaltic action is increased, and not to any mechanical effect. In the case of faecal accumulations, however, which can be felt and which yield to pressure by the fingers, probably also undergoing modification in shape by that means, the mechanical agency is not without its effect.

Weir Mitchell Treatment.—In this form of treatment general massage plays an important part. The success, however, that attends this method, especially in cases of hysteria and of nerve prostration, is attributable to the combination of the several factors that constitute it—namely, (1) rest, (2) isolation, (3) systematic feeding, (4) massage, and (5) electricity.

Each of these is important, and it is to Dr. Weir Mitchell that we are indebted for recognizing the value of the combination. In his excellent little work entitled "*Fat and Blood*," Dr. Mitchell points out that these several means are all employed by physicians, but as a rule, only one or two of them at a time, and not all of them in combination.

The combined elements of the treatment must not be forgotten, isolation with rest, massage, with or without electricity, and excessive feeding. Dr. Weir Mitchell lays least stress upon electricity, observing that, if he had to omit one part, he would have no hesitation in leaving out the electrical treatment.

Although the patients who derive most benefit from such a course of treatment are those of the neurotic type, often more or less markedly hysterical, still the method is not restricted to the hysterical class alone.

Isolation takes them away from and out of their old and often too sympathetic surroundings, thus giving the nervous system a fair chance of recovering its tone and stability. Under the influence of properly regulated massage, their nutritive functions receive a notable stimulus. Massage more than supplies the place of exercise, tissue metamorphosis becomes rapid, and waste products are more effectually eliminated. A steady increase in flesh and colour, along with improved muscular and nerve power, is the result.

The duration of the treatment will vary in different cases, but six weeks may be said to be the shortest time that should be allowed for such a course, and ten or twelve weeks are required in most cases.

During the first part of the time—four to six or eight weeks in extreme cases—the patient should be kept altogether in bed, being lifted on to a couch only for, perhaps, an hour in the morning and evening. The room should be airy, with, if possible, a sunny aspect, but in cases of extreme sensitiveness to light and noise, the quietest room available may have to be selected, for the commencement of the treatment, and the change made as the case progresses.

Much depends upon the choice of the nurse; she must not only be a perfectly trustworthy woman, but she should also combine brightness and cheerfulness, with tact and firmness. It rarely happens that one person can be both nurse and masseuse, but in some instances this can be managed, or the nurse can do part of the massage.

With regard to the diet, milk not too rich, and slightly warmed, should, during the first few days at least of the treatment, constitute the entire diet. It should be given in small quantities of three or four ounces at first, every two hours, and should be sipped very slowly. The quantity taken at a time may be gradually increased, and the interval between the supplies correspondingly lengthened.

Constipation is a usual result of this diet, and may often be obviated by giving a small cup of black coffee early in the morning. If that does not suffice some slight aperient will be required.

In five or six days, a small breakfast, consisting of a cup of cocoa and a slice of bread and butter, may be added to the dietary. A few days later, a mid-day dinner of fish or mutton chop, with a little milk pudding may be also taken,

still keeping up the same quantity of milk as before.

At the end of a fortnight from the commencement of treatment, a light evening meal, like breakfast, or of strong soup with bread, will complete the dietary. Extract of malt and some preparation of iron are useful adjuncts to the treatment.

This large amount of food with vigorous massage is kept up for three or four weeks. At the end of that time, the quantity of food is gradually lessened, and the massage and electricity applied at longer intervals.

Passive movements of the limbs are then begun gradually; the patient is allowed to sit up in bed for a short time, and soon to sit up in a chair for a few minutes daily. This is increased by degrees along with exercise, until, at the end of the treatment, the patient is only required to rest for three or four hours daily.

The return to the ordinary ways of life must be gradual. In many cases, a sea voyage, or a prolonged tour, where this is possible, does much to confirm the cure. Unfortunately, relapses occasionally recur in patients who have been treated by this method, but as at present, equally successful results are not obtained by any other means, this fact does not tell against its adoption in suitable cases.

R. W. BURNET.

MEASLES (Morbilli; Rubeola).—

A highly infectious, acute disorder, characterized by an eruption which spreads over the whole body in the course of thirty-six hours, and is preceded and accompanied by marked fever and catarrh of the eyes, nose and respiratory passages.

Symptoms.—As a rule, the health is undisturbed during the period of incubation. The stage of invasion is ushered in by the usual symptoms that accompany a febrile attack—viz., malaise, headache, anorexia, nausea, drowsiness and fever, the temperature reaching perhaps 103° F., or even higher, but it is not uncommon for it to fall to normal the next day, causing the erroneous belief that the illness is at an end. Catarrh of the eyes, nose and air-passages soon appears, and the suffused look about the eyes, the frequent sneezing and the hard cough put the experienced observer on his guard. Epistaxis is not uncommon at this stage. The soft palate will be found to present a well-defined blush with numerous small red spots on it, and

these spots may also be seen spreading on to the cheeks; the tongue is coated. In children predisposed to them convulsions often occur at this period.

The stage of invasion usually lasts till the fourth day, when there is an increase of the general symptoms and the eruption makes its appearance. This is first seen, as a rule, either on the cheeks, or temples or in the neck, just behind the jaw, and consists of small, dark red maculopapules, the colour being darkest in the centre. These increase in size and become slightly elevated, they have a velvety feel, and are roundish or crescentic in outline, their margins being sharply defined. The intervening skin is pale or injected, and the patches tend to coalesce, forming larger blotches or a diffuse redness, which disappears on pressure.

The eruption comes out very rapidly, the face being covered in a few hours and the rash spreading on to the trunk and finally to the limbs; it is generally complete in twenty-four hours. Whilst it is coming out a peculiar odour is sometimes noticeable. When the eruption is at its height there is a certain amount of subcutaneous infiltration, the face appears swollen, and the hands and feet feel tight and uncomfortable. The fever continues to rise after the eruption has appeared, and its greatest height corresponds to the greatest intensity of the rash. The pulse is generally proportionate in frequency to the degree of fever.

The general symptoms are aggravated whilst the rash is coming out, there is marked photophobia and lachrymation, profuse secretion from the nostrils, and a troublesome, hard, hoarse cough. In rickety children the cough and breathing are often croupy in character. The tonsils are sometimes swollen and there may be deafness from extension of the catarrh along the Eustachian tubes; the glands behind the jaw and in the groin are occasionally enlarged. The urine is scanty and high coloured, but rarely contains albumen. Not infrequently profuse diarrhoea is among the early symptoms, if so it usually subsides spontaneously.

The rash fades in the order of its appearance, clearing off the face first; its total duration is usually four days; it leaves reddish-brown stains, which may persist for two or three weeks, and a slight branny desquamation, only perceived, however, on the parts which are uncovered—*e.g.*, the face and hands. With the disappearance of the rash the

temperature rapidly falls to normal, and the other symptoms gradually subside.

The above constitutes what may be considered the normal type and course of measles; many departures from this are met with. Sometimes no prodromal fever is observed, the malady appearing to commence suddenly with the rash; in some there is no catarrh, or the rash is absent. Such cases could only be recognized during an epidemic of the disease. All degrees of severity may be met with, from the mildest to the most malignant form in which the eruption is hæmorrhagic (black measles). In the severer forms great prostration is at once the most marked and important feature, the pulse is very frequent, small and feeble, the respirations hurried, and although the temperature is very high, the extremities are cold. The rash in such cases is imperfectly developed or of a livid tint, there is delirium or subsultus tendinum, and convulsions or coma may precede death.

Variations in the character and site of the first appearance of the rash may be met with. For instance, it may begin on the buttocks, and at first the eruption may be quite papular but it is never vesicular. In a few cases a relapse of the eruption has been observed.

Diagnosis.—The catarrhal symptoms are of the greatest importance; they are not met with in any of the other acute infectious disorders. Another diagnostic point is that the fever does not subside on the appearance of the rash, but goes on increasing. In *rötheln* the eruption is very similar but the spots are paler and less crescentic, and there is no catarrh and often there are no prodromata. The enlargement of the lymphatic glands in the latter disease is another important diagnostic feature. In scarlet fever the period of incubation is much shorter, the temperature is higher, the pulse more frequent, vomiting is often present, there is no catarrh, but the throat is sore and the tonsils very red. The eruption consists of minute bright red spots followed by flaky desquamation.

In variola there is lumbar and sacral pain and vomiting, but no catarrh; the fever subsides when the rash appears; the papules are very shotty and speedily become vesicular; vesicles may be found in the mouth. In syphilitic eruptions there will be other evidence of syphilis. catarrh is absent and the face is often unaffected.

Complications and Sequelæ.—These are more numerous and of greater gravity

in relation to the original disease than in any of the other infectious disorders.

Capillary bronchitis and catarrhal pneumonia are the most common and the most dangerous; some catarrh of the air passages is always present, and in young children, especially the rickety, this is very likely to spread to the smaller tubes, the condition being then very serious. Under these circumstances the lividity of the lips and the amount of recession of the chest will form the best guides both in prognosis and treatment. Enteritis, colitis, laryngitis and epistaxis may also occur at this stage. At a later period otitis, with perforation of the tympanum, is very common. Ulceration of the gums, chronic laryngitis and chronic broncho-pneumonia are apt to follow. Caseation of the bronchial glands, with subsequent general tuberculosis, is by no means uncommon, whilst empyema is also frequently seen: gangrene and noma of the face or vulva are rare complications of measles. Membranous pharyngitis and laryngitis may occur together or separately, the condition then for all practical purposes being diphtheria. Whooping cough is so often met with as a sequela of measles as to suggest that there must be something more than an accidental connection between the two disorders. Scrofulous children are especially liable to have some sequela left by measles; it may be chronic ophthalmia or otorrhœa, enlarged glands in the neck, or some lung mischief.

Prognosis.—This is generally favourable, but much will depend upon the state of health of the patient; a very guarded opinion should be given in the case of rickety children. The probability of some sequela resulting in the case of scrofulous children should also be borne in mind. The character of the epidemic must also be considered, as they vary much in degree of severity. Usually high fever during the stage of invasion is of bad omen, also the persistence of the fever after the rash has faded, as this is an indication of the presence of some complication. Great prostration is a very unfavourable sign, and "black measles" is almost invariably fatal. The presence of any complication naturally increases the danger.

Pathology.—The eruption is due to hyperæmia around the orifice of a sebaceous follicle; this is followed by congestion and the exudation of a certain amount of plasma, which is the cause of the swelling. The rash disappears after

death and there are no characteristic post-mortem appearances, though inasmuch as the lung complications are usually the cause of death, some evidence of this and some enlargement of the bronchial glands will generally be present.

Ætiology.—On this subject very little is known, no specific contagium having as yet been discovered. There is the best evidence that the disease may be communicated by the breath or by the nasal mucus, and it is also certain that it may be carried by fomites in the clothes of a third person. The risk of infection is very great during the period of invasion and whilst the rash is coming out, and it continues for two or three weeks after this, but there is no reason to believe that it can be communicated during the period of incubation, the duration of which is about ten days. All ages are susceptible to the disease, and as most people have it in childhood it follows that it is most common amongst children. As an epidemic disease it is less common in the summer months, but in populous cities it is practically endemic. The recent epidemic in the Fiji Isles shows that when it attacks a people who have no protection, hereditary or otherwise, it is a serious malady. Some persons are so susceptible that they have a second, third, and even sometimes a fourth attack; in such cases each attack is often very severe.

Treatment.—In a mild case it will be sufficient to keep the patient in bed for a week and in the room or house for two or three weeks more. Whilst the fever lasts he should only be allowed liquid diet. Diaphoretics may be useful. The diarrhœa need not be checked unless it be very severe and persistent, and in that case cold compresses should be applied to the abdomen, and astringents and bismuth given internally. The inunction of lard or vaseline with a little carbolic acid is often useful. If the temperature be very high, quinine or some other antipyretic drug should be given, and the patient packed or treated with cold baths. It is a mistake to attempt to bring the rash out again if it disappear early, as such cases are often of an asthenic type and require a stimulating treatment. The cough and hoarseness will often be relieved by wet compresses to the front of the throat, and by painting the fauces with glycerin or glycerin and borax.

The various complications must be treated as they arise. As regards the general management of the sick-room

and the means for preventing the spread of the complaint, reference may be made to the article on DISINFECTION.

JOHN ABERCROMBIE.

MEDIASTINUM, ANATOMY OF.—The mediastinum is the space in the thorax between the two pleural sacs. This interval is, for the sake of convenience, divided into two parts, according as they are situated before or behind the heart, and the term anterior or posterior mediastinum is applied to these parts. In the upper part of the anterior mediastinum are contained the remains of the thymus gland, and the origin of some of the hyoid and laryngeal muscles. It is narrowed at the centre, and in the lower part there is some areolar tissue, together with the left triangularis sterni.

The posterior mediastinum, or the part behind the heart, is larger than the anterior. In the posterior mediastinum are contained the aorta, the vena azygos and the thoracic duct, the œsophagus with its nerves, the trachea, the splanchnic nerves at the lower part and some lymphatic glands. Some authors describe a middle mediastinum, and give as its contents the heart and the great vessels connected with it, and the bifurcation of the trachea.

F. DE HAVILLAND HALL.

MEDIASTINUM, EMPHYSEMA OF.—The presence of air in the cellular tissue of the mediastinum.

Dr. Champneys has directed attention to the frequent occurrence of mediastinal emphysema in fatal cases of tracheotomy; thus in twenty-eight cases of tracheotomy Angel Money found it present sixteen times, and in two of these cases it was associated with pneumothorax; sometimes it exists apart from emphysema of the neck. It has also been found in fatal cases of diphtheria in which tracheotomy had not been performed. The route taken by the air has been proved, by experiment, to be behind the deep cervical fascia. The existence of mediastinal emphysema, especially when combined with pneumothorax, may account for some of the deaths occurring after tracheotomy. "The conditions favouring the production of mediastinal emphysema are division of the deep cervical fascia, obstruction to the air passages, and inspiratory efforts. The dangerous period during tracheotomy is the interval between the division of the deep cervical fascia and the efficient introduction of the

tube. The incision in the deep cervical fascia should not be longer than necessary in the direction of the sternum. It should on no account be raised from the trachea, and this should be particularly remembered during inspiratory efforts" (Champneys, *Med.-Chir. Trans.*, vol. lxx. p. 85). F. DE HAVILLAND HALL.

MEDIASTINUM, INFLAMMATION OF (Mediastinitis).—Inflammation of the cellular tissue found in the mediastinum.

Symptoms.—The two prominent symptoms of inflammation of the anterior mediastinum, when the condition has gone on to suppuration, are dyspnoea and constant, severe pain referred to the post-sternal region. The usual constitutional symptoms attendant upon the formation of pus are, of course, present. On physical examination nothing may be detected, but if a large formation of matter occur, a fluctuating tumour may be felt above the episternal notch, or in one of the upper intercostal spaces, usually on the left side, and this bulging may have an impulse on coughing, or an apparently expansile pulsation may be communicated to it from the heart.

The symptoms of posterior mediastinitis are still more vague; there may be local pain and tenderness, and possibly dysphagia from pressure on the œsophagus. Physical examination does not render much assistance in the diagnosis.

Diagnosis.—In most of the cases of abscess of the anterior mediastinum some history of the cause is obtainable, in its absence it may be very difficult to distinguish a pulsating swelling due to suppuration from an aneurysm.

Prognosis.—This must be guarded, in view of the possibility of pus making its way downwards and bursting into the lung or pleural cavity.

Pathology.—Suppurative mediastinitis may be set up by the extension of inflammation from the neck, as after tracheotomy or when, in treating bronchocele by injection the fluid has passed into the connective tissue of the thyroid gland instead of into its substance. Tubercular disease of the lymphatic glands is another cause. Many cases own a traumatic origin, resulting either from blows on the sternum, or from the impaction of foreign bodies.

Treatment.—Surgical treatment is imperative as those cases of mediastinal abscess which have been operated on and freely drained have recovered, whereas if the pus remain pent up, a fatal termi-

nation of the case is almost certain. In a case reported by Ballance (*Proc. Med. Soc.*, vol. xii. p. 13) trephining the gladiolus was followed by recovery.

F. DE HAVILLAND HALL.

MEDIASTINUM, TUMOUR OF.

—A new growth, taking its origin from the anterior or posterior mediastinum.

Symptoms.—These are at times very obscure, a frequent pulse and increased rapidity of respiration, with vague pains through the chest, perhaps attributed to rheumatism, may be all that exist to awaken suspicion. In fact, until the tumour begins to attain the bulk sufficient to cause symptoms due to pressure on neighbouring parts, it may be impossible to speak with any degree of certainty as to the nature of the case. The symptoms of mediastinal tumour are almost entirely due to direct or indirect pressure. The one which, as a rule, first attracts the patient's attention, is *pain*. This may be so slight as to be hardly noticed, or it may be extremely severe. It may be limited to the affected side and fixed to one spot, or it may radiate over the chest and arm; the pain may be either dull or lacerating in character. In some cases the attacks of pain resemble angina pectoris.

Dyspnœa is a very constant symptom in cases of mediastinal tumour, and, as a rule, it comes on early and is progressive; it may, however, be paroxysmal, and bouts of distressing orthopnœa may occur. The dyspnœa is due to a variety of causes; for instance, the trachea may be compressed by the tumour, though tracheal stenosis is an infrequent sequence in mediastinal tumours, more frequently there is compression of one or other primitive bronchus. Besides being due to direct pressure on the air passages, the dyspnœa may be of laryngeal origin due to paralysis of the crico-arytenoidei postici from pressure on one or both pneumogastric nerves or on both recurrent laryngeal nerves. Dyspnœa may also be due to the changes brought about in the lungs as the two-fold result of the pressure and irritation of the new growth, *i.e.*, pleurisy, bronchitis, and œdema or gangrene of lungs. Obstruction to the vascular system by pressure on the blood-vessels may also cause dyspnœa.

Cough generally demands attention in connection with dyspnœa. In some cases it is of a particularly harsh, reverberating character, causing the patient much distress; in others it

comes on in paroxysms like whooping-cough.

Expectoration varies much both in character and amount in individual cases. In some patients the cough may be quite dry, in others one of the most troublesome symptoms may be a copious watery or muco-purulent expectoration. In cases where erosion of blood-vessels has occurred or a vascular growth has given way, the sputa may be blood-stained or the hæmorrhage may be so profuse as to cause death from suffocation or from mere loss of blood. A gangrenous condition of the lung will be commonly revealed by the fœtor of the breath and expectoration.

The *voice*, as in cases of aneurysm, may be affected by pressure on the recurrent laryngeal nerve causing the corresponding cord to assume the cadaveric position, or the hoarseness may be due to the chronic laryngitis resulting from extension upwards of inflammatory changes in the lungs or trachea.

In addition to the anginal symptoms already referred to, the patient may complain of *palpitation* and discomfort in the cardiac region. In a few cases the only symptom of which the patients have complained has been *dysphagia*; this is particularly apt to occur when the malignant growth starts in the posterior mediastinum.

Emaciation is the rule in mediastinal growths, and is, of course, especially marked when there is any obstruction to the lumen of the œsophagus.

Temperature.—Fever is a symptom which cannot be associated with pressure. In some cases a regular daily rise and fall of temperature has been recorded, and it has been suggested that the rise of temperature is more characteristic in cases of lymphadenoma than in cancerous disease. In many cases, however, a very probable explanation of the rise of temperature is to be found in the presence of an intercurrent pleurisy.

In making a physical examination of the patient it is most important to pay attention to the combination and succession of the physical signs.

On *inspection*, the patient may be found pale or cyanosed, or possibly he may have the aspect of health. Distended veins, and œdema of the head, trunk or extremities, especially when confined to one side, are very important signs. In one case a lympho-sarcomatous mass extending along the heart had exerted so much pressure on the inferior vena cava

that œdema of the lower extremities, and enlargement of the superficial veins on the abdomen, were the most prominent symptoms. The fingers may be clubbed. On examining the chest, loss of movement, diminished or increased bulk of one side, obliteration or retraction of the intercostal spaces, and the presence of local bulgings may be noticed. Contraction of the affected side is met with, especially in cases of pressure on the main bronchus. The apex beat may be much displaced. The writer has put on record a case in which during life the impulse of the heart was felt in the right axillary line, and at the autopsy the apex was found in this position. The results obtained on *palpation* are variable; if there be a mass pressing upon and occluding one bronchus, there will be a great diminution, or even entire absence of any vocal fremitus: but in cases where there is a solid mass intervening between the chest wall and the bronchus, without compressing the latter, the vocal fremitus may be augmented. The *Cyrtometer* may be employed to show the changes in shape which the thorax has undergone. On *percussion*, a marked sense of tactile resistance is experienced if the growth extend to the surface; in some cases a characteristic amphoric note may be elicited if healthy lung be compressed by the tumour: in other cases the dullness may be due to collapse of the lung from pressure on the main bronchus, but in a case observed the writer, notwithstanding that the respiratory murmur was absent, the note on percussion was hardly to be distinguished from that on the sound side, though the post-mortem examination showed that the bronchus was occluded by the pressure of a cancerous mass. If there be great œdema of the chest walls it is frequently impossible to attain any correct results from percussion.

On *auscultation* the respiratory murmur is usually suppressed over the site of the tumour; at times, however, when the tumour exists as a solid mass intervening between chest wall and bronchus, without obliterating the latter, bronchial breathing may be heard over the dull area. Vocal resonance, like vocal fremitus, is usually absent. The heart-sounds may sometimes be so well conducted through a solid mass as to suggest a suspicion of aneurysm.

As regards the *pulse*, an inequality in the radial pulses, as is met with in aneurysm, is not of infrequent occurrence; it is generally brought about by

pressure of the tumour on the subclavian artery of the side corresponding to the weaker pulse. The *pupil* also exhibits changes similar to those seen in aneurysm, *i.e.*, at first the pupil may be dilated from irritation of the sympathetic, and later on complete paralysis of the sympathetic supply to the iris leads to uncontrolled action of the third nerve, and consequent contraction of the pupil.

Laryngoscopically, the changes met with in aneurysm may also be seen in mediastinal tumours, but perhaps not quite so commonly in the latter as in the former. At first the vocal cord may be seen in the position of phonation, this being due to the abductor filaments of the recurrent laryngeal nerve succumbing first to the pressure; after a time the adductor filaments are affected, and the cord falls into the cadaveric position, *i.e.*, the position midway between phonation and inspiration.

Diagnosis.—Aneurysm and pleural effusion are the two conditions from which a mediastinal tumour has most frequently to be diagnosed. The differential diagnosis of mediastinal tumour from *aneurysm* will be first considered. As regards symptoms there are none which are of any value in distinguishing between the two conditions, and this will be readily admitted when it is remembered that in both these diseases the cause of the symptoms is one and the same, *i.e.*, they are either directly or indirectly the result of pressure. It has been stated that in malignant tumour of the mediastinum the onward progress of the disease is much more sure and steady than in aneurysm, in which the patient is liable to alternations of improvement and retrogression, but the writer can recall at least one case which controverts this view—*viz.*, the case of a patient suffering from a malignant growth in the mediastinum (as was proved post-mortem), in whom the improvement, which ensued after the administration of iodide of potassium and the enforcement of rest, was so great as to strengthen the idea that an aneurysm was the real cause of the trouble. It therefore appears that one must rely almost entirely on physical signs for the diagnosis, though such conditions as the youth of the patient, the female sex, and a healthy state of the arteries, may assist in deciding adversely to an aneurysm.

In favour of a tumour would be the absence of the sounds of the heart, or of any impulse over the dull area, especially if this be large and the evidence of ex-

tension of the tumour in several directions at the same time. The existence of glandular swellings or lumps in the thoracic parietes also go to prove the presence of a tumour. For the diagnosis of an aneurysm the diastolic shock, particularly when combined with pulsation, is of the greatest value. Severe pain, especially pain felt posteriorly, is in favour of aneurysm.

The diagnosis of mediastinal tumour from *effusion into the pleural cavity* is sometimes even a more difficult matter than to distinguish it from aneurysm; the writer has recorded in the *Transactions* of the Clinical Society (vol. xiii.), a marked example of this difficulty. In the case in question the whole of the left pleural cavity was filled with a mass of round-celled sarcoma, not much more solid than thick pus; there was uniform dulness over the whole of the left chest, the dulness transgressing the median line, the heart was displaced, and there was an entire absence of respiratory murmur, vocal resonance and fremitus, in fact all the physical signs usually met with in pleural effusion were present. In favour of the diagnosis of a tumour as against effusion, is the limitation of dulness to the apical region and the comparative clearness at the base, the respiratory murmur being audible there, or irregularity in the dulness, resonant patches cropping out in the midst of the dull region, the presence of unilateral œdema, glandular swellings or tumours in the chest walls. The aspirator will often give valuable information, *i.e.*, a blood-stained fluid is in favour of pleurisy set up by a malignant growth.

Prognosis.—In the case of the malignant growths the tendency is slowly but surely towards a fatal issue, death usually occurring in from about three to six months after the commencement of symptoms of pressure, life being seldom preserved for over a year. Inasmuch as it is almost a matter of impossibility to diagnose the nature of the tumour, it is, therefore, advisable always to give a guarded prognosis, though if the symptoms be due to gumma they may clear up under the exhibition of full doses of iodide of potassium, and occasionally enlarged bronchial glands may subside if the patient be placed in favourable circumstances.

Pathology.—Though at one time almost all the tumours met with in the mediastinum were considered to be carcinomatous, and usually described as encephaloid cancer, primary carcinoma of the

mediastinum is rare, and the majority of the growths belong to the class of sarcoma or lymphoma, or partake of the structure of both, and are therefore termed lympho-sarcoma. Gummatous tumours have also been met with in this situation. The lymphomata occur as masses of enlarged glands in tuberculosis or in Hodgkin's disease.

It is usually difficult to decide as to the point of origin of mediastinal tumours; the lymphatic glands, the remains of the thymus gland, and the connective tissue itself are regarded as the points of departure.

Ætiology.—Nothing is at present known as to the causation of tumours of the mediastinum. All that can be said about them is that the sarcomata are more frequently met with in young people, and the carcinomata occur later in life. The majority of cases of mediastinal tumour have occurred under thirty. As regards sex mediastinal tumours are perhaps slightly more frequent among females, whereas aneurysm of the aorta is much more common in males.

Treatment.—This must be almost entirely of a palliative nature, except in those rare cases in which the tumour is of a gummatous nature, when iodide of potassium in full doses will generally have a striking effect. Even when there is no reason to suspect any syphilitic affection iodide of potassium often benefits the patient, and should therefore always be tried. Relief from pain must be sought for by the use of morphia, preferably hypodermically. Rubbing in the liniment of belladonna or the application of a belladonna plaster will sometimes alleviate the radiating pains over the chest. Where there is inability to take food from stenosis of the œsophagus, the patient must be fed per rectum, or gastrostomy may be undertaken. If dyspnoea be increased by effusion into the pleura, the patient may be relieved temporarily by paracentesis, but recurrence of the exudation is almost certain.

F. DE HAVILLAND HALL.

MEDICINAL RASHES.—An eruption on the skin is a not uncommon result of the internal administration of certain drugs. The occurrence may be due to the administration of the drug in excessive doses or for an undue length of time, but more generally depends upon an individual susceptibility of the subject.

Idiosyncrasy also modifies the nature of the eruption, the same drug giving rise to different forms of rash in different

persons. In individuals possessing a natural proclivity to diseases of the skin, drug eruptions may persist indefinitely, even after the complete elimination of the drug from the body. Minute doses of certain drugs (bromides, iodides) appear to be more apt to produce rashes than large ones.

Medicinal rashes may be conveniently divided into two groups:—

(1) Those which usually become pustular. *Bromine* and the *bromides* cause acneiform or furuncular pustules, in which, however, the sebaceous glands are not specially involved. The eruption occurs upon the face, back and chest, especially in persons with thick, oily skins. Macular discolorations, pale papules about the elbows and knees, *large, dusky, purple suppurating papilomatous-looking nodules*—often arising from scar-tissue—bullæ, rupioid lesions and conditions resembling erythema nodosum and urticaria, have been occasionally observed. Their appearance is often prevented by the simultaneous administration of arsenic.

Iodine and the *iodides* may cause erythema, sometimes papular, on the arms, face and neck, or a weeping and itchy eczematoid condition of the scalp, scrotum, chest, or limbs, but the commonest rash resulting from their use is pustular and acneiform, and has a similar appearance and distribution to that caused by the bromides. The bullous iodide rash is a rare but severe form which attacks chiefly the head and neck, hæmorrhage into the blebs occasionally occurring. Purpura from iodides generally occurs on the legs; it may simulate purpura hæmorrhagica and sometimes even proves fatal.

Renal disease and cardiac weakness strongly predispose to the occurrence of bromide and iodide rashes owing to the deficient elimination of the drugs in the presence of such conditions.

(2) Those which are erythematous in character.—These often cover extensive areas, develop suddenly, are sometimes preceded by a chill and accompanied by pyrexia and gastric disturbances. They disappear rapidly after discontinuance of the drug. *Belladonna* rash resembles scarlatina, and the throat is usually dry and red. *Chloral* rash is erythematous or urticarial; it itches, often involves the fingers and hands, and may terminate in hæmorrhage, ulceration and sloughing. The *copaiba* rash is a multiform erythema affecting by preference the hands, arms, feet, knees, and abdomen. *Mercurials*

occasionally cause an erysipelatoid condition, beginning on the face and spreading over the trunk. *Opium* and *morphia* cause itching, followed by a scarlatiniform rash on the trunk and inner and flexor sides of the limbs, followed by desquamation. *Quinine* may give rise to an erythematous or urticarial rash, accompanied by irritation of the conjunctivæ and fauces. *Salicylates* and *antipyrin* produce severe erythema with cedematous swelling, especially of the eyelids, and sometimes ecchymoses. *Arsenic* may cause an erythematous or urticarial rash, especially on the face and neck, more rarely a pustular eczema or purpura; herpes zoster develops with apparently undue frequency during its administration, and diffuse deep brown pigmentation often results from its free employment.

Erythematous rashes are said to occur occasionally from the use of cannabis indica, cubebs, digitalis, santolin, stramonium, quinine, strychnine and turpentine. Borax is supposed to cause a rash like psoriasis, and phosphoric acid to cause pemphigoid blebs.

Treatment consists in stopping the causative drug. The dose of bromide or iodide, if small, may be tentatively increased, and often with advantage.

J. J. PRINGLE.

MEDITERRANEAN FEVER is the most convenient term under which to describe a specific febrile disease observed at many points in the islands and littoral of the Mediterranean. It is characterized by long, irregular pyrexia, frequent relapses, rheumatic complications, constipation, and the absence of ulceration of Peyer's patches. It has been variously described under the names febris complicata, febris audoralis, gastro-bilious fever, fæco-malarial fever, Mediterranean gastric remittent fever, Malta fever, Italian fever, and Neapolitan fever.

The *symptoms* commence after an incubation period of six to nine days, and, as a rule, the onset is insidious. The earliest symptoms are loss of appetite, nausea, severe headache, pains in the limbs and general malaise. The tongue is large, indented by the teeth, and has a thin, yellowish fur; the pharynx is congested, the bowels as a rule are constipated, and the spleen and liver enlarged. There is slight cough, but no distinct bronchitis. Lumbar pain is frequently a troublesome symptom, and sciatica is not uncommon. Perspiration is profuse and may produce sudamina,

but no other eruption is present. The temperature curve is not constant; in severe cases it tends to be continuous, in mild intermittent, but the intermittent type may be observed to pass into the continuous, and *vice versa*.

The temperature is high, reaching 104°—106° F.; in fatal cases it may run up to 110°. After the symptoms described above have lasted ten days, the tongue cleans, appetite partially returns, delirium, if previously present, ceases, and the patient sleeps fairly well. But headache, the lumbar and sciatic pains, and the perspirations continue; anæmia increases and the temperature remains high. The pulse which at first was not much increased in frequency, now beats 110 to 120 in the minute, and palpitation is often complained of. In nearly half the cases one or more of the joints, sometimes several in succession, become red, swollen, and very tender. In this way the case drags on, often for many weeks. Ninety days is a common period to elapse before convalescence is established, and if relapses occur, as is frequently the case, the illness may be prolonged for nine months, a year, or even, it is said, two years.

The *diagnosis* requires to be made from enteric and from remittent fevers. From the former it may be distinguished by the irregular character of the pyrexia, the absence of diarrhoea, tympanites, and gurgling in the iliac fossa, the absence of rash, and the long duration of fever. From remittent fever the diagnosis is more difficult, and by many physicians this fever is classed with the remittent fevers. It is, however, unaffected by quinine, and the temperature curve does not, as a rule, present regular periodic remissions.

The rate of mortality is low, probably not exceeding 2 per cent. The most unfavourable elements in *prognosis* are, very high temperature and rapid pulse. In expressing an opinion the great liability to relapses must be remembered.

The *pathology* of the disease is obscure. It appears to originate in association with imperfect disposal of excremental matters during the warm season. A micrococcus has been found (Bruce) in the tissue of fatal cases, and a cultivation of this organism inoculated into a monkey has caused death in twenty-one days, the micrococcus being recovered from the spleen and liver. *Post-mortem* there is no swelling nor ulceration of Peyer's patches; the mesenteric glands are slightly enlarged, the spleen is large,

soft, diffluent, and intensely congested; the liver is congested and there is glomerular nephritis; micrococci are seen in enormous numbers in the spleen, and also in the liver and kidneys.

The *treatment* is unsatisfactory. The patient should, as soon as possible, be removed from the locality in which the disease was contracted, although the course of the fever is not thus cut short.

Quinine does not exert any directly curative action, and seldom has any beneficial influence. Antipyrin, given to the amount of 60 or 90 grains, reduces the temperature, relieves headache, and favours sleep. A short course of aconite has been recommended at the commencement of the disease. Advantage is derived from the occasional exhibition of calomel in combination with ipecacuanha and rhubarb, or colocynth. Italian writers have recommended the systematic administration of calomel. Salicylic acid and its salts appear to be injurious, depressing the heart and increasing the anæmia. The joint affections and the lumbar and sciatic pains may be treated by the liniments of aconite, opium, or belladonna; blisters are useless. The most important part of treatment is attention to ordinary hygiene and the systematic administration of liquid, easily digested food. DAWSON WILLIAMS.

MELÆNA signifies the presence of altered blood in the motions, the blood being more or less black in colour, and of tarry consistence. Properly speaking, the term should not be used when the motions are found to contain bright blood. It is a condition met with in several diseases. The blood need not have come from the intestines, or the portal system, or even from the stomach or œsophagus, as it may have been taken into the stomach from the mouth, having perhaps originally come from some vessel within the lungs. The presence of blood in the motions is by no means uncommon after a profuse attack of hæmoptysis.

MELANCHOLIA.—When the normal sense of well-being is absent, when the tension of nerve-force has fallen below a certain standard, an individual is said to be depressed. Not every one, however, who is afflicted with lowness of spirits is suffering from melancholia. This affection begins when gloom and despondency prevail for which no cause, or no adequate cause, exists in the environment.

Depressed feeling then is the cardinal

and salient feature of the affection under consideration, and this may exist without any intellectual aberration, or with so slight a degree of it that it may easily be overlooked. The individual becomes dull and moody, listless, incapable of mental or physical exertion. He takes no interest in his surroundings, but is dejected, sad, and weary of existence. At times, however, he may be able to rouse himself, and for a short time may appear to be himself again.

A stage more advanced may be reached without the intellectual faculties being notably impaired. The patient may now sit all day with his hands before him, gloomy and taciturn, taking but little notice of his surroundings, and unable to occupy himself in any way, but yet, if questioned, his answers may be rational, his memory good, and he may even assign plausible reasons for the change in his disposition. No distinct delusions being present, the person may appear to be sane, but the prevailing sense of misery casts its shadow over everything and, tinged with gloom all the patient's relations with the world, causes a false estimate to be made of things in general.

The more purely organic functions share in the general languor. The circulation is feeble, and the respiratory rhythm slow. The appetite is usually poor, the digestion disordered, and the bowels constipated.

On the physical side there is widespread nervous depression, on the mental side, pain; and these two characteristics sum up the cardinal features of a case of *Simple Melancholia*, which is the mildest form of the disease.

The case may progress no further, recovery taking place; but more often delusions are developed, and with them hallucinations and illusions are often associated. The most common hallucinations in melancholia are those of hearing "voices," ordering, accusing or reproaching. Hallucinations of sight present themselves in the form of "visions" of various kinds. Perversions of common sensibility may give rise to ideas of electricity being at work. A disordered stomach may lead a person to think that he is poisoned.

It is most important to recognize that in melancholia the derangement of feeling is primary, and the derangement of intellect secondary; that the association of the two is not a mere accident, but that the latter is distinctly developed out of the former. This may at least be safely affirmed of the great majority of

cases. It is exceedingly common for the delusions of melancholiacs to take the form of self-accusation of imaginary crimes, or the patients may live under perpetual dread of impending imprisonment or death. Their countenances express the terror which lies upon them, nor does the daily experience of non-fulfilment of their fears abate in any way the tenacity of their beliefs. Some patients, again, are extremely suspicious, and believe themselves the object of conspiracies or persecutions.

When the disease has attained this well-marked development, and when delusions constitute a prominent feature of the disease, it is often specially designated *Delusional Melancholia*.

Another type of the disease, in which the delusions have reference mainly to the state of the patient's viscera, has been described under a special name as *Hypochondriacal Melancholia*.

This form bears much the same relation to hypochondriasis that delusional melancholia does to the simple form of the affection. In it the morbid ideas are concentrated upon the more purely organic functions. A patient will assert that he has no heart, or liver or stomach; he will declare that his bowels are sealed up and never act, nor will the demonstration of a copious evacuation in any way alter the idea that has taken possession of him. Delusions with reference to the sexual organs are also very common.

To obtain, then, a picture of the developed form of the disease we have to add to the physical depression and the mental pain the presence of different forms of sense perversion, and of various kinds of delusions. The delusions may lie on the surface, or have to be sought for; they may be frequently and urgently expressed, or hidden in the depths of morbid feeling. But *passivity* may be said to be a feature of all cases alike. Such cases constitute well-marked clinical pictures, which may progress no further, and from which complete recovery may take place.

But there are other types of the disease, which may either develop out of what has been described above or present their own peculiar characters from the first. The passivity may be so strongly pronounced that the patient is plunged into absolute mental stupor. In a well-marked case of this kind external stimuli produce no effect on the patient, who appears to be perfectly insensible to surrounding things. He will stand like a

statue, or sit in a bowed attitude with his head bent forward on his chest, his eyes closed, his hands hanging helplessly by his side. The limbs may be flexible, and sometimes resemble those of a cataleptic patient in remaining for a time in any position in which they are placed. The saliva frequently dribbles from the mouth and saturates the patient's clothes. The urine and feces are usually passed in the position in which the patient stands or sits without his appearing to be aware of it. He has to be washed, dressed, and fed, and in fact treated in all respects like an infant.

Such cases have received the designation *Melancholia with Stupor*, *Stuporous Melancholia*, or *Melancholia Attonita*. They closely approximate to another form of mental disease, which has been described as *acute dementia*.

In the true melancholia with stupor, however, the face is expressive, not so much of fatuity, as of self-absorption or terror. The mind of the patient is considered to be so absorbed with the contemplation of some horrifying delusion as to be quite insensible to the environment. That this is so in certain cases is probable, both from the expression of countenance and the statements made by some patients after recovery, but it cannot be safely affirmed of all cases.

Allied to stuporous melancholia is a form which has been described as a special type under the name of *Resistive Melancholia*. This is best looked upon as a variety of the stuporous form, although some cases present much resistance and little stupor, and others much stupor and little resistance.

In this form the limbs, instead of being flexible, are rigid, and become more so when attempts are made to move them. The patient is sullen, morose, obstinate and taciturn; he resists, more or less strongly, everything that is done for him, and is fed and kept clean with much difficulty.

Cases of melancholia may, however, vary in a direction directly opposite to that of stupor, and instead of passivity, *activity* may prevail. The patient indeed is so restless that this type has received the designation. *Excited or Motor Melancholia*, or *Melancholia Agitans*. Than it, no form of mental disease is more distressing. Here the mental agony rises to such a height that it finds expression in muscular reactions. The unhappy patients may pace wildly up and down the room, as if endeavouring to escape from the terror which appals them.

Despair is depicted on their countenances. Sometimes they will tear at their throats, or pull out their hair till their scalps are bald; or they will tear their nails off, and pull pieces out of their flesh; or again, gnaw their lips and bite their fingers, or be perpetually picking them. They are usually very active in the expression of their delusions, which are all of the melancholic character, such as, that their souls are lost, that they are eternally damned, that they are to be tortured and executed, &c. &c., or they may be continually asserting their innocence of some imaginary crime.

Patients in this condition are almost always actively suicidal; to escape from the terrors which hang over them, they will, if possible, terminate their existence. They often refuse food in the most obstinate manner, with the deliberate intention of destroying themselves, and would indeed succeed in their endeavours were they not forcibly fed. A variety of this form occurs in which the patients are worked up into a perfect frenzy of panic and alarm; they rush wildly about the room, and are so completely possessed with terror as to be absolutely incapable of understanding anything said to them. In this state they may commit acts of violence of which they are quite unconscious afterwards when the panic has subsided. Such a condition seldom lasts long, but is liable to recur at different periods in the course of the case.

We have then six leading types of the affection under consideration:—(1) simple melancholia; (2) delusional melancholia; (3) hypochondriacal melancholia (a variety of No. 2); (4) stuporous melancholia; (5) resistive melancholia (a variety of No. 4); (6) excited or motor melancholia.

It must not be understood that the above are distinct forms of disease, they can scarcely even be said to be varieties. They blend one into another, and may at times all be illustrated in one and the same case in the course of its evolution. The names simply stand for groups of symptoms which are presented to us in practice, and which it is convenient to remember.

There are certain other points in connection with the mental condition of melancholiacs which require consideration.

It was mentioned at the outset that in the milder forms intelligence might be apparently perfectly retained, and especially that the memory might be quite

good. It may now be added that even in the severer forms in which distinct delusions are present, the patient, on ordinary topics unconnected with his delusions, may still appear rational, and his memory may still be perfectly retained, though this is by no means always the case.

But in proportion as these cases are receded from, either in the direction of mental stupor, or in that of mental agitation, grave impairment of memory, in addition to other mental defects, is commonly observed. This may, especially in stuporous cases, be due to incapacity on the part of the brain-cells to register new impressions; but it is frequently dependent upon want of attention, the patient being too much absorbed in his own misery to care for, or to take any notice of, surrounding things, and hence these pass to a great extent unregarded.

The suicidal tendencies observed in melancholia constitute an important feature of the disease. It would not be correct to say that every melancholiac is suicidal, but it is certainly the case that every such patient has the potentiality for self-destruction, and the immense majority exhibit such tendencies at some period or other of the case. The excited cases are probably on the whole most prone to suicide; but the tendency is present in many cases of simple melancholia. Occasionally suicide is directly dependent upon auditory hallucinations, the patient hearing voices commanding him to kill himself.

Though melancholia, as a rule, constitutes a more or less well-marked clinical entity, a melancholic condition is frequently merely a stage in the development of other mental disorders; thus it very generally precedes an attack of mania, and sometimes ushers in general paralysis, or is associated with this disease throughout its course.

The *physical condition* of melancholiacs has been alluded to when describing the simple form of the affection, but it requires more detailed consideration. The weakness of the circulation is most pronounced in stuporous cases, in which the extremities may be constantly cold and livid, and even œdema of the feet is not uncommonly observed. There is marked slowness of the respiratory rhythm. More or less insomnia is almost invariably in recent cases, and sleep is often wanting in proportion to the severity of the attack. The digestive functions are very generally disturbed, and the gastric

trouble is often an important factor in the disease. The tongue may be dry and thickly loaded with fur, the breath offensive, and the bowels confined; and along with this there may be total lack of appetite and great difficulty in administering food.

This condition may be either a cause or a consequence of the melancholic state. In some cases probably, the gastric derangement may actually precipitate an attack of melancholia which may pass off when a healthy condition of the gastro-intestinal tract is restored. But more commonly the derangement has its origin in the general lack of nerve force which has been shown to be so widespread a feature of the disease, or it is dependent upon the refusal of food which is so common in these cases. The stomach always becomes much disturbed in fasting cases. The refusal of food may itself be due to the general apathy and torpidity, or it may be the result of a deliberate resolve on the part of the patient to go without sustenance in order that he may starve.

The nutrition of the whole body suffers, and the patients almost invariably lose weight. Trophic lesions of the nails and skin are not unfrequently observed.

In women menstruation is usually suppressed, though in a prolonged case it very generally reappears even though there be no improvement in the mental condition.

Etiology.—Melancholia may occur at all periods of life from youth to old age, but it shows a special preference for the epoch of middle life.

Any cause which depresses the general health, or any mental shock, may act as the exciting cause of an attack. Thus melancholia is common in women who have been exhausted by prolonged lactation, and it is not infrequent in pregnancy and the puerperal state. Losses in business, domestic bereavement, grief and anxieties of all kinds operate powerfully in producing the disease. Drink is also a frequent cause. But it is not every brain which has the capacity for developing melancholia however unfavourable may be the conditions of the environment. For the exciting cause to be operative there is needed a predisposing cause, which is to be found in most cases in the inherited cerebral constitution.

Hereditary tendency is obvious in a large proportion of cases and exists in many others in which it cannot be traced. By hereditary tendency is to be understood not merely the direct transmission

of insanity, but the existence in the ancestral tree of any form of neurotic taint including alcoholism.

Pathology.—This is in many respects obscure, but a few facts may be noted. In death from acute melancholia, the cerebral changes to be observed are slight. In the recent forms there is commonly evidence of excess of blood in the cerebral cortex, the surface of the convolutions frequently presenting a more or less diffused patchy pink staining, and there being in places congestion of the deeper layers of the cortex. In the chronic forms the brain may appear absolutely normal to the naked eye, or there may be nothing noticeable beyond a little unusual pallor.

The chief *microscopical change* observed by the writer has been the presence in excess of the so-called "fuscous degeneration" in the brain cells, these being more or less filled with clusters of yellow granules. This change, however, is by no means confined to melancholia. It is met with extensively in dementia, and occurs normally to a slight extent as age advances. It appears to connote a defective power of energizing on the part of the brain cells, and hence when occurring to any extent in early adult age, it must be looked upon as distinctly pathological.

There can be little doubt that in melancholia the brain cells, from some inherent or acquired defect, are incapable of appropriating sufficient nutriment to admit of their discharging in the normal manner, and that the tension of nerve force is exceedingly low.

The melancholic diathesis, indeed, connotes a perennial difficulty in keeping up the brain nutrition to the proper standard and a great liability for it to fall below the minimum of working power upon the occurrence of the least adverse change in the environment.

The pulmonary lesions in melancholia are important. As might be expected from the slowness of the respiratory rhythm and the general immobility of these patients, a large number of them fall victims to phthisis, which is indeed the most common cause of death in this disease. Occasionally, indeed, phthisis precedes the mental disorder and acts as its cause. It is, moreover, very common, especially in the acute cases, for a low form of pneumonia which is very fatal to be developed. Actual gangrene of the lungs is also not unfrequently noted, either as a primary affection, or as a sequel to the pneumonia just mentioned. It has appeared to the

writer that this is sometimes occasioned by minute particles of food passing into the larynx and getting drawn into the smaller bronchi, in cases in which there is much difficulty in administering food, and when, as often occurs, the food is retained for a long time in the mouth and back of the fauces before it is swallowed. Pulmonary disease may develop in a very insidious manner, and all the ordinary symptoms may be latent until the fatal termination is within sight.

The occurrence of organic disease within the abdomen is much less frequent. It appears, however, occasionally to occur in direct association with the melancholic state, and visceral delusions seem to have thus at times a visible origin, but it is much more common for these latter to exist with abdominal organs apparently perfectly healthy.

Diseases of the uterus and its appendages, such as prolapsus, tumours, &c., are not uncommon, and occasionally stand in a causal relation to the disease.

Terminations.—(1) *Recovery.*—This is by far the most common termination, especially in the simple forms of the disease. The great majority of the cases that recover do so within a year from the first onset of the symptoms.

(2) *Death.*—This occurs in various ways. It may result, especially in the acute forms, from sheer exhaustion of nerve power, all the residual stock of nerve force being used up and collapse ensuing; or it may be, and frequently is, occasioned by some intercurrent affection such as pneumonia or phthisis, to which the low nervous vitality of these patients renders them peculiarly prone. Or, again, it may be the result of suicide.

(3) *Chronic Melancholia.*—This is merely a chronic form of the acute affection. Although it occasionally issues in recovery, the more usual course is a gradual lapse into the following state.

(4) *Dementia.*—This is simply mindlessness of greater or less degree, and is the goal towards which all forms of insanity tend. At times it is a somewhat rapid sequel to the acute forms of the disease; but it is more usually of slower onset and of less degree of intensity than when it occurs in succession to other kinds of mental disease.

(5) *Mania.*—A few cases terminate in subacute or chronic mania. That is, after melancholia has lasted a few months, a year or more, the character of the symptoms entirely changes, maniacal excitement is developed, which lasts a variable

time, and from this the patient, as a rule, gradually lapses into fatuity.

Prognosis.—This is good in proportion to the youth of the patient, the suddenness of onset, and the absence of well-marked hallucinations and delusions. It is unfavourable according as the reverse of these conditions obtains. Persistent refusal of food and loss of body weight are bad signs. The severer forms of melancholia agitans are unfavourable, especially if the excitement be long continued. Cases of deep melancholic stupor frequently make excellent recoveries. The longer a case lasts, the less chance there is of permanent recovery.

Treatment.—It is of no avail to attempt to argue a patient out of his delusions, or to point out to him that his hallucinations are purely subjective phenomena. Attention should be concentrated upon removing the condition of brain upon which the morbid feeling depends, and the intellectual defects will usually disappear *pari passu*. The first and most obvious indication is to endeavour to improve the general health and restore the exhausted nerve force by abundance of fresh air, good food, and nervine tonics. In warm weather it is desirable for the patients to live as much as possible in the open air, without, however, fatiguing themselves by too much muscular exercise. In the early stages the stimulus of foreign travel is at times highly efficacious, but a quiet rest in some suitable health resort is more beneficial to the majority of cases. Complete rest, indeed, with change of air and scene are the first requisites. Such measures will frequently suffice to restore a case which has not progressed far.

It is often quite unnecessary to send a patient of this kind to an asylum, provided he has sufficient means to ensure his being properly looked after; for the suicidal tendencies of melancholias should always be borne in mind, and it is never either safe or advisable to allow them to be by themselves. Hence, if sent from home, it should always be under suitable escort, and it is well to be very cautious in prescribing sea voyages, on account of the facilities thus afforded for the gratification of suicidal impulses. There is no question, however, that removal to an asylum is often productive of great benefit, the change to an orderly, settled life, and the subjection to discipline being highly efficacious in many cases.

Gastric derangements must be com-

bated by ordinary means. Refusal of food is often an exceedingly troublesome symptom, and one most difficult to treat. If obstinate it must be overcome by the use of the stomach-pump, and the patients must be forcibly fed two or three times a day with milk, meat extracts, liquid custards, &c. The food may, with advantage, be peptonized before administration. Stimulants are undoubtedly useful in many cases and should be given with food.

Insomnia is best treated by keeping the patients in the open air as much as possible—all day long if the weather be favourable, and the strength permit. Hypnotic drugs, such as chloral, morphia, henbane, &c., should be given with caution, as though they may be useful and desirable as occasional adjuvants, continued persistence in them has a deleterious effect on the nervous centres, and lessens the chances of recovery.

In some cases, especially those in which much stupor is present, the continuous current applied to the head is productive of distinct benefit.

J. WIGLESWORTH.

MENIÈRE'S DISEASE (Labyrinthine Vertigo).—An affection characterized by sudden attacks of giddiness, preceded or accompanied by noises in one or both ears and deafness.

Symptoms.—The attack often commences quite suddenly with a buzzing or humming noise in one or both ears, usually more marked in one. This is soon followed by vertigo, which may be either objective or subjective, or the patient may experience a sensation of falling, generally in a forward direction, but sometimes backwards or to one side. He reels and clutches neighbouring objects, but rarely falls, though occasionally he may do so, or in severe cases may be thrown violently to the ground. There is some doubt as to whether there is ever loss of consciousness, if so, it is only momentary, as the patient can always give an exact account of his sensations after the attack is over.

The attack lasts a few minutes, and passes off gradually, leaving the patient deaf and with noises in his ears. Towards the end of it, he is pale, with a cold clammy skin, and often experiences nausea or even vomits. Lateral nystagmus is sometimes present during the attack, and apparent movement of objects from side to side is complained of. Subsequent attacks are liable to come on at varying intervals and are generally

announced by an increase in the tinnitus, which is usually more or less permanent. A shrieking or a whistling noise is a common precursor of an attack. The intervals between the attacks gradually become shorter until the patient is reduced to a state of permanent vertigo, liable to exacerbations. The deafness gradually becomes more marked, and the tinnitus less prominent, and, finally, in some cases a spontaneous cure is effected when the deafness becomes absolute, the vertigo then disappearing.

Vertigo, tinnitus and deafness when united in one person generally indicate an affection of the labyrinth either from actual disease—*e.g.*, inflammation or hæmorrhage—or from disease of the middle ear causing pressure on it, but obstruction of the Eustachian tube or of the external auditory meatus, as by the accumulation of cerumen, may lead to the same symptoms.

Some writers do not regard Menière's disease as a severe form of labyrinthine vertigo, but as a distinct affection. According to this view, it is characterized by a sudden and severe attack such as that above described in a person who had no previous ear disease. The attack may never recur, it is nearly always confined to one ear, the deafness is extreme, the tinnitus and giddiness diminish or cease after the attack, and there is no evidence of disease of the middle or external ear. In labyrinthine vertigo, on the other hand, there is usually pre-existing ear disease, and severe tinnitus, with more or less deafness, the attacks are less sudden and more frequent, the giddiness is less severe but more chronic. Fagge believes that in true Menière's disease there is no affection of the labyrinth or cochlea, but some disturbance of the centres for hearing and equilibrium.

Treatment.—During the attack the patient should maintain the recumbent position, and may suck ice if there be much nausea or sickness. Bromide of potassium in 20-grain doses is sometimes useful. In the intervals any ear disease should be treated and the general health improved as far as possible. Quinine in large doses has appeared to do good, and electricity has also been recommended.

JOHN ABERCROMBIE.

MENINGES, CEREBRAL AND SPINAL, DISEASES OF.—The following affections are described under this heading:—

ACUTE CEREBRAL AND SPINAL MENINGITIS—

1. Tubercular meningitis.
2. Simple meningitis.
3. Leptomeningitis infantum.
4. Epidemic cerebro-spinal meningitis.

CHRONIC MENINGITIS—

Hæmatoma of the Dura Mater (Pachymeningitis hæmorrhagica).

Chronic hypertrophic pachymeningitis of the Cord.

ACUTE CEREBRAL AND SPINAL MENINGITIS.—An acute inflammation of the membranes of the brain and spinal cord.

Inflammation of the dura mater is termed pachymeningitis. Inflammation of the pia-arachnoid is known as leptomeningitis.

Varieties of the disease are recognized according to their intensity, duration, nature, seat and origin. Purulent and tubercular meningitis affect the pia mater almost exclusively, but tubercles may be seen on the visceral surface of the dura mater of the brain and cord. Tubercular meningitis is the most common form of brain disease in children. Infants a few weeks or months old are liable to a form of simple, non-tubercular meningitis which is called "occlusive," "posterior" and "leptomeningitis infantum."

1. Tubercular Meningitis.—*Symptoms.*—These are mainly due to the irritation and destruction of those parts of the brain and cord which happen to be affected, but doubtless many of the symptoms may be termed pure neuroses; at puberty hysterical neuroses are often the first symptoms of tubercular meningitis.

Premonitory symptoms are very frequent in children. A history of emaciation, poor health, vomiting, headache, lassitude, fretfulness, altered temper, capricious appetite, irregular action of the bowels, and pyrexia are some of the symptoms; they may be met with in various combinations, but are often so vague that they give no clear indication of the nature of the illness. This period may last from a fortnight to three months or longer. In some cases in children and in many cases in adults no premonitory signs may be observed, or the symptoms have been set down to a "cold" or to existing phthisis.

The symptoms of the actual illness have usually been arranged in three categories representing three periods, but in

practice the variations observed in the clinical course are very wide.

The first or *stage of irritation* is characterized by vomiting, which may be frequently repeated and "causeless," having no special relation to the ingestion of food. There is fever of an irregular remittent type, the temperature not usually rising higher than 102° , but the curve may be inverted—i.e., the highest temperature may occur in the morning instead of the evening. The pulse is usually increased in frequency, but the rate may be unaltered or slower than the normal. When the pulse is slow, vomiting is more common. The respiratory rhythm may show similar changes, and the breathing may be attended with a moan or groan. The bowels are constipated even when there is no vomiting.

Not only is there evidence, as just stated, of perturbation of the functions whose centres are seated in the floor of the fourth ventricle, but mental, motor, vaso-motor, and sensory symptoms may be noted, and are doubtless due to disordered action of those regions of the brain which subserve such functions. Severe headache, a tender hot scalp, fretfulness, headache, restlessness, sleeplessness, twitching and rigidity of muscles, tremors, squinting, contracted or unequal pupils, delirium, losses of consciousness, epileptiform attacks, hyperæsthesia of the various senses are some of the principal symptoms. Transient paralysis, such as ptosis or hemiplegia, may be noted, and may be simply neuroses.

In the *middle or transitional stage* the "irritative" phenomena tend to subside; drowsiness, low temperature, persistently slow and irregular pulse, irregular respiration, and a general apathetic tendency supervene. The pupils become dilated, optic neuritis may appear or become more marked, the "hydrocephalic cry"—a shrill shriek—may be heard. It indicates irritation, but is often present when the other symptoms indicate absence of irritation. The belly may become boat-shaped or concave, or simply flattened; the *tâche cérébrale ou méningitique* (of no diagnostic value) may be marked.

The *final stage* is but a further development of the paralytic or drowsy stage; collapse, convulsion, and coma are its leading signs. The pulse and breathing become again frequent, and often very feeble. Cheyne-Stokes' breathing may be witnessed—a series of respirations of increasing depth and frequency followed by a series of diminishing depth and

frequency, terminating in a period of apnœa, during which no breath may be taken for more than half a minute.

The typhoid state may develop, and is marked by a dry, brown tongue, low muttering delirium, sordes on the teeth and lips, picking at the bed-clothes, subsultus tendinum, and great prostration. The delirium and picking at the bed-clothes may be absent, coma and paralysis being profound. There may be no pyrexia, or the temperature may sink to 94° , or rise to the hyperpyretic degree as death supervenes.

Duration.—This varies, but many cases die within a fortnight of the commencement of the attack; the duration of the different stages is also variable.

Diagnosis and Treatment are considered at the end of the article on MENINGITIS.

Prognosis.—The disease is generally fatal, but good grounds exist for believing that recovery does rarely occur; when the termination is favourable it cannot be ascribed with any certainty to the use of any special method of treatment.

Pathology and Morbid Anatomy.—The inflammation is excited by the presence of tubercles in the meninges; the tubercles are developed chiefly along the distribution of the middle cerebral artery. Sometimes, however, no milary tubercles can be discerned, even in cases in which phthisis or tuberculosis exists elsewhere.

A gelatinous turbid, but never purulent, infiltration of the loose meshes of the pia mater is present most abundantly about the base of the brain, and along the Sylvian fissures; the sulci elsewhere may rarely show a considerable amount of infiltration. There is an excess of fluid within all the ventricles of the brain, and the fluid is usually turbid and contains leucocytes. The extreme anterior apex of the upper surface of the cerebellum almost always exhibits thickening of the pia mater; this thickening is evidently in direct continuity round the cerebral peduncles with that of the base, and the pressure of it on the venæ Galeni may be one cause of the ventricular dropsy (acute hydrocephalus).

When there is marked hydrocephalus the surface of the pia-arachnoid often feels dry and sticky, the sulci tend to be obliterated, and the convolutions are flattened by the increased pressure. The ependyma of the ventricles may show a granular shagreen appearance. The walls of the ventricles may be the seat of white softening; and when the ventricles are opened, the septum lucidum and

fornix may be ruptured. The tubercles may be detected in other parts of the brain than those supplied by the Sylvian arteries; sometimes they are localized in a part of one motor area on the convex surface and then typical attacks of Jacksonian epilepsy may have been observed. Around and near the tubercular foci capillary blood extravasations and thrombosis may be observed. There may also be larger nodules which may show caseation, and bacilli may be found in their substance.

Ætiology.—The causation of tubercular meningitis is the same as that of tuberculosis (*q.v.*), but various exciting causes such as blows and falls on the head, chills, excessive sunlight and heat, mental overwork and anxiety must be recognized.

2. **Simple Meningitis.**—*Symptoms.*—The number and combination of symptoms and the clinical course of this variety of meningitis have a general resemblance to the tubercular form, but the prodromata are usually absent; a differential diagnosis between the two varieties may be impossible, owing to the fact that either form may be markedly erratic in its mode of origin, course and progress. Any nervous symptom and any combination of symptoms may appear.

Headache, delirium, convulsions, vomiting, optic neuritis, hyperæsthesia and mental apathy, with retraction of the head are common symptoms. Convulsions are said to be more frequently present, and to be more dominant symptoms in this form of meningitis; this is probably true only when the motor area is most involved.

Duration.—The clinical course of this affection is, as a rule, shorter than in the case of tubercular meningitis. Death may occur in a few days, fulminating varieties being described in which the symptoms precede death by only a few hours or a day or two. In the case of an infant aged four months, observed by the writer, convulsions lasting two hours were the first and last signs of a purulent cerebro-spinal meningitis.

Pathology and Morbid Anatomy.—There is no special predilection for the base of the brain, the products of inflammation being often most abundant on the vertex; the material exuded is frequently purulent, spotted hæmorrhages and thrombosis of veins may be noted as in tubercular meningitis. It is not uncommon to find the whole brain and cord coated with an even layer of green pus which is

beneath the pia-arachnoid membrane; the fluid in the ventricles is often purulent also.

Ætiology.—Most cases of meningitis occur in children under the age of puberty, illustrating the doctrine that growing tissues are more prone to disease than finished organs, even when the exciting causes are the same.

The causes are numerous and difficult to group, they include blows and falls on the head, sunstroke, local and general pyæmia, as in disease of the bones of the middle ear and skull generally; facial carbuncle, necrosis of the jaw, erysipelas of the face and scalp, acute specific fevers—typhus, typhoid, measles, scarlet fever; pleurisy and pneumonia, and syphilis.

The association of pus over the brain with pus over the pleura, pericardium and peritoneum has been noted several times. Granular and large white kidneys have been associated with meningitis. Inflammation may extend from the skull to the meninges; simple or syphilitic caries or necrosis of any part is liable to be followed by meningitis, caries of the petrous portion of the temporal bone is perhaps the commonest. In suppurative disease of the nose and orbit the mechanism of the meningitis which sometimes results is of the same kind. Otitis without bone disease is frequently found with meningitis, but the sequence of events is uncertain. Otitis may be cause, consequence or companion of the meningitis.

For *diagnosis and treatment* see end of article.

Prognosis.—This is serious, but least so in the traumatic cases. The early supervision of deep coma is rarely followed by recovery. The less severe and acute the symptoms the better is the chance of recovery. Recovery may be slow and lingering and yet finally perfect; occasionally it is rapid and complete. It is, however, only in exceptional cases that health is fully restored.

Leptomeningitis Infantum.—This variety of simple meningitis deserves a short separate notice because of its peculiarities.

Symptoms.—These are few in number, as the symptoms of any form of meningitis are apt to be in very young infants. The disease occurs during the first months of life. As a dominant symptom cervical opisthotonos (retraction of the head) is most important. Optic neuritis is rare.

Prognosis.—This is less serious than in most forms of meningitis; a few cases

recover, some end in chronic hydrocephalus.

Morbid Anatomy and Pathology.—The region affected is the posterior part of the base of the brain, whence the names "posterior" and "basilar." The under surface of the cerebellum is glued to the posterior fossa of the skull and to the posterior boundaries of the fourth ventricle, thereby shutting up the foramen or foramina of Magendie, by means of which the cerebro-spinal fluid communicates with the sub-arachnoid space and the cerebral ventricles. This occlusion leads to the development of hydrocephalus and gives the disease its other name, "occlusive" meningitis.

Etiology.—Syphilis is one of the causes of this affection; for others the reader is referred to the article on MENINGITIS. Otitis without bone disease is believed to be a common cause.

Treatment.—Daily inunction of blue ointment into the back of the neck is a useful measure.

4. **Epidemic Cerebro-spinal Meningitis.**—*Symptoms.*—There are a few symptoms of meningitis which occur more frequently in this than in the other forms. The severity of the pains in the limbs and trunk may be ascribed to the irritation of the posterior nerve roots. The prevalence of cutaneous eruptions, apart from the cerebral maculæ, is a noteworthy feature. Erythemata, urticaria, herpes and purpura may be noted alone or in combination. The onset is usually sudden, with chills, high fever and vomiting. Deafness is apt to remain after the disappearance of all other symptoms, and headache is sometimes a sequela. The deafness is occasionally accompanied by a difficulty in maintaining the body equilibrium; both symptoms may be due to effusion into the labyrinth. Pneumonia is a rather frequent complication.

Duration.—The average duration is about two weeks; it sometimes lasts much longer, even some months. In two such cases a collection of pus was found beneath the cerebellum; the clinical course resembled that of abscess of the brain.

Prognosis.—If deep coma intervene within a week of the onset of the illness recovery is almost unknown. Still the prognosis is less grave than might be expected from the nature of the illness, and the case should never be abandoned as hopeless.

Morbid Anatomy and Pathology.—The inflammatory products are often puru-

lent, the changes are much the same as those found in simple meningitis.

Ætiology.—The disease is believed not to be contagious, or only slightly so; it most frequently affects young males under the age of twenty; it is epidemic; the actual cause may be an organism like that supposed to cause malarial fevers.

Diagnosis of all Forms of Acute Meningitis.—Brain symptoms like those occurring in meningitis may be due to altered blood states in any severe illness. In children brain symptoms are very frequent and marked. Definite signs of local paralysis may not be present in meningitis. If these considerations be borne in mind, no wonder need be expressed that a correct differential diagnosis is sometimes most difficult and even impossible. Typhoid fever sometimes mimics meningitis by causing constipation and a retracted belly. Tuberculosis may give rise to abdominal symptoms—tympanites, rose spots, delirium, pea-soup stools, large spleen—very like those of typhoid fever. The concurrence of headache with delirium is held to be diagnostic of meningitis; in fevers headache subsides as delirium comes on.

If there be disease of the middle ear, purulent meningitis is most probably present. If phthisis exist, or scrofulous scars, or hip-joint disease, or vertebral caries, the diagnosis should be tubercular meningitis; but with any of these affections hysterical symptoms may occur resembling those of meningitis. Under the age of one year tubercular meningitis is rarer than after that period.

Choroidal tubercle may be noted during life.

It is not always possible to diagnose abscess of the brain from purulent meningitis; nor crude tubercles or other "coarse" brain lesions from tubercular or simple meningitis. Since meningitis may commence its clinical course with hemiplegia, with epileptic fits, with signs like those of delirium tremens or even like those of uræmia, the question may arise whether the case is not one of these latter affections.

The occurrence of skin rashes in meningitis sometimes causes a resemblance to rheumatic fever, and this the more so since multiple arthritis has been noted in alleged cases of epidemic meningitis.

Severe lumbago sometimes suggests small-pox, which also begins suddenly with high fever, chills and headache; but the supervention of muscular rigidity

is special to meningitis. Meningitis may arise as a complication of the specific fevers, of inflammation and blood poisoning, thus increasing the difficulties of diagnosis.

Treatment.—If the meningitis be secondary to disease of the middle ear, surgical treatment of the latter affections may still be advisable, if only for the reason that many of the symptoms may be due to the condition of the ear.

The nature and the seat of the meningitis have but little influence on the treatment.

Powerful antiphlogistics, strong counter-irritants, blood-letting, severe purging and free blistering are measures which should be avoided. Absolute rest for the mind and body in an agreeable apartment is essential, the chamber being so situated that quiet and darkness can be obtained. It should be well ventilated, and kept at a temperature of about 60° to 65° F.

The bowels should be kept regularly open by simple means. The diet should be digestible and nutritious. Stimulants should be prescribed only when the state of the pulse and breathing indicates their use. Ice-bags or cold applications may be applied with advantage to the shorn scalp to relieve headache, vomiting, insomnia and mental or muscular restlessness. The same symptoms may be abated by the use of bromides, chloral, hyoscyamus, paraldehyde, sulphonal or opium. Injections of cocaine or morphine may be used to relieve pain. Leeches behind the ears may be employed with advantage if there be great heat of head and circulatory excitement. Iced or effervescing drinks, or, rarely, hot drinks, may relieve vomiting. Saline purges may reduce the cerebral and circulatory tension.

Mercurials may be employed to the extent of just "touching the gums;" the most useful preparations being calomel and grey powder in small doses. Iodides and mercury are useful to promote the absorption of inflammatory products, and they may be used at the termination of the acute stage, and with this object in view in cases which are more sub-acute and chronic. The limbs and trunk may be kept in good condition by shampooing and warm ablutions during the period of convalescence and during the treatment of chronic cases. The inunction of iodoform ointment into the scalp in cases of tubercular meningitis is valueless.

CHRONIC MENINGITIS.—This chiefly affects limited parts of the brain or cord, and generally leads to adhesions between

the pia and dura mater. The disease often occurs in the form of chronic hypertrophic pachymeningitis. Its pathology is a matter of contention; when the cerebral meninges are affected, the condition has been described as hæmatoma of the dura mater. Some authorities believe that the meningitis precedes the extravasation of blood, others teach that blood is first extravasated, and that this sets up meningitis and leads to fibroid formation.

Hæmatoma of the Dura Mater (*Pachymeningitis Hæmorrhagica*).—*Symptoms.*—These are by no means unequivocal. Epileptiform or apoplectiform attacks, headache, a full, slow pulse, drowsiness, contracted, dilated or unequal pupils, coma and convulsions, and slight hemiplegia have all been noted. It may be stated that there are no symptoms distinctive of the affection.

Duration.—The clinical duration of the disease is variable. Death may result soon after the occurrence of an epileptiform or apoplectiform attack, or the subjects of the disease may have been long resident in an asylum.

The *diagnosis* is exceedingly difficult. In cases of chronic syphilitic meningitis the diagnosis rests on the following points and is often easy. A history of syphilis, physical evidences of this disease in other parts of the body, unequal and irregular distribution of paralysis of cranial nerves and occurring frequently on both sides of the body. Of course, headaches, giddiness, vomiting, impairment of sight with optic neuritis, or atrophy, may be present as with any kind of meningitis. In one case, for example, the right seventh nerve was paralysed, its muscles wasted, and the faradic reactions lost; there was right hemiplegia of the graduated kind, with paralysis of the left external ocular rectus, and hemiatrophy of the left half of the tongue. The necropsy revealed a gumma on the right facial nerve at its superficial origin, and one on the left hypoglossal nerve; the left sixth nerve was compressed by thickened meninges. There was also thrombosis of the left Sylvian artery and wasting of the motor convolutions.

The *prognosis* is as variable as the duration.

Morbid Anatomy.—The pia mater and dura mater are bound together by the products of the disease. The lesions are usually unilateral and most marked over the convexity of the brain. Recent blood extravasation or brick-red or ochre-yellow discoloration is found in or between the new-formed membrances. There are

superimposed layers of membrane on the inner surface of the dura mater. These are soft and vascular when recent; but tough, white or brownish and fibrous when old. The hæmorrhage takes place into the sub-dural space; the affection is sometimes bilateral. The membranes on this view result from condensation and organization of the blood clot. Virchow's view is that membranes are formed one within another, and that they contain thin walled capillaries which burst and yield blood—a condition to which the term pachymeningitis hæmorrhagica is applied. The layers are often so arranged as to form cysts which may enclose a serous fluid, and then the disease is a form of external hydrocephalus. Cysts may also develop in the substance of the brain as the result of hæmorrhage into it; this is also a form of hydrocephalus externus.

Chronic meningitic thickening may be associated with syphilitic arteritis as well as with atrophy and sclerosis of the brain. Gummata may be found on the cranial nerves, aneurysms on the cerebral arteries, and thrombosis of the vessels may be present.

Etiology.—The disease is most frequently observed in men of advanced age, especially in those who have been hard drinkers. Alcohol and syphilis are recognized causes; insanity is often associated.

Treatment.—Anti-syphilitic treatment should be tried in all cases.

Chronic Hypertrophic Pachymeningitis of the Cord.—This disease usually affects the cervical enlargement of the cord.

Symptoms.—Exceedingly severe "root" or "radicular" pains shooting down the arms and neck are the most important early symptoms; anæsthetic areas may be found on the arms, shoulders, or neck. Amyotrophy of these regions subsequently supervenes; weakness of the trunk and legs usually occurs later, and is associated with rigidity of the affected muscles, and the phenomena of hyperkinesis, exaggerated knee jerks, ankle and rectus clonus, and front-tap contraction.

Any sensory, vaso-motor or motor symptom may be noted in the arms; sometimes they are pale and cold, at others blue and cold, and they may, however, be hot, burning, and sweating, or there may be sweating without any flushing. Eruptions may appear along the path of the lightning pains. Spasms may occur in the limbs, and a claw-shape of the hand may appear as the result of the wasting of the muscles supplied by the ulnar

nerve, which comes from the lowest part of the cervical cord. The pupils may be contracted; they may not dilate when they are shaded nor when the cervical skin is pinched or faradized.

The disease begins insidiously, and slowly advances in the course of months, the hyperæsthesia and pains being the first symptoms.

Duration.—The affection usually lasts from one to two years or even longer.

Diagnosis.—This has to be made from amyotrophic lateral sclerosis, sub-acute spinal atrophy and from progressive muscular atrophy but none of these diseases are accompanied by the agonizing pains and sensory disturbances which mark the affection under consideration. In an advanced stage rheumatoid arthritis of both shoulders may be simulated, owing to the existence of pains and amyotrophy, but grating in the joints does not occur as a rule in meningitis. The simultaneous onset of severe sensory symptoms in both arms is an important element in the diagnosis of meningitis of the brachial enlargement. The absence of pain is the most conspicuous feature of myelitis. The presence of pain and muscular spasm are the most conspicuous features of meningitis as contrasted with myelitis. A limited area of anæsthesia on the trunk or a limb is almost always due to meningitis.

Prognosis.—This is always grave and nearly always devoid of hope.

Morbid Anatomy.—This consists in concentric laminated thickening of the dura mater with compression of the nerve roots and cord; the spinal marrow may be softened or diffuent; secondary degenerations may be noted above and below the seat of compression.

Treatment.—Iodides and mercury should be prescribed. Half-drachm doses of bromides, given frequently, sometimes relieve pain better than injections of cocaine or morphine. ANGEL MONEY.

MENOPAUSE (Change of Life).—The cessation of menstruation.

This event usually occurs at about the age of forty-five, but it may precede this age, or be postponed until a later period, without any detriment to health. The complete cessation of menstruation is often preceded by a period of irregular menstruation, known by women as the "dodging time." This irregularity, and the final stoppage of menstruation, is, as a rule, not attended with any disturbance of health. But in some cases it appears as if the cessation of the rhythmical in-

crease of vascular tension and accompanying loss of blood, which are parts of the menstrual process, in some way interferes with the normal vaso-motor tone, and in consequence vaso-motor disturbances occur. Women thus often complain of palpitation, chills, "flushings," "heats" and perspirations, occurring without known cause. The liability to these troubles sometimes lasts for two or three years after the cessation of the menses, but ultimately, and often in less time, these symptoms cease. During the "dodging time," the hæmorrhages which occur are sometimes excessive, or may be unusually prolonged, without there being any change in the uterus appreciable by the methods of examination known to us. Hæmorrhages from other parts, as from the nose, or from hæmorrhoids, may occur, and this at such intervals that the hæmorrhage may appear to replace the missing menstrual flow. The presence of fibroids in the uterus usually delays the menopause. When premature menopause is brought about artificially (by spaying) the same vaso-motor disturbances are apt to occur, as are noticed at the natural menopause.

Women are very apt to accept "change of life" as an explanation of almost any symptoms occurring between forty and fifty, and eminent authorities have taught that many diseases are prone to attack women at this epoch. Among these are vertigo, epilepsy, cerebral hæmorrhage, dipsomania, hypochondriasis, melancholia, flatulent dyspepsia, pseudocyesis (*q.v.*), obesity, gout, gall-stones. These are diseases prone to develop in advanced life; but there is no scientific evidence to show that they are more common at the menopause than in the years which follow it.

Treatment.—The vaso-motor disturbances which occur at the menopause are best treated by saline purgatives. If the patient be florid, and there be any pelvic discomfort, benefit will be found from leeches to the cervix uteri or inguinal regions. Hæmorrhages, so long as they do not make the patient anæmic, should not be checked. If they render the patient anæmic, they must be treated according to the methods usual for such hæmorrhage at other periods of life. The menopause should not without careful examination be accepted as a sufficient explanation of uterine hæmorrhage occurring in a middle-aged woman, for such hæmorrhage may be the first symptom of disease, the early detection of which is extremely important. G. E. HERMAN.

MENORRHAGIA.—An increase of the menstrual flow. The causes which lead to increased hæmorrhage at the normal times commonly soon induce hæmorrhage at times other than the normal period; such hæmorrhage is called **METORRHAGIA**, and to that heading the reader is referred.

MENSURATION.—The act of measuring. A means of physical diagnosis especially applicable in diseases and deformities of the chest.

The methodical examination of the chest concludes with mensuration, by which means the actual shape and dimensions of the chest as a whole, and the relative measurements of corresponding parts on the two sides, may be ascertained and recorded.

The instrument in general use for this purpose is the *Cyrtometer*, which consists of two lengths of soft metal united by a short piece of india-rubber tubing.

The centre of the junction is applied to the vertebral spine at the desired level, and the metal pieces are accurately moulded to the chest wall, and are marked where they overlap in the mid-sternal line on a level with the point of application to the spine.

The instrument is now removed and placed upon a large sheet of paper and a tracing taken of its outline. The antero-posterior, transverse, or other measurements are then determined.

In medical practice such records are chiefly of value in cases of pleurisy in the stage of effusion, or subsequently when collapse of the lung has occurred, and treatment is being directed to promote its re-expansion; also in cases of phthisis in the stage of quiescence, or arrest, when it is desired to ascertain the effect of climatic or other treatment upon the capacity of the chest.

It is necessary to bear in mind that the outline is that of the chest wall only, and that its shape will be altered by the development of muscle or the deposition of fat as well as by expansion of the lung, a source of fallacy which to some extent militates against conclusions derived chiefly from this method of examination.

By means of a tape the circumference of the chest can be determined, and differences on the two sides, either during expansion or in repose, can be determined by the use of single or double tape measures.

For the detection of sub-clavicular de-

pression the trained eye is of more service than any instrument.

J. K. FOWLER.

MERCURY, Poisoning by.—The effects of the absorption of the salts of mercury are manifested in an **acute** and **chronic** form, the difference depending mainly upon the length of the period during which the poison has been gaining entrance into the system and the quantity absorbed.

Large doses of soluble salts of the metal administered at short intervals are likely to produce the train of symptoms which characterize the former affection, whereas chronic poisoning as a rule results from the administration of small doses of the less active preparations or from the inhalation of vapours charged either with the metal or its compounds.

Acute Poisoning.—The salt most frequently taken is the perchloride or corrosive sublimate.

The *symptoms* of acute mercurial poisoning are a metallic taste in the mouth, with constriction in the throat and an intense burning pain extending down the œsophagus to the stomach. The patient speedily becomes collapsed. The mucous membrane of the mouth becomes white and shrivelled; nausea and vomiting soon set in; the vomit may contain blood. Purging and griping pains in the abdomen, increased by pressure, will also be present; the urine is scanty or suppressed.

Fatal Dose.—A drachm of corrosive sublimate nearly always causes death.

Post-mortem Appearances.—The mucous membrane of the mouth and œsophagus is whitened; that of the rest of the alimentary canal more or less inflamed. Ecchymoses are common in the stomach, the cæcum and colon are inflamed and sometimes ulcerated, the kidneys are usually inflamed.

Treatment.—Vomiting must be promoted by the administration of such emetics as mustard (ʒss in water) or sulphate of zinc (gr. xx in water). It is generally recommended that the stomach pump should not be used. Albuminous substances, such as unboiled white of egg in water should be given in unlimited quantities, in order to render the poison inert; or, failing this, flour and water, arrowroot, or barley-water may be given freely.

Chronic Poisoning.—Mercurialization may manifest itself either by salivation or tremor. Salivation may result

from the medicinal use of mercury, tremor is only found in those exposed by their trade to the effects of the metal—*e.g.*, water-gilders, looking-glass makers, and barometer makers. In the former case the gums are swollen and recede from the teeth so that these may fall out; the breath has a peculiar fœtor; the amount of saliva is increased, and in bad cases the flow of it is incessant; the whole face may be swollen, and sloughing of the tongue or cheek may follow. In those who are the subjects of renal disease the chances of recovery are very small.

Mercurial tremor is preceded by a general loss of power; the trembling first shows itself in the arms, involving the legs at a later date; ultimately the sufferer is incapacitated from all employment; he cannot even stand alone; and his mental faculties undergo deterioration. There is usually also profound anæmia and a dark line along the gums.

Treatment.—The essential measure to attend to in all these cases is the removal of the exciting cause. Where the person is taking mercury internally, the medicine must be stopped. In a case of tremor, the patient must change his trade.

J. ABERCROMBIE.

MESENTERIC GLANDS, DISEASES OF.—The mesenteric glands are liable to acute and chronic inflammation, and to certain specific processes.

Acute Inflammation and Congestion.—Inflammatory conditions of the mesenteric glands are generally found associated with acute affections of the intestines; with catarrhal diarrhœa, cholera infantum, enteric fever, dysentery; it is in the two last named only (*q.v.*) that the condition is of importance.

Chronic Inflammation.—Chronic enlargement of the mesenteric glands may be due to chronic or often repeated intestinal catarrh, the glands may, in children, even undergo caseation (Hænoch).

Tubercular Disease.—Tubercular disease of the mesenteric glands is the most important affection to which they are liable; it is secondary to tubercular enteritis or peritonitis, exceptions to this rule are rare, and probably all more apparent than real. (*See LYMPHATIC SYSTEM, DISEASES OF; TABES MESENTERICA; TUBERCULOSIS.*)

Atrophy.—In old age and after enteric fever the mesenteric glands may atrophy. They not infrequently undergo calcareous degeneration, probably as a sequel to tubercular disease.

Malignant Disease.—The glands are liable to be affected secondarily in cancer of the intestines. Lymphadenoma may affect these glands, and in this disease they often attain a very large size.

METRORRHAGIA.—Hæmorrhage from the uterus—*i.e.*, hæmorrhage from the unimpregnated uterus, excessive in frequency, duration or quantity. It may arise from either general or local causes. Both are very numerous and include:—

1. *General.*—Hæmophilia; purpura; scurvy; phosphorus poisoning; acute yellow atrophy of the liver; Bright's disease; acute fevers, such as scarlet fever, small-pox, typhus, measles, &c.; diseases obstructing the return of blood from the uterus in a slight degree, such as heart, lung, or liver disease (these conditions in high degree lead to amenorrhœa); fatigue, over-exertion or excitement; residence in hot climates.

2. *Local.*—Among the most common local causes of hæmorrhage from the womb are fibroid tumours and polypi; endometritis; malignant diseases; retroversion and retroflexion; sub-involution; inversion; retained membranes or placenta; and disease of the uterine appendages.

Treatment.—The hæmorrhage is generally a symptom, and the cause must be sought for. In a virgin, or a patient who objects to examination, we must treat the symptom. No drug is comparable to ergot in its efficiency against uterine hæmorrhage, although there are many that have been recommended. If ergot fail, and the hæmorrhage, judged of by its effect on the colour of the skin and mucous membranes, be injuriously great, it is advisable to insist on an examination. If bimanual examination fail to detect a cause for the hæmorrhage, then it will be necessary to dilate the cervix and explore the uterine cavity.

G. E. HERMAN.

MICRO-ORGANISMS.—Among the micro-organisms or microbes of especial interest and importance in medicine are *Bacteria* and *Protozoa*. They belong respectively to the vegetable and animal kingdoms.

Bacteria at one time were included among the minute organisms which stand on the borderland between animals and plants. They are now considered to be vegetables, as they are able to derive their nourishment from ammonia compounds; but they differ from the higher

vegetable cells in being unable to split up carbonic acid into its elements, owing to the absence of chlorophyll.

Bacteria may be defined as minute vegetable cells destitute of nuclei. They possess a cell wall and cell contents. The cell wall consists of cellulose. Some bacteria are capable of bending and twisting, while others remain perfectly stiff; this depends on the property of the cell wall, which is either pliable or rigid. Of the cell contents, the protoplasm is in some homogeneous and in others granular, and varies in its microchemical reaction in different species.

The effect of the aniline dyes, which are employed to render the organisms more clearly visible, depends on the affinity of the protoplasm for dyes. Hence the different methods employed in the preparation of microscopical specimens. The protoplasm in some bacteria contains starch granules, which give the iodine reaction; in others it contains sulphur granules, and in others again certain colouring matters. In some cells, either as the result of secretion from, or absorption and swelling up of, the cell wall, a gelatinous envelope develops, and sometimes this forms a matrix in which numbers of bacteria are embedded—a *zoogloea* (Fig. 1).

Bacteria differ greatly in shape, but certain typical forms are recognized.

Spherical and egg-shaped cells are called *cocci* (Fig. 2). A coccus increases by fission, and if the resulting elements remain attached to each other, a *diplococcus* (Fig. 3) is formed. These may in turn divide, and if the resulting elements remain linked to each other, a *streptococcus* (Fig. 4) is produced. Streptococci vary considerably in length, sometimes consisting of only a few elements, and sometimes stretching right across the field of the microscope.

When a cell divides in two directions the four daughter cells form a *tetrad* (Fig. 6); and if, in addition, those elements divide in a third direction, eight elements result from the division of a single cell, and form a *sarcina-coccus* (Fig. 7).

A common form-type is the rod; a short rod is often distinguished as a *bacterium* (Fig. 8), and a long rod as a *bacillus* (Figs. 9, 10, 13, 14). The bent rod or *vibrio* is intermediate between the straight rod and the corkscrew rod or *spirillum* (Fig. 11).

There are also filamentous forms, which are distinguished as *leptothrix* if they are straight, or *spirochæta* if they

From Crookshank's Bacteriology.

are of a wavy character. There is an unusual form, the result of a wavy filament becoming curled and twisted on itself, termed *spirulina*.

Bacteria may be divided into four classes according to their form-types:—

Sphero-bacteria, or globular forms (micrococcus);

Micro-bacteria, or short-rod forms (bacterium);

Desmo-bacteria, or long rods (bacillus, vibrio);

Spiro-bacteria, or spiral forms (spirillum, spirochæta).

This classification, however, is not scientifically correct, as these different forms are not constant for all microbes. The same species, if polymorphic, may exhibit several forms at different stages of its growth.

Some bacteria are motionless; others are endowed with locomotive power. By examining a drop of any putrefying liquid or vegetable infusion under the microscope, the peculiar characteristic movements of many species may readily be studied. Some appear to undulate; others glide along, or spin round like a top, or progress with a peculiar tremulous motion; others appear to move backward in one direction, then turn round and progress in another; others have a very characteristic corkscrew movement. The movement of micrococci is probably only brownian.

It is not fully explained how locomotion is effected. In some cases it appears to be due to the contractility of the protoplasmic contents of the cell. In others, movement is produced by a delicate lash-like filament, which may be present at one or at both ends of the micro-organism as in *Bacterium termo*. *Spirilla* are exceedingly active in their movements, and the flagella can be readily demonstrated by suitable methods of staining.

Bacteria reproduce their like by a very simple process, *division*. Hence they are called *fission-fungi*. A single cell increases in size, and a constriction takes place in the middle. This goes on until the two parts are divided one from the other. These new individuals may pass an independent existence, or remain linked together.

By another process representing true fructification, spores are formed. In the anthrax filaments, for example, under suitable conditions the protoplasm becomes granular, and a little speck appears which gradually increases, becomes highly refractive, and has a sharply

defined contour. It grows at the expense of the protoplasm, and develops into an oval spore. Finally, the sheath of the bacillus gives way, and the spore is set free. These spores have a thick investment, consisting of two layers. It is probably owing to this that they possess the property of retaining their vitality when dried, and also of resisting heat, chemical, and other agents to a remarkable degree.

It is because of the power of spores to resist destruction that outbreaks may occur again and again in a district which has once been infected with anthrax. Spores cannot be stained by the ordinary methods, but require special treatment, so that the dye may penetrate the tough capsule.

Bacteria, like all living structures, must be supplied with food. They require nitrogen, oxygen, carbon, water, and certain mineral salts. Access to free oxygen is necessary for some, but others can derive it from the oxidized compounds in the medium in which they grow. Nitrogen is necessary for building up the protoplasm of which bacteria consist. It can be derived from albumins or from ammonia and its derivatives. Carbon is derived from such substances as cane-sugar, milk-sugar, glycerin, and the splitting up of complex proteid bodies. Water is also essential to their growth.

In the laboratory various liquid media are employed for growing bacteria; chicken broth, beef broth, hydrocele fluid, liquid blood serum, milk, urine, decoctions of carrot, cucumber, turnip, or grape juice; or solid media, such as nutrient gelatin, nutrient agar-agar, solid blood serum, potatoes. All these media have to be rendered sterile, and precautions have to be adopted in carrying on the cultivations to prevent the access of foreign micro-organisms.

Nutrient jelly, for example, which usually consists of beef juice, salt and peptone, stiffened with gelatine or agar-agar, is prepared as follows:—First of all, the glass vessels and test-tubes employed in the process are thoroughly cleansed. Test-tubes and flasks are stoppered with a plug of cotton-wool, and then placed in the hot air chamber at 150° C. for an hour. All pre-existing micro-organisms in the cotton-wool and in the glass vessels are thus completely destroyed. In pouring the liquid jelly into the test-tubes there is danger of contamination with the germs in the air, therefore they must again be submitted to sterilization. They are placed in a

steaming apparatus for fourteen or fifteen minutes, on three or four successive days; the tubes containing the nutrient medium will then be perfectly free from any pre-existing organisms, and may be kept without change for any length of time. To inoculate the test-tubes an inoculating needle made of platinum wire fixed at the end of a glass rod is used. By holding the wire in the flame any organisms that may be upon it will be destroyed. In a few moments the wire is cool; it can then be dipped into the material to be examined. The cotton-wool plug is quickly removed from the test-tube, and by tracing the needle on the surface the bacteria are sown upon the jelly. In this way a series of cultivations of different species may be obtained.

When bacteria are grown in this way, very striking results are obtained. The bacteria may be divided into four classes, according to the effects produced on the media in which they grow. Living animals are included among these media, for inoculation affords a means of cultivating certain organisms, more particularly those which refuse to grow on any artificial nourishing soil.

The four classes are—

- The *Chromogenic*, or pigment forming;
- The *Zymogenic*, or fermentative;
- The *Saprogenic*, or putrefactive; and
- The *Pathogenic*, or those which produce disease.

The **Chromogenic** produce various colour stuffs. One of the most striking is the *Micrococcus prodigiosus*, which forms a blood-red growth in bread, potato, and other media. *Bacillus violaceus* produces a violet pigment, and *Bacillus pyocyaneus* a delicate green. The magenta micrococcus forms a brilliant magenta growth with a metallic lustre. In this species the pigment is retained within the cells. The surface of sterilized potato is a very favourable medium for the cultivation of the chromogenic groups.

The **Zymogenic** are those which produce fermentation such, for example, as the bacterium which produces acetic fermentation in wine. Owing to the growth of this organism the alcohol takes up oxygen and is converted into vinegar and water, $C^2H^6O + O^2 = C^2H^4O^2 + H^2O$. Other examples are afforded by the fermentation of urea and the conversion of sugar of milk into lactic acid.

The **Saprogenic** or putrefactive bacteria produce changes, very similar to fermentation, in complex organic sub-

stances. They are present in all putrefying substances. They abstract the elements they require for their growth, and the remainder enter into new combinations. Associated with these changes in media undergoing putrefaction, poisonous substances or *ptomaines* are produced.

The **Pathogenic** species are believed to be the active agents in producing certain diseases in man and animals, but before bacteria or other micro-organisms can be regarded as the contagia of disease they must fulfil the following conditions:—

(1) The micro-organisms or bacteria must be found in the blood, or lymph or diseased tissues of man or animal suffering from or dead of the disease.

(2) These micro-organisms must be isolated from the blood, lymph or tissues and cultivated on suitable artificial media, and these pure cultivations must be carried on through successive generations.

(3) Such pure cultivations must, when introduced into the living body, produce the disease in question.

(4) Lastly, in the inoculated animal, the same micro-organisms must again be found.

Statements that micrococci or bacteria are found in this or that disease are by themselves of little value. The bacteria must be isolated and successive cultivations carried on, and if on inoculation of a susceptible animal, the disease be produced, then and then only can they be asserted to be pathogenic. The bacillus of septicæmia in mice, for example, may be cultivated for several generations, and such a cultivation will reproduce the disease on inoculation. The tubercle bacillus may be cultivated in blood serum or glycerin-agar-agar, and a trace of such a cultivation will produce tuberculosis. And until some fallacy is pointed out in these experiments, we must accept as proven that the tubercle bacillus is the principal agent in the production of tuberculosis.

Another well-known pathogenic micro-organism is the *Bacillus anthracis*; this also may be sown in artificial media, cultivated for successive generations, and with an artificial cultivation the disease can be readily reproduced in any suitable animal. The bacillus grows readily on the potato, and the scraped-off growth may be mixed with sterilized water and silk threads impregnated into the spores. The silk threads may be kept for years, and the minutest portion introduced

under the skin of an animal will produce anthrax.

Nearly forty years ago the anthrax bacillus was discovered in the blood of animals suffering from splenic fever, but it was not until 1877 that Koch, by the methods of cultivating, clearly demonstrated that anthrax could be reproduced, not only by inoculation of blood containing the bacillus, but also by the isolated organism.

Chicken cholera and many different forms of septicæmia in rabbits and guinea-pigs are produced by bacteria. In leprosy, Asiatic cholera, relapsing fever, and in glanders, swine fever, swine measles, and other diseases in man, and in animals there are micro-organisms which are intimately related to these diseases.

In other cases, such as small-pox, scarlet fever, foot-and-mouth disease, cow-pox, sheep-pox, and pleuro-pneumonia, bacteria have been discovered and described as the contagia, but the evidence is most unsatisfactory, and in many instances entirely misleading.

There is a great fallacy in these investigations, which it is very necessary to bear in mind. In diseases in which there are lesions of the throat or intestinal canal, micro-organisms may get access to the circulation and be swept into the internal organs. The presence of these bacteria is all the more misleading in that some species, when isolated, cultivated and inoculated, may produce death in lower animals. The bacteria in such cases do not reproduce the disease from which they were isolated, but they produce symptoms which are frequently misinterpreted. If, therefore, from a disease an organism be cultivated which produces death in lower animals, the organism is not necessarily the virus of the original disease, as is proved by the fact that there are a number of organisms which can be isolated from healthy fæces, saliva, and other discharges which have this effect.

Several explanations have been suggested of the way in which bacteria produce their effects. In examining sections of tissues of animals which have died of anthrax, the small vessels and capillaries are sometimes found to be completely blocked by bacilli. Hence arises the mechanical theory; this, however, falls to the ground when it is found that far more frequently there are, comparatively speaking, very few bacilli present.

Another theory is suggested from

analogy to the putrefactive bacteria; the pathogenic bacteria being credited with the production of poisonous alkaloids or ptomaines. From the fact that bacteria are living bodies requiring nutrition, the theory has been suggested that they starve the tissues of their host. But if such were the case, death by a slow process would be expected, and it would be difficult to account for such acute symptoms as are present in anthrax.

That poisonous products are formed is very probable, but at the same time no one has satisfactorily demonstrated that these substances are elaborated by the pathogenic bacteria. Possibly the methods of detecting and isolating these poisons, are at the present time inadequate.

Protozoa.—Minute forms of animal life are found in the intestinal and other secretions, but there are others which are found occasionally in the blood of man and animals.

The peculiar bodies found in the blood in malaria are regarded as stages in the life-history of an amoeboid organism, and this constitutes the only instance of an animal micro-parasite credited with pathogenic properties. The malarial organisms or microbes of paludism were first observed by Laveran, a French physician in Algiers, who communicated his researches to the Academy of Medicine in 1881 and 1882, and published a work on this subject in 1884. Laveran described peculiar bodies, or *corps kystiques*, of two kinds, which he called Nos. 1 and 2, mobile filaments; and bodies called No. 3, or cadaveric forms.

The *corps kystiques* No. 1, or semi-lunar bodies of Laveran, are cylindrical elements with pointed extremities curved in the form of a crescent, and pigmented centrally. They are 8 to 9 μ in length, and 3 μ in width. They are transparent and colourless, and sometimes exhibit on the concave side the appearance of a very fine line uniting the extremities of the crescent, being in reality the edge of a delicate membrane.

Laveran also described oval forms which seem to be intermediate between Nos. 1 and 2. The pigment is often arranged in the form of a crown. These bodies are non-motile; several forms can be observed which vary in shape from the oval to the crescent. These forms are less numerous than the second kind, No. 2. The latter are spherical bodies in the interior of red blood cells and exhibit amoeboid move-

ments. They consist of a transparent hyaline mass enclosing pigment grains.

The mobile filaments are three or four times as long as the diameter of a red corpuscle. They are sometimes free and move about rapidly among the corpuscles, setting the latter in movement.

The observations of Laveran have been confirmed and extended by Richard, Marchiafava and Celli, Connalman and Abbot, Osler, Sternberg and Carter. Marchiafava and Celli have described more particularly a non-pigmented amoeboid form, or *plasmodium malariae*, and Golgi has described another stage, the "rosette" form.

These various forms are believed to be the different stages in the life-history of this singular organism. It has not been cultivated outside the living body. But its presence in the blood in malaria, and its disappearance after the administration of quinine, are considered as indicating a causal relation to the disease.

Flagellated protozoa have been found in the blood of equines suffering from a disease known in India as *Surra* (Evans, Crookshank). Similar, if not identical, bodies have been found infesting the blood of fish (Metrophanow), the hamster (Wittich, Koch), and rats (Lewis, Crookshank).

In stained preparations of the blood of animals suffering from *surra*, the somewhat tapering central portion or body of the parasite is continuous at one end with a whip-like lash, and at the other end terminates in an acutely pointed stiff filament, or spine-like process. By very carefully focussing the upper edge of the central portion the existence of a delicate longitudinal membrane with either a straight or undulating margin can be discovered. Owing to the somewhat curved and twisted shape of the parasite and the curling of the flagellum, it is difficult to make exact measurements, but the width varies from 1 to 2 μ , and the length of the body from 20 to 30 μ . The flagellum is about equal in length to that of the body.

Similar micro-parasites exist in the blood of common sewer-rats. These bodies are highly polymorphic. They present for the most part slightly tapering bodies which terminate at one end in a stiff, non-motile, acutely pointed flexible filament, or spine-like process, and at the opposite end are provided with a long flagellum, while, longitudinally attached, a delicate undulating fin-like membrane can be traced, which starts from the base of the posterior filament

and becomes directly continuous with the flagellum.

The monads in the rat, and the *surra* parasite are morphologically identical with each other, and both, as far as one can judge from mere description, are morphologically identical with the monad in the blood of the carp. These organisms may be conveniently termed *Trichomonas sanguinis*.

The organism in *surra* is believed by some to be pathogenic, but it has never been isolated from the blood and put to the test of inoculation. It is quite possible that the parasites in *surra* are only associated with the disease, the impoverished blood affording a suitable nidus for their development, while contaminated water may be the common source of the organism and the disease. On the other hand, the organism of the rat is found in apparently perfectly healthy, and in well-nourished animals.

EDGAR CROOKSHANK.

MICTURITION, Frequent, in the Female.—Irritability of the bladder, a common symptom in women, must be distinguished from incontinence of urine. The latter means that the urine cannot be retained, and is continually running away, a result either of a fistulous opening between the bladder and the uterus or vagina, of which injury and cancer are the common causes, or of abnormal patency of the urethra. This latter condition sometimes follows over-dilatation and laceration of the urethra. Incontinence of urine is suggested by the urinous smell of the patient's clothes, and confirmed by the fact that no urine is found in the bladder.

Irritability of the bladder implies that the patient cannot restrain herself from emptying the bladder sooner or oftener than she would like. In this case, although the patient complains that the urine runs away, some urine can be retained in the bladder.

This symptom is present in almost all diseases of the bladder and urethra (in connection with which one important fact to remember is that it may be an effect of retention), also in certain diseases of the kidney, and of the uterus or its appendages; in uterine displacements, in diabetes, and in disease of the spinal cord. It may be a reflex effect of almost any irritation of the pelvic organs. It is usually, as in the above-named conditions, a symptom to which a definite date can be assigned, but there are some women who, from infancy, have

been unable to retain the urine so long as most. Temporary frequency of micturition occurs at the menstrual period and during pregnancy, and is a frequent result of colds and coughs, and of diarrhoea.

Treatment.—The treatment will depend entirely upon the nature of the underlying cause.
G. E. HERMAN.

MIGRAINE (Megrim).—A typical attack of migraine readily admits of being roughly divided into two parts, the first consisting of the sensory phenomena and the second of the headache.

Of the former, none are so frequent or so impressive to the patient as the disorders of vision. A blurring of images on one side or the other is noticed, very much like that which is experienced after looking at the sun. It generally commences a little to the outer side of the centre of the field of vision, and spreads thence on the temporal side till it affects nearly one lateral half of the field. The outer boundary often acquires a zigzag arrangement, illuminated or not with the most gorgeous colours, and having the appearance of a rapid molecular, oscillating, or undulatory movement (teichopsia). On the inner side, however, the cloud is gradually clearing off, and thus the scotoma takes on a horse-shoe shape, with the concavity towards the centre of the field of vision. The clearing-up process continues until in from ten to twenty minutes from the commencement sight again becomes normal.

Affections of common sensation are frequent, and consist of a feeling of pins and needles or of numbness, sometimes followed by anaesthesia. They occur most frequently in one or the other arm, less often in the face, and very rarely in the leg. The affection is nearly always unilateral in the face and extremities, but bilateral when it attacks the mouth and tongue. When vision and common sensation are coincidentally affected, the hemiopic defect and numbness are on the same side.

Taste, smell, and hearing are very seldom implicated.

Aphasia is not at all uncommon, and varies from a simple difficulty in framing a clear sentence to complete loss of speech. It is usually associated with some degree of numbness, commencing as a rule in the fingers, and nearly always on the right side.

In the earlier part of the paroxysm there is sometimes a certain amount of

psychical disturbance, manifested by a confusion of intellect, temporary suspension of memory, or an unaccountable sense of fear.

Vertigo is not infrequent, and consists of the apparent revolution of surrounding objects or of the patient himself. It has been observed that a hemiplegic weakness sometimes occurs during the preliminary stage. The fact, however, that patients occasionally drop things they hold in their hands may possibly be explained by the loss of the muscular sense.

Any one or any combination of these sensory symptoms may initiate the full migrainous seizure or may exist alone, constituting a larval, or masked form of the disease. In the former case the headache supervenes in from ten to thirty minutes from the commencement of the attack, and, although it generally follows immediately after the sensory symptoms, occasionally the two appreciably overlap one another. It usually commences over an area which can be covered with the tip of the finger, and commonly radiates thence over both sides of the head, though in some cases it is distinctly one-sided. Frequently overwhelming in its intensity, and of a boring, stabbing or throbbing character; it is greatly intensified by exposure to light and noise, or by any movement.

It is generally markedly cumulative in its nature, attaining its maximum steadily or by leaps and bounds, and then gradually subsiding. During the acme of the pain, vomiting frequently occurs, in some cases inducing almost immediate relief, but in others the accompanying retching only increases the distress. The pulse rate is often reduced in the attacks, sometimes to 48-50.

Many affections of the sympathetic system have been described, but are very inconstant—*e.g.*, contraction and dilatation of arteries, retraction of eye, dilatation of pupil on the affected side, pallor and flushing of face. The duration of the seizures varies considerably in different individuals, and may be as short as two and a half hours, or as long as two and a half days. Xanthelasma palpebrarum and patches of grey hair are comparatively common in those subject to migraine.

Diagnosis.—No difficulty should arise in a fully developed case, but much care is sometimes required in differentiating some of the masked forms of the disease from dyspeptic headache, neuralgia of the fifth nerve, and even *petit mal*.

Prognosis.—No definite rules can be laid down; some cases are as easily curable as others prove intractable. Generally speaking the longer the disease has been in progress, the more severe the attacks, and the greater the number of special senses involved in the onset, the more difficult is the cure. It frequently happens in cases of gouty origin that with the first outward manifestation of gout the migraine disappears. As a rule the attacks diminish in intensity and number with increasing years, till they eventually disappear, in women about the time of the menopause.

Pathology.—It is only possible in this article to briefly notice a few of the many theories advanced. Most of them are based upon far too circumscribed a view of the disease; for instance, upon the by no means invariable presence of sympathetic symptoms no less than three theories have been constructed. One would explain the phenomena by a paresis of the sympathetic causing cerebral congestion; another, by a tetanic spasm in the territory of the cervical sympathetic, inducing exactly the opposite condition; the third ingeniously combines these two self-destructive theories and ascribes the sensory symptoms to a spasm of the cerebral vessels, and the headache to a subsequent dilatation. The fact, however, that sometimes the headache ensues before the sensory symptoms have ceased seems fatal to this hypothesis, since it would be impossible to get both constriction and dilatation at the same time. The frequency of errors of refraction and the observation that in some cases a bright light induces the paroxysm suggested the ophthalmic theory. Probably, however, the eye, though undoubtedly the most frequent, is only one of many points of departure of the disease.

Many considerations lead to the belief that migraine is a nerve-storm traversing the sensory centres and having a fundamental relationship with epilepsy, although differing so greatly in its outward manifestations. If this be so the discharging centres are probably of about the same level as those which in the motor region would give rise to epileptiform or Jacksonian convulsions.

In the present state of knowledge in regard to the position of the sensory centres, it would seem safer as yet not to attempt to localize exactly the seat of the lesion. It seems likely that there is a congenital deficiency of controlling power of one or more of the sensory

centres, and that if it be still further weakened by exhaustion or strained to the utmost by excessive stimulation or irritation of the lower centres, inhibition eventually breaks down altogether and a paroxysm occurs.

Etiology.—Heredity is the most potent predisposing cause of migraine. Sometimes it owns a gouty origin and occasionally a malarial. It is rather more common in women, and frequently commences at the age of seven or eight, seldom after thirty, but may start at any intervening age. Very often there is some defect of the visual apparatus, an error of refraction or some weakness of the internal or external recti. Mental or physical exhaustion, whatever may be its origin, is the most frequent exciting cause. Sometimes the attacks occur at the catamenial epochs, more rarely they follow upon some error of diet or exposure to a bright light.

Treatment.—This is directed towards two ends—(1) to diminish the frequency of the attacks, and if possible to prevent them altogether, and (2) to mitigate their severity.

The first indication, after treating any causal influence which may seem to be at work, is to prevent any unnecessary excitement, any over-exertion, mentally or physically, so as to procure for the patient an equable existence. The encouragement of a "healthful life, a healthful growth and healthful education" is of the very first importance in the young. In all cases the diet should be liberal, the bowels carefully regulated and moderate exercise encouraged. The most useful of the many drugs recommended are the bromides, alone or in combination with quinine, strychnine alone or combined with ergot, cannabis indica, iron, arsenic, cod-liver oil, belladonna and hyoscyamus. Occasionally iodide of potassium and chloride of ammonium are very useful. Patients having a gouty history are treated successfully with alkalies.

During the paroxysm the patient spontaneously retires to a dark room and seeks absolute quietude. If the feet be cold they should be wrapped in blankets or immersed in hot water, with some mustard added. A cup of strong tea or coffee is often now of use. In some cases antipyrine, preferably effervescent, in doses of 10 to 20 grains is able not only to diminish the severity of the attacks, but even to abort them, if given at a sufficiently early stage. Guarana and caffeine have a similar effect in some

cases, but are quite useless in others. Hydrate of chloral in doses up to 20-30 grains is frequently successful by inducing sleep.

Other less generally useful remedies are ergot, nitrite of amyl, nitro-glycerin and the constant current passed from one mastoid process to the other.

WM. GAY.

MOLLUSCUM.—This name has been given to two distinct and dissociated diseases of the skin, owing to a fancied resemblance in their lesions to some molluscs.

MOLLUSCUM CONTAGIOSUM (*Molluscum Sebaceum*; *Meliceris*; *Epithelioma Molluscum*; *Acne Varioliformis*—Bazin).—A contagious disease of the skin, characterized by the presence of tumours, generally of small size, but numerous, and presenting peculiar features, to be afterwards described.

The growths usually vary in size from a pin's head to a split pea, but sometimes attain the dimensions of a hazel-nut or even greater. They are almost always multiple, sometimes extremely numerous. They grow slowly, and may either remain discrete or coalesce to form compound tumours. At first they are sessile, rounded, firm, mortar-like, wart-like, waxy or horny. The skin over them is sometimes pinkish, but generally pearly white; afterwards it often becomes yellowish. In the centre of each tumour is a depression or umbilication, giving the characteristic "mother-of-pearl button" appearance, from which the milky-white, opaque, semi-fluid or waxy contents can be extruded by pressure. When several of these coalesce, the composite growth presents several such pit-like depressions, the larger growths generally becoming pedunculated.

The favourite seats for the disease are the face (especially the eyelids), the neck, the mammae (especially in women who are suckling), and the genitalia, but it has been known to occur on any part of the body, except on the palms and soles, and even on mucous surfaces.

The growths may remain quiescent indefinitely, it may be for months; may disappear by spontaneous involution, or may undergo chronic inflammatory induration. Most frequently, however, they suppurate, discharge, and heal; only in the latter circumstance do they give rise to any subjective symptoms beyond disfigurement. They do not necessarily leave scars.

Pathology.—Until quite lately the lesions were universally supposed to be merely enlarged sebaceous glands, a view rendered probable by their never occurring on the palms and soles, but recent researches prove almost conclusively that they arise from the cells of the *rete Malpighii*, and are continuous with that inversion of it which constitutes the outer root-sheath of the hairs. The inter-papillary processes enlarge, the papillae themselves being thereby narrowed and finally becoming mere fibrous bands. The fully developed tumour is surrounded by a firm fibrous capsule, from which septa pass inwards to the centre which corresponds to the umbilication. The lobules then formed are lined by large, columnar, epithelial cells, those of the outer layer having big oval nuclei like those of the normal mucous layer. The centre of the lobule is occupied by a whitish mass, composed of large, ovoid, opaque, or vitreous-looking cells along with egg-shaped nuclear bodies—the "molluscum corpuscles"—the result of a degenerative process. These bodies are, however, not "specific," as they are sometimes found in old comedones and in some epitheliomata, although in less abundance than in molluscum contagiosum. No specific micro-organism has yet been definitely demonstrated, nor has the immediate cause of infectivity been discovered. A recent statement that the molluscum corpuscles are psorospermia, although highly probable, has not been universally accepted, nor has it been confirmed by inoculation experiments.

Differential Diagnosis.—Early cases may be mistaken for ordinary warts or for the simple sebaceous tumours common about the scrotum and penis. Inflamed mollusca have sometimes some resemblance to chancres; confusion with molluscum fibrosum seems hardly possible.

Ætiology.—It is decidedly common in London, but rare in Scotland, and even more so on the Continent and in America. Occurring, as it does, chiefly among the children of the lower classes or in establishments where children are closely aggregated together, little doubt exists in the mind of the profession in this country that the disease is decidedly infectious, and is always communicated by actual contact with an affected person. Its frequent communication from mother to child at the breast, or *vice versa*, is another evidence of its infectiousness, but many dermatologists, especially in Germany, invoke as its sole

cause a special tendency in the cells of the mucous layer of the skin of rapidly growing children towards this peculiar form of degenerative change. Admittedly, inoculation experiments have yielded negative, or at all events ambiguous results.

Treatment.—It must always be borne in mind that the disease tends to undergo spontaneous, albeit slow, recovery. It is usually advisable, however, to expedite cure by touching the smaller mollusca with nitric acid or the acid nitrate of mercury. Pure carbolic acid is also very useful, the growths being afterwards covered with flexible collodion. The larger growths are best incised, their contents squeezed out, and the interior lightly cauterized. J. J. PRINGLE.

MOLLUSCUM FIBROSUM (M. Simplex, M. Pendulum, Fibroma, F. Molluscum) designates a rather rare congenital disease in which tumours, usually multiple, grow from the subcutaneous tissue and lower layers of the true skin. Occasionally the condition is hereditary and present in more than one member of the same family. In a certain proportion of cases it is associated with defective mental development. The growths are usually numerous, sometimes innumerable, their favourite sites being the trunk, head, face, and neck. They are seldom present on the limbs, and, if present, are never numerous. They have been known to occur in the mouth, especially on the cheeks and gums.

They vary in size from that of a small pea to a walnut or even a hen's egg, while many of them, especially in early life, are quite subcutaneous, and their presence can only be ascertained by touch. They increase slowly and progressively with age, and, although their existence at birth is indubitable, they are often not noticed before the age of five or even ten years.

The growths present an infinite variety of character; some, as already mentioned, are subcutaneous, others are sessile with a broad base, others distinctly pedunculated, others pendulous; some are tough and elastic, others soft and flabby; some become mere pouches of loose skin, owing to the atrophy of their contents. The skin over them is generally normal in colour, but occasionally pinkish from excessive vascularity. In exceptional cases there is diffuse pigmentary change over the skin; sometimes, but more rarely, multiple neuro-fibromata have been asso-

ciated with the condition. The tumours are painless, and cause no subjective symptoms beyond a sense of strangeness and disfigurement. They do not inflame or undergo malignant degenerative changes unless irritated, and that only very rarely.

Pathologically speaking, the growths consist of all the constituent elements of the skin and subcutaneous tissue (fibrous tissue, fat, vessels) in very varying proportions. The connective tissue in the centre is always softer and more gelatinous than at the periphery, where its condensation results in the formation of a distinct capsule, so that, if the skin be incised, the little tumour can be shelled out. There is no special connection with the peripheral nerves.

Dermatolysis.—This condition is only an exaggerated form of the preceding, where large flaps or folds of hypertrophied skin are present, their commonest sites being the neck, face, buttocks and chest. Their appearance is often ascribed to an injury or to a fright to the mother during pregnancy. The skin composing these hideous excrescences is often deeply pigmented, thickened, indurated and warty; hypertrophy of the bones or other subjacent tissues is also occasionally present, as in the case of the well-known "Elephant Man." Troublesome dermatitis beginning as intertrigo is apt to arise in these folds of skin, especially if careful cleansing of the parts be not habitually carried out.

Diagnosis.—Fibromata may be mistaken for fatty tumours, fibro-neuromata, multiple sebaceous cysts, molluscum contagiosum, or for keloids, especially their subcutaneous form. Dermatolytic growths must not be confounded with elephantoid conditions.

Treatment.—The small withered growths may be snipped off, the larger ones excised. If the lesions are few in number, small, and subcutaneous, their destruction by electrolysis has been recommended. Ablation of even enormous dermatolyses has been successfully practised. J. J. PRINGLE.

MONOMANIA.—This term has been employed in many senses, and it would be well to abolish its use in scientific nomenclature. It does not indicate a distinct disease, and generally leaves out of sight the fundamental condition. It may possibly be useful to retain the term to express the existence of either a fixed delusion, or a set of delusions of the same general character, but such cases

fall naturally under the head of chronic delusional insanity, which includes both maniacal and melancholic conditions, and to which the reader is referred for a full description.

The fixed delusions just mentioned fall under three chief heads, (1) of imaginary greatness, (2) of secret agencies and persecution, (3) of suspicion. It is generally held that monomania implies the power of reasoning upon topics other than the subject of delusions, but this is a familiar feature in many cases which have nothing else in common with monomania.

GEORGE REVINGTON.

MORPHINOMANIA.—A craving for morphine induced by its habitual use.

The habitual use of morphine, in draught or subcutaneous injection, or in one of the patent medicines containing the drug, is generally found to have commenced (in this country at least) under medical advice, for the relief of pain or sleeplessness, and to have been incautiously allowed to continue. Occasionally it has been resorted to as a solace in mental trouble. In Paris it is said to be frequently employed from the outset as a pure luxury. After some weeks or months or years, during which increasing tolerance of the drug has generally demanded augmented doses, the effects of morphine become very marked. They consist in mental depression, lassitude, restlessness, and a vague sense of discomfort. They are relieved only by renewed administration of the drug, which, as the after-effects grow more and more distressing, gradually becomes an imperious necessity. At first, honest efforts are made to break off the habit; but before long the urgent craving gains an easy victory over an enfeebled brain. The moral tone becomes seriously relaxed, the will is paralysed, and no consideration of truth, honour or duty is allowed to obstruct the overpowering desire to obtain and ingest the coveted poison.

The confirmed morphine-taker becomes pale, sallow, emaciated and prematurely old. His normal condition, when not under the direct influence of morphine, is one of dejection, feebleness and want of interest in life. He is constantly restless, can seldom remain long in one position, and changes his attitudes with sudden jerks or starts. He is liable to fits of tears and to outbursts of violent rage. He suffers from palpitation and tinnitus. His appetite is small

and his digestion painful and imperfect. The bowels are usually loose. He sleeps badly, and is troubled with distressing dreams. Fits of sweating often occur. Untruthfulness and untrustworthiness are painfully obvious, even when the possession of morphine is not concerned. The sexual powers are diminished or absent. The pupils are usually dilated. The pulse is weak and thready.

If the habit be not discontinued, progressive weakness and emaciation end in death from asthenia or from some intercurrent inflammation, as lobular pneumonia. Sometimes the condition merges into genuine insanity.

As to the duration of such a case, it is impossible to frame any general statement. Much depends on the quantities taken.

Treatment.—This consists essentially in the total discontinuance of the drug, but it is seldom that it can be accomplished unless the patient can be subjected to external control. His sufferings on first omitting the accustomed dose are very severe. In addition to restlessness, sleeplessness and mental depression, he experiences a sense of "sinking" at the epigastrium, nausea and, at times, persistent vomiting; and hyperæsthesiæ of various kinds add to his troubles. After a few days the severity of the symptoms usually abates somewhat, and in a few weeks the condition may become tolerable with ordinary resolution.

As a rule, it is best to discontinue the drug at once and wholly, but in some cases a gradual reduction of the dose is found desirable. It is chiefly a matter of mental or moral idiosyncrasy on the part of the patient, and it is impossible to formulate any rule on this point. The closest watching is needed to ensure genuine discontinuance, the cunning of these patients and their capacity for deception being almost incredible.

Drug-treatment may be of some service. Strychnine and caffeine are useful in combating the mental depression and the anorexia. Both must be used in fairly full doses, 5 minims of the liq. strychninæ and 4 or 5 grains of caffeine being given every six hours. The addition of from 5 to 10 minims, or more, of tincture of capsicum and the use of camphor water as a vehicle may tend to relieve the "sinking." Vomiting is best checked by stimulating applications (mustard plasters, turpentine stupes, &c.) to the epigastrium. A warm bath will sometimes benefit the restlessness.

It may be necessary to procure sleep at night by some drug other than morphine, and for this purpose one should be selected which is not likely to establish another "habit" in place of the morphine taking. From 15 to 20 grains of sulphonal cautiously increased may (*at present*) be employed; but most benefit is obtained from hyoscyamus, alone or in combination with cannabis indica. These drugs may be given in the form of pills made of their extracts, or as a mixture into which their tinctures enter. The hyoscyamus should be prescribed in full doses—8 grains of the extract or a drachm of the tincture; the Indian hemp, which is an uncertain drug, in guarded doses at first $\frac{1}{2}$ grain of the extract or 15 minims of the tincture. Bromides are not often of real service, and alcohol is best avoided altogether. Digitalis may be required if the heart's action be feeble. A brisk dose of calomel is advisable at the outset, even when diarrhoea is present. Should the bowels continue loose, chalk or astringents must be resorted to, with warm applications to the abdomen. Food must be pressed as the capacity for taking it returns.

ISAMBARD OWEN.

MUMPS (Idiopathic Parotitis).—An acute infectious disease characterized by swelling of the parotid and salivary glands, running a definite course, and terminating in recovery.

Symptoms.—The period of invasion is short, usually less than twenty-four hours, and is marked by some discomfort in the region of the parotid gland, especially on moving the jaw, also by a rise of temperature, lassitude, headache, and anorexia.

Sometimes there are no premonitory symptoms, and at others the disease is heralded in an alarming manner by vomiting, diarrhoea, and convulsions.

The first symptom is a stitch-like and increasing pain in the region of one parotid (generally the left) spreading to the jaw, and aggravated by any movement as in talking, &c. Soon a swelling appears, at first in the hollow between the mastoid process and the jaw, but rapidly spreading on to the face in the masseter region; the swelling is wedge-shaped, the apex being downwards. Then the neighbouring tissues, if not from the first involved, become infiltrated, causing a rapid extension of the swelling in the neck, both downwards and towards the spine, to which in severe cases it may reach. The overlying skin is tense and

shiny, it is occasionally reddened, and sometimes pits on pressure. The swelling continues to increase for about three days, it remains stationary for about two days, and then rapidly subsides, completely disappearing in the course of about five days. The submaxillary gland and the tissues in its immediate neighbourhood may be affected in an exactly similar manner.

In rare instances the disease is confined to one side, but much more frequently the other parotid becomes affected within two days, and in very rare instances both sides are attacked at once. So long as one side only is involved the head is inclined to that side, afterwards it is held stiffly erect. The movements of the face are in abeyance, owing to the pain in the jaws, and it is consequently expressionless, whilst the swelling in the parotid and submaxillary regions gives the patient a grotesque and most unnatural aspect. The mouth is either closed or permits of such very slight opening that the patient is reduced to liquid food, and even this causes much pain. Other symptoms usually present are thirst, anorexia, and constipation. The temperature seldom rises above 104° F. The pulse is frequent and the tongue furred. The saliva is not, as a rule, altered either in quantity or character, but owing to the difficulty in swallowing, it accumulates in the mouth and dribbles away, giving rise to the mistaken belief that the secretion is excessive. The general symptoms abate in severity as the swelling subsides.

The most common complication is the so-called metastasis, to the testes in the male, or to the ovaries (?) or mammae in the female. This is most common in those who are attacked about the period of puberty, and is more often observed in males than females. Some six or eight days after the commencement of the illness swelling of the body of one testis appears, and fluid collects in the tunica vaginalis. In the course of a day or so the other testicle is similarly affected, but it is rare for both to be simultaneously attacked. The swelling is accompanied by great pain and tenderness, and some oedema of the scrotum is often present. The course of this affection is precisely similar to that of the parotid, and there is a separate recurrence of fever and febrile symptoms. Atrophy of the testicle has been known to follow, but such an event is rare.

Rheumatic symptoms with heart lesions have been observed, and in very

rare cases meningitis has supervened, as also disease of the spinal cord. Deafness is a complication to be feared, though when it is due to an extension of the inflammatory process from the pharynx (for in a few cases the pharynx and tonsils are affected), along the Eustachian tube it usually passes off in a few days; but when it begins suddenly without any such cause, it is generally permanent; in a few cases it has been due to suppuration taking place in the parotid. and the subsequent bursting of the abscess into the auditory passages. Facial paralysis has been occasionally observed.

As a rule recovery is complete, though a good deal of general debility may be left, and in scrofulous children enlargement of the lymphatic glands is often set up.

The *diagnosis* can only be doubtful when the second side is not yet affected, and the swelling does not obviously extend on to the jaw.

Pathology.—The first change is hyperæmia of the gland with an exudation of serous fluid, the parotid is swollen, reddened, and on section is of a uniform fleshy aspect. There is a good deal of serous infiltration of the surrounding tissues, and it is believed that sometimes the gland itself may be unaffected. It is probably not the result of the extension of a specified catarrh along the duct of the parotid, otherwise in affections of the mouth inflammation of the parotid would be more common.

Ætiology.—The disease is hardly known in infants, and is decidedly rare in early childhood, being most common between the ages of five and fifteen, but it is seen in adults, though not in old people. A second attack is almost unknown. It is more common in males than in females, and is said to be most prevalent in the spring. Epidemics are apt to occur either directly before, or during, or directly after, outbreaks of measles, and to a less extent of scarlet fever and diphtheria. The children of the poor do not seem to be so susceptible to it as those of the well-to-do. The period of incubation is from two to three weeks or even longer, during which time there are no symptoms. The disease is probably most contagious at first, but it is believed that a person is not free from infection for a month from the onset. Of the nature of the contagium nothing is known; it is supposed to be conveyed by the breath.

Treatment.—In many cases it will not be necessary to do more than keep the

patient in a warm even temperature, on such light diet as can be swallowed, with an occasional saline purgative. When the swelling is great, warm fomentations with or without opium, water dressings or light poultices may be used. Iced drinks and drop doses of tincture of aconite every hour are useful. Sleeplessness may be overcome by bromide of potassium. The orchitis should be treated by supporting the testicles and applying warm anodyne lotions. During convalescence tonics and cod-liver oil may be given with great benefit.

JOHN ABERCROMBIE.

MUSHROOMS, Poisoning by.—Various species of these fungi possess poisonous properties, but the one which in this country most commonly gives rise to urgent symptoms is the *amanita muscaria* or fly-fungus, the active principle of which is *muscarine*.

Symptoms.—The effect of the poison is exerted chiefly upon the gastro-intestinal and nervous systems. Colic, nausea, vomiting and diarrhœa follow a few hours after the ingestion of the poisonous fungi. Excitement and delirium, ending in a condition of stupor and coma, are the prominent nerve symptoms.

In severe cases the symptoms somewhat resemble the algide stage of cholera, collapse, cyanosis and muscular contractions preceding a fatal termination.

Morbid Anatomy.—The chief signs are those of a very acute gastro-enteric catarrh. Portions of the fungi may be found adherent to the mucous membrane of the stomach and intestine.

Prognosis.—Severe diarrhœa, with rice-watery stools and violent delirium, are very unfavourable symptoms.

Treatment.—The stomach should be washed out immediately with a syphon tube, or an emetic of sulphate of zinc (gr. xx in water), or mustard (ʒss in water) may be administered. Atropine, the physiological antagonist of muscarine, should be given at once, either in the form of the tincture of belladonna (℥xx in water), or 2 drops of an injectio atropinæ hypodermica (gr. $\frac{1}{10}$), to be repeated in half an hour if necessary. The best purgative is castor-oil, of which an ounce should be given as soon as possible.

If there be much depression stimulants will be needed, brandy, ether and ammonia being the most suitable. The patient should be kept warm, and should

remain in bed for some days after the urgent symptoms have disappeared, owing to the liability to cardiac paralysis.

MYELITIS, ACUTE.—A term applied to any inflammatory affection of the spinal cord of rapid onset.

Such a condition may be primary or secondary. The symptoms vary according to the amount of the cord affected and the position of the lesion.

Symptoms.—In primary or idiopathic acute transverse myelitis there is rapid paraplegia, motion and sensation becoming profoundly affected in a few hours, or sometimes in a few days. The initial spinal symptoms are often accompanied, and sometimes preceded for a short period, by fever and general malaise. Pain in the back and limbs, unlike what occurs in spinal meningitis, is frequently absent, and if present, slight and transitory. Spasms and twitchings of the muscles, moreover, are of comparative rarity in the early stage of myelitis.

Numbness, tingling and such-like sensory disorders commonly attack the limbs, and then ensue, after a varying interval, loss of motor power and sensibility in the extremities.

The paralytic symptoms in acute myelitis do not supervene so suddenly as in spinal hæmorrhage. In the former the onset may extend over a period varying from a few hours to several days, whereas in the latter the onset is quite sudden.

In exceptional cases the commencement of acute myelitis is comparatively abrupt, and it occasionally happens during the course of the disease and when the symptoms have attained a high degree of intensity that a sudden exacerbation takes place. In such cases it is highly probable that spinal hæmorrhage has occurred secondarily. When the symptoms of acute myelitis have reached their height, there is, more or less, complete paralysis with anæsthesia of the affected limbs.

Control over the sphincters is usually lost from the first. The urine frequently becomes ammoniacal at an early period, and cystitis is common. Bed sores over the sacrum and other parts subjected to pressure often occur with great rapidity and in spite of all precautions. The temperature of the paralyzed muscles is usually slightly raised in the early stage, but subsequently it falls a degree or two below the normal.

Since the lower part of the spinal cord is the most frequent seat of myelitis, it

follows that the lower limbs only are affected in the majority of cases.

If the cervical region be involved, the arms suffer as well as the legs, and, if the disease be above the origin of the phrenic, paralysis of the diaphragm will occur.

When the disease is above the lumbar enlargement, the muscles of the lower limbs are at first flabby, but later on they recover tone, and still later they may become the seat of spasm from descending degeneration of the pyramidal tracts.

When the lumbar and sacral regions are involved, the muscles of the legs remain flabby, waste, and exhibit the reaction of degeneration.

Sensation is sometimes lessened, sometimes absolutely lost. Just above the upper limit of the anæsthesia there is frequently a zone of hyperæsthesia, or a feeling of constriction—the so-called “girdle pain.” A hot sponge passed down the spine will usually detect the hyperæsthetic point by the feeling of pain caused. The hyperæsthetic line is often situated about the level of the epigastrium, but, whatever its position, it indicates the upper limit of the lesion in the cord.

The condition of the reflexes depends on the vertical extent of the spinal lesion. When the mischief is in the dorsal region, the reflexes of the lower limbs may be temporarily abolished by shock. Later on, reflex action returns, and exaggeration occurs if descending changes take place. When the lumbar and sacral regions are implicated, the superficial and deep reflexes are permanently annihilated. The condition of the cremasteric, abdominal and the various trunk cutaneous reflexes give valuable aid in determining the vertical extent and the upper limit of the spinal lesion.

The pupils are occasionally affected when the cervical region is involved. In a few instances optic neuritis has been described, and in most of such cases the myelitis has been of the disseminated form.

The *course* of acute myelitis is variable. In the severe cases death frequently ensues from respiratory disorders, or from pyæmia following on bed sores, or from the extension upwards of inflammation from the bladder to the kidneys. In other cases sensation returns almost in its entirety, the motor power being regained later on, though often imperfectly.

Muscular spasm, as has already been

pointed out, may occur when the mischief is above the lumbar enlargement. Under such circumstances a state of spastic paraplegia may slowly supervene, the lower limbs being sometimes in extension, sometimes in flexion. The latter condition unfortunately renders the upright posture and walking impossible, and hence the patient is permanently bedridden.

Sometimes very great improvement, occasionally amounting to a practical recovery, takes place in acute myelitis, and it is well to bear in mind that a favourable change may occur, even when paralysis has been present to a marked degree for many months.

Myelitis of traumatic origin, that due to slow compression by growth, caries or other agents, and that which results secondarily in spinal meningitis do not call for special notice here (*see SPINAL CORD, SLOW COMPRESSION OF*).

Varieties.—The foregoing description does not apply to all cases of acute inflammation of the spinal cord. In some instances the disease may consist of a single limited patch of inflammation (*focal myelitis*) or the foci may be multiple and scattered (*disseminated myelitis*). Under such conditions the symptoms may be of limited extent, or, on the other hand, irregular in distribution. Many cases of infantile paralysis are, doubtless, instances of focal myelitis involving the anterior grey matter (acute anterior polio-myelitis).

Diagnosis.—The points which serve to distinguish most cases of myelitis from spinal hæmorrhage have already received attention. Granted the diagnosis of acute myelitis, it is then necessary to decide whether it is primary or secondary. Caries and malignant growths of the vertebræ will sooner or later make themselves manifest by their characteristic signs, although not uncommonly all indications of their existence are absent at the onset of the spinal mischief.

Pain of any severity and persistency suggests myelitis by compression, meningitis or meningeal hæmorrhage (*see SPINAL CORD, HÆMORRHAGE INTO*).

Acute ascending paralysis (Landry's paralysis) resembles closely an acute ascending myelitis. In the former, however, sensation is unimpaired and the muscles preserve their electrical excitability.

Prognosis.—A guarded opinion should always be given in the early stage, inasmuch as extension of the lesion upwards

may take place. When this occurs, danger to life from paralysis of the intercostal muscles or of the diaphragm is possible. The acute formation of bed sores, or the rapid onset of cystitis, which occur mainly when the diseases affect the lumbar and sacral regions, are grave indications, though not necessarily leading to a fatal result.

When the lesion is limited to the dorsal part of the cord, the patient often becomes the subject of spastic paraplegia, and if the lower limbs be in extension, the power of walking may be regained. An early return of sensation is a favourable symptom, fair motor power often subsequently being acquired in such cases.

Morbid Anatomy.—In the acute stage, the pia mater is injected and the affected part of the cord swollen and softened. On section, the distinction between grey and white matter is lost or ill-defined, and the tissue is often diffuent and of a red or reddish-brown colour. This is sometimes termed the stage of "red softening," and when the extravasation of blood is considerable the affection has received the name of "hæmorrhagic myelitis." The changes which the effused blood undergoes, and the fatty degeneration which attacks the damaged nerve-elements, lead, in course of time, to alterations in colour of the affected part of the cord (yellow and white softening). Still later, the cord assumes a greyish tint, becomes atrophied, and finally cicatrices may form and occasionally cavities. In chronic cases, moreover, sclerosis of the various spinal tracts supervenes.

On microscopical examination the capillaries and small arteries and veins are distended with blood. The walls of the vessels are thickened by cells, and the peri-vascular sheaths filled with leucocytes. In the grey matter the ganglion cells are first swollen, granular, and cloudy, the nucleus and nucleolus being in process of division or sometimes vacuolated. The cell-processes, at first swollen and irregular, finally shrivel and disappear. In the terminal stage the cells are represented by small, irregular, structureless masses, or may disappear altogether.

In the white matter the nerve-fibres become irregular, the medullary sheath showing granular and fatty degeneration. The axis-cylinders are commonly granular and enlarged, exhibiting in their course irregular swellings. The fibres frequently undergo atrophy, the axis

cylinders however persisting for a long period.

In transverse sections of the cord clear spaces may often be seen, formed by the removal of degenerated nerve-fibres. The neuroglia becomes swollen and amorphous in aspect, except for scattered nuclei. The cells of Deiters and their processes undergo marked enlargement. After the lapse of time the affected area may become fibrous, but numerous nuclei and the cells of Deiters, together with dilated and thickened vessels, are visible for a considerable time. The spinal nerve-roots and the peripheral nerves show degenerative changes.

Ætiology.—Males are more frequently affected than females, and the disease is most common between the ages of ten and forty. Prolonged exposure to wet and cold, especially to both combined, and over-exertion, are frequent exciting causes. Myelitis is often dependent on injury to the cord, such as concussion or fracture-dislocation of the vertebrae. The disease sometimes follows variola, measles, typhus and other acute specific fevers. Syphilis and alcohol have a possible share in the production of myelitis. Compression of the cord by growths involving either the membranes or substance of the cord, spinal caries, malignant affections of the vertebrae and spinal meningitis not unfrequently give rise to secondary inflammation of the spinal cord. Lastly, it may be mentioned that in many cases of acute myelitis no cause can be determined. It has been suggested that occasionally an infective agency may be at work, and this idea is borne out by the appearance of thrombi and micrococci in the small vessels, described by some observers.

Treatment.—In the early stage absolute rest should be enforced, the prone position being strongly advised by some authorities. Dry or wet cupping, the choice to be determined by the general condition of the patient, and stimulating applications to the spine, may be employed. Strong counter-irritants, such as blisters and the actual cautery, should be employed with extreme caution. The danger of the formation of obstinate sores from such remedies must be remembered. Chapman's ice-bag to the spine is sometimes of service. It is of the utmost importance to guard against the formation of bed sores, and with this object in view the most scrupulous cleanliness should be enforced. Parts exposed to pressure should be sponged with spirit and then carefully dried and dusted.

The effects of pressure may be considerably obviated by the use of cotton wool. When there is incontinence of urine the tendency to bed sores is increased. Absorbent cotton wool, frequently renewed, may be used. If there be retention the regular use of the catheter is required. The instrument should be absolutely clean, and just before use should be cleansed with carbolic solution and then lubricated with carbolic oil. If cystitis occur the bladder must be washed out with an antiseptic solution.

Bed sores demand constant attention, and the slightest appearance of redness must be anxiously watched. The application of fine oakum over the dressing is often of great use in obviating the factor of bed sores.

The influence of drugs in myelitis is doubtful. Ergot and belladonna are recommended in the early stages. Mercury and iodide of potassium seem to be of little avail, even in cases in which there is a probable syphilitic origin. In the later stages of myelitis, preparations of iron, quinine, arsenic and strychnia may be employed. Rubbing and the use of electricity are of service when the acute period is over. W. B. HADDEN.

MYXŒDEMA (Adult Sporadic Cretinism, Cachexia Pachydermique of Charcot). *History.*—This disease was first described by Sir William Gull in 1873, in a paper entitled "On a Cretinoid State supervening in Adult Life in Women" (*Clin. Soc. Trans.* vol. vii.) The name "Myxœdema" (mucus, œdema) was suggested by Dr. Ord, on the ground that a mucin-yielding œdema was the chief observable condition (*Med. Chir. Trans.* vol. lxi.). In 1883, Kocher of Berne called attention to a series of symptoms which he had observed to follow total extirpation of the goitrous thyroid gland in man. This morbid state, to which he applied the term "cachexia strumipriva" was shortly afterwards discussed by J. L. Reverdin, who then directed attention to the resemblance between this condition and myxœdema. These communications were brought before the Clinical Society in 1883, by Dr. Felix Semon. A committee of investigation was subsequently nominated by the Society and a report on the subject of myxœdema and its associated conditions was issued in 1888 (*Clin. Soc. Trans.* "Report on Myxœdema," supplement to vol. xxi.). The description of the disease here given is based on this report.

Definition.—Clinically, myxœdema is characterized by a peculiar physiognomy, by an increase in the bulk of the body, by nutritive changes in the skin and elsewhere, and by slowness and imperfection of both bodily and mental processes. The only constant pathological condition is destructive change of the thyroid body.

Symptoms.—The physiognomy is characteristic and has been variously described as cretinoid, mask-like, placid, heavy. The features are broad, puffy and coarse, the nostrils swollen, the lower lip thickened, everted and livid, the mouth widened transversely. Over the cheeks and nostrils there is a well-defined red patch, contrasting in a marked degree with a pale, wax-like orbital area. The body is bulky and unwieldy, and the skin everywhere dry, scaly and thickened. Moles and warty growths are very frequent. There is almost invariably an absence of perspiration and of sebaceous secretion. Localized tumefactions, dependent probably on the accumulation of fat, are often present, the usual site being the supraclavicular regions. The hands are broad, swollen, and clumsy-looking, and the nails not uncommonly stunted and brittle. The feet are affected like the hands. The hair of the scalp is dry, ragged and broken. Sometimes there is marked baldness. The eyebrows, eyelashes, and the hair on the pubes and in the armpits suffer in the same manner. The teeth often become brittle or undergo caries, the gums being spongy and swollen. The tongue is usually enlarged, and the uvula and soft palate swollen. The thyroid gland, as shown after death, is almost always diminished in size; sometimes this can be ascertained during life, though very often this point cannot be satisfactorily determined in consequence of the fulness of the neck, so common in myxœdema. Changes in the character of the speech are well-nigh constant, the utterance being slow, monotonous, thick and guttural, as though the tongue were too large for the mouth. In almost all cases there is marked intellectual torpor, the patient being sluggish, placid and indifferent. A tendency to undue persistence in thought and action has been described by Dr. Ord. Occasional attacks of irritability or fretfulness may occur; and in nearly one-half the cases absolute insanity has been noted, chiefly in the advanced stages of the disease. Memory is usually impaired from an early period, especially

for recent events. Somnolence during the day is frequent, and sleep at night is often disturbed by unpleasant dreams. The only disorder of sensation which occurs with any marked frequency is retardation. With respect to this point, it must be remembered that these patients are dull of perception, and hence this form of sensory disorder must probably be looked upon as part of the general intellectual hebetude. The special senses often suffer. Deafness to a varying degree occurs in about one-half the cases. As regards sight, the most common defect is general diminution of acuteness of vision. Excessive watering of the eyes has been sometimes observed. Exophthalmos has occurred in the early stages in a few instances, and as an equally rare condition cataract may be mentioned. Subjective sensations, referable to both common and special sensation, are common. Among the less frequent symptoms may be noted, occipital headache, convulsions, and agoraphobia. The bodily movements are performed slowly, though usually without imperfection. Falls leading to injuries such as fracture of the patella, sometimes occur, and there is not unfrequently some degree of inco-ordination. The ordinary duties of life, such as dressing, are not only performed with great deliberation, but entail an amount of lassitude quite out of proportion to the muscular effort put forth. The muscles of the neck are often enfeebled, so that the head falls forward, the chin resting on the sternum, as in cretins. The gait is slow, ponderous, and elephantine. The reflexes, superficial and deep, are usually normal; sometimes they are diminished or delayed, in exceptional instances absent. Occasionally they have been described as brisk or exaggerated. Sensations of cold are practically constant, and this is not merely subjective. The temperature, especially when the average is taken over a long period, is almost invariably sub-normal. A temperature four or five degrees below the normal standard, persisting for weeks, is frequent. As regards the urine, it may be noted that the specific gravity is often sub-normal, that albuminuria in the later stages may be present as an accidental condition, and that the amount of urea is probably always diminished, sometimes the excretion falling to a half or even less of the average quantity. Glycosuria occurs as a rare condition. No characteristic changes are present in the blood, though rarely there is diminution

in the red corpuscles or the hæmoglobin. The heart is usually normal; accentuation and reduplication of the sounds have been occasionally noted. The pulse is weak, soft, and slow; in only exceptional cases is excessive tension present. Respiratory troubles sometimes occur, in some instances being the immediate cause of death. The appetite is generally much impaired. As a rule the bowels are constipated, but occasional watery purging is not uncommon. True dropsy sometimes supervenes, though usually it is slight and limited to the feet and ankles; in rare cases ascites to a marked degree has occurred. The onset of œdema or effusion has been observed to coincide with an amelioration in the general condition. Irregularities of menstruation are frequent, sometimes the flow being scanty, sometimes profuse. An early disappearance of the catamenia has been recorded in some cases. Uterine hæmorrhage, either subsequent to parturition, or more often occurring independently, is not uncommon. It may be observed here that myxœdema is no bar to pregnancy. Even in the advanced stages gestation may take place and go on to the full period. Hæmorrhages from the nose, gums, teeth and bowels, as well as from the uterus, have been frequently recorded.

Death usually results from intercurrent maladies, such as bronchitis, phthisis or pneumonia. In a certain number it is the direct result of the disease, mental disorder supervening, with subsequent coma.

Diagnosis.—The facies is so characteristic, that, once seen, no difficulty in diagnosis will henceforth present itself when the disease is in the fully developed stage. The peculiar physiognomy of myxœdema was in the past mistaken for that of chronic renal disease, and even now the two conditions are occasionally confounded. The points of divergence are so numerous and striking that it would be superfluous to enumerate them. In the initial period of the disease it is a matter of considerable difficulty to pronounce a positive diagnosis. Indeed, in the writer's experience, it is often impossible to do so. It may be mentioned, however, that fugitive œdema, especially when affecting the face, ought to excite the suspicion of early myxœdema. In a doubtful case it is only by a comprehensive survey of all the symptoms that an opinion of any kind can be formed.

Occasionally the embarrassment of speech is so obtrusive that the possibility

of bulbar paralysis has been entertained. An instance of this recently occurred in the experience of the writer. The affection known as "Acromegaly" (*q.v.*), has many important features in common with myxœdema. It will be sufficient, however, to mention that in the former there is great enlargement of the hands and feet, without any increase in the general bulk of the body, that the skin presents none of the alterations seen in myxœdema, that the hair is normal, and that bodily and mental torpor are not present, except perhaps in the terminal stage. In acromegaly the cartilages of the nose, eyelids and ears become hypertrophied, but the characteristic cretin-like aspect is wanting. Lastly, certain of the bones become enlarged in acromegaly, and this is especially striking in the lower jaw. Other points of difference will be obvious on referring to the article on acromegaly.

Prognosis.—The disease is chronic, and the tendency is usually from bad to worse. Periods of temporary improvement occur, sometimes unconnected with treatment; in a few instances marked amelioration has taken place during or after pregnancy. There is little doubt that judicious treatment is of the greatest service. The duration of life is doubtful, but it is certain that existence may be prolonged for twenty years or more after the disease has attained its fully developed state.

Morbid Anatomy and Pathology.—The disease is essentially an affection of the thyroid gland, which to the naked eye after death is small, pale or yellowish white, firm and fibrous-looking. Microscopical examination shows in the early stage a small-celled infiltration of the walls of the vesicles with epithelial proliferation in the vesicles themselves. Later the gland becomes converted into delicate fibrous tissue, in which are seen clumps of small round cells, clearly the remnants of vesicles. Finally, the gland structure is replaced by fibrous tissue, in which small islets of round cells are sparsely placed. Death occasionally ensues before the anatomical change reaches the advanced stage, and sometimes before the entire gland becomes invaded. Alterations in other organs and tissues occur, but they appear to have no causal relation with the disease. In the skin there is very frequently nuclear hyperplasia and the development of connective tissue, mainly in the neighbourhood of the sudoriparous and sebaceous glands and around the hair follicles, anatomical changes which explain

some of the conditions already described in the clinical account. Occasionally there is to be seen an unusual interval between the bundles of fibrous tissue in the corium, and this open-textured appearance has been found in the lower eyelid. In the Clinical Society's Report no opinion is offered by the sub-committee as to the significance of this condition. Dr. Ord, however, is of opinion that the spaces described probably contained mucin. Interstitial change does not occur in the organs as a generalized condition, though occasionally it is present to a varying extent in the sympathetic, kidneys, liver, heart, and submaxillary gland. As regards macroscopic appearances, it may be mentioned that the subcutaneous fat, as well as the fat elsewhere, is abundant, that at the time of death anasarca and serous effusions are frequent, that the kidneys often exhibit more or less interstitial change, that the left ventricle of the heart is hypertrophied in those cases in which the kidneys are markedly affected, and that some degree of degeneration of the larger arteries is common. In exceptional cases tubercular disease of organs and cirrhosis of the liver have been found.

Pathology.—It is well-nigh certain that myxœdema is identical in essential points with cretinism, both endemic and sporadic, as well as with cachexia strumipriva. All these conditions are dependent on loss of function of the thyroid body, whether that loss be due to destructive change occurring sporadically in adult life from causes yet unknown, to congenital absence, or to early developmental arrest, or to total extirpation of the gland by the surgeon. Certain clinical differences exist between myxœdema and cretinism, but such points of divergence are related to the period of life at which the disease begins. The arrest of growth and general development found in cretins does not occur in adult sporadic cretinism or myxœdema because in the latter the disease supervenes at a time when the organism has already attained full development; in short, it is a question of decay, not of arrest. Mr. Horsley's experiments on animals, particularly on monkeys, have shown that symptoms of cretinism follow complete removal of the thyroid gland. Furthermore, it has often happened that extirpation of the goitrous thyroid gland in man has given rise to symptoms identical with those of myxœdema. It may be mentioned here

that in some instances no indications of cretinism have followed supposed complete removal in man, and that in others the symptoms of cachexia strumipriva have occurred after partial removal. The immunity in the first case is probably due to the presence of accessory thyroid glands and their subsequent compensatory hypertrophy, or to the fact that the removal has really been incomplete, or, lastly, to insufficiently long observation after the operation. As regards the second apparent fallacy, it is probable that the part of the gland left behind was functionally inactive in consequence of structural change. (For full information on this point see "Report on Myxœdema," section vi, by Dr. Semon.) The origin of the term "myxœdema" has already been explained. The careful analyses of Dr. Halliburton show that the increase of mucin described in Dr. Ord's first case has not been found in anything like the amount in subsequent cases. Various causes no doubt would account for this fact, but it is sufficient here to say that an increase in mucin is not constant at all stages of the disease. The term myxœdema has now passed into common parlance; nevertheless it is imperative to bear in mind the intimate relations which this disease has to cretinism and cachexia strumipriva.

The cause of the destructive change in the thyroid gland in myxœdema is quite unknown. The exact physiological function of the gland, moreover, has not yet been determined. That it regulates nutrition in some manner is undoubted. It would appear that in myxœdema the normal destruction of the tissues and their consequent removal, which is essential for the maintenance of health, is much diminished. The lowered temperature and the diminished excretion of urea point to this, and it is instructive to note in this respect that many of the most salient features, such as the bodily and mental torpor, may be explained on the assumption that the normal metabolic processes are partially arrested.

Ætiology.—It is curious that those districts in Great Britain in which goitre is endemic, and others in which cretinism is known to occur, do not supply cases of myxœdema in a disproportionate amount. It should be mentioned, however, that Dr. Morvan has reported eleven cases of myxœdema occurring in Lower Brittany. Professor Kocher, of Berne, has informed the writer that he has neither seen nor heard of any instance of ordinary myxœdema, or adult sporadic cretinism in

Switzerland. Nothing of a decisive character has been ascertained with respect to causation. The disease is much commoner in women than in men, the proportion being as six to one. The onset may occur at any period between early adolescence and extreme old age, but the majority of cases arise between thirty and sixty-five. Syphilis, alcoholic excess, and social condition have no influence. The disease has, in a few instances, attacked members of the same family, and rarely it has been transmitted to the offspring. Among possible predisposing causes may be mentioned tubercle, neuroses of various kinds, mental disturbance, acute rheumatism, prolonged lactation, pregnancy, catamenial irregularities, and hæmorrhages.

Treatment.—In many instances periods of marked improvement have been noted, and in one case an actual recovery is alleged to have taken place. The natural

conditions under which these favourable remissions occur are but little understood. The influence of warmth is particularly striking. The bodily heat should be promoted by suitable clothing, by friction of the body, and by massage. Turkish or hot air baths may be employed. If possible, the patient should be removed during the winter to a warm climate. Of all drugs jaborandi is the most useful; it may be given in doses of 30 minims of the tincture, increased gradually to a drachm, three times in the day. Pilocarpine has a similar beneficial action, and may be used subcutaneously. Nitro-glycerine, which has been employed in a limited number of cases with good result, deserves a more extended trial. Iron, quinine, strychnine, nux vomica, arsenic, iodide of potassium, mercury, cod-liver oil, and many other remedies have been employed, the majority with doubtful effect.

W. B. HADDEN.

N

NASAL POLYPI.—Tumours, usually of a soft, jelly-like character, growing in the nasal passages.

Symptoms.—These may be divided into local and general. A sense of fulness and stuffiness in the nostrils, with difficulty in breathing through the nose, in some cases passing on to complete obstruction, a constant secretion from the nostrils, partial or complete loss of the sense of smell, and frequently more or less deafness, are the chief local symptoms. Among the general or remote symptoms must first of all be enumerated asthma, which, as Voltolini was the first to point out, may owe its origin to the existence of nasal polypi. Even when not directly due to polypi, asthma is always aggravated by their presence. Cough, hay-fever, epilepsy, giddiness, nightmare, &c., have been met with in patients suffering from polypi, and have disappeared after the removal of these growths.

Polypi may frequently be recognized without instrumental aid, as they sometimes even protrude from the nostrils. The most convenient method of examining the nostril is by means of Duplay's bivalve speculum. Polypi almost invariably take their origin from the middle or superior turbinated bodies, or from the outer wall in the middle meatus, occasionally from the inferior turbinated

body, but hardly ever from the septum. They are usually of a pinkish or pearly-grey colour, round or pear-shaped, unless distorted by pressure, and of a gelatinous consistence. They are almost always multiple and frequently occur on both sides.

Diagnosis.—Hypertrophy of the inferior turbinated body is sometimes mistaken for a polypus; the situation, firm consistence and red colour should suffice to prevent the mistake. Erectile swelling of the anterior end of this body may also be confounded with a polypus. The effect of cocaine in causing a disappearance of this swelling will suffice for the diagnosis. A deviated septum might also give occasion to error. Malignant growths in the nose are generally more firmly attached than polypi, are harder, more painful, and bleed freely.

Prognosis.—Polypi, though not dangerous to life, are exceedingly troublesome to eradicate. In a case now under the care of the writer the history shows the condition to have been present for thirty years. The mucous membrane is now of a myxomatous character throughout, so that it is only possible to prevent the formation of fresh polypi by using the galvano-caustic loop every four or five months.

Morbid Anatomy.—Mucous polypi belong to the myxomata, consisting of a

loose form of connective tissue, the meshes of which are filled with stellate cells and with a mucin-yielding substance.

The papillomata are another form of nasal polypi; these almost invariably spring from the inferior turbinated body.

Nasal polypi generally occur at the middle period of life, and are very rarely met with before the age of sixteen. The writer has met with a case in a girl of fifteen. Mackenzie's youngest case was sixteen years old.

Treatment.—The rough-and-ready mode of removal of polypi by forcible avulsion by means of forceps is now becoming a thing of the past, and the question at present is as to the employment of the galvano-caustic loop as opposed to the loop of cold wire. To a large extent this is determined by individual custom; the cold snare requires less apparatus, but then the tug requisite to remove the polyp is a somewhat painful procedure. The writer has from the first employed the galvano-caustic loop, and he has been so satisfied with it that he has not been tempted to try other methods. The application of a 20-per-cent. solution of cocaine by spray or brush much facilitates the operation, by causing contraction of the mucous membrane and by rendering it anæsthetic. But when the polypi have been removed, whatever process be employed, there still remains the difficult task of preventing their recurrence. The most convenient plan is to burn down the pedicle by means of the galvano-cautery, cocaine having been previously employed to render the part anæsthetic, or caustics such as chromic acid in the form of crystals, or the 90-per-cent. solution of carbolic acid, may be applied to the base of the polyp, but in the case of multiple sessile growths the tendency to recurrence is so great that the utmost patience and perseverance are required in order to attain the desired end.

F. DE HAVILLAND HALL.

NEURALGIA.—Much difference of opinion has existed in regard to the limitation of the term neuralgia. Derivatively meaning nerve-pain, it has been applied to all disorders in which pain referred to the peripheral nerves has been a prominent symptom. Thus it used to include migraine, which, indeed, in many of its characters bears a strong likeness to neuralgia, but differs so much in others that it is now generally regarded as a substantive affection. Scia-

tica is still regarded by some as essentially neuralgic in character, but for reasons stated in the article upon that subject it is probable that most instances of that disease are really due to a perineuritis, and should be so considered. The application of the term neuralgia would in this way be restricted to cases of functional nerve-pain, which, however, may originate in irritation of the sensory nerve terminations. Such a definition would exclude all cases of peripheral neuritis, whether idiopathic or depending upon injury to the nerve by wounds, or the presence of a tumour, &c., but, on the other hand, would include those instances in which nerve pain is reflected to a nerve-tract from peripheral irritation.

Symptoms.—The onset may be sudden, but more generally the patient becomes aware of certain anomalous sensations in the course of some nerve—e.g., tingling, numbness, and pins and needles, the meaning of which he soon learns to appreciate. Actual pain is soon experienced, and this is paroxysmal and spontaneous or excited by movement, so that the mere act of eating may cause the greatest discomfort. It is variously described as lightning-like, stabbing, boring, darting, or burning, and is generally confined to the distribution of one nerve, but in severe cases radiates into other surrounding nerve regions.

The pain is nearly always unilateral, and even when symmetrical it is usually much more intense on one side than on the other. Symmetry has been supposed to be the characteristic of diabetic neuralgia, but it is certainly present in other cases. In some subjects the pain is invariably referred to one nerve, which seems particularly vulnerable, but in others it is migratory, attacking first one nerve-tract and then another. The skin in the affected region is often hyperæsthetic, so that very slight influences excite pain or exaggerate the neuralgic paroxysms. Tender points, the *points douloureux* of Valleix, are in about half the number of cases to be found in the course of the nerve. They are very circumscribed, and correspond, as a rule, to the place where the nerve pierces a fascia to become superficial or emerges from a bony canal. Certain definite tender points are therefore to be found in the course of most superficial nerves, and will be noticed hereafter when the general distribution of neuralgia is considered. Trousseau has described a tenderness over the spinous process corre-

sponding to the origin of the painful nerve, but it is not constant and may occur under other conditions.

Vaso-motor disturbances are common, and usually lead at first to constriction of vessels, causing pallor, and subsequently to their dilatation and blushing, which may be accompanied with an increased secretion of sweat. If long continued, the congestion of the tissues leads to tumefaction and hypertrophy, changes which are sometimes associated with an erythematous condition simulating erysipelas.

When the pain is very severe, reflex spasm may be induced in the related muscles, and is especially liable to occur in those of the upper lip and nose.

The pain in an ordinary neuralgic attack is not constant, but subject to remissions and exacerbations of indefinite duration. The symptoms gradually decline, leaving a feeling of bruising and soreness, and may not recur for months or years until revived by some debilitating influence. On the other hand, the attacks may be extremely frequent, and become more aggravated as they increase in number. Distinct periodicity is sometimes observed in cases other than those of malarial origin.

According to the situation of the neuralgia, two great classes are formed, the superficial and the visceral.

I. SUPERFICIAL NEURALGIAS.—This is further subdivided into groups, depending upon the area affected.

Neuralgia of the Fifth Nerve (*Tic Douloureux; Prosopalgia*).—This is by far the most frequent situation for neuralgia, which usually affects one or possibly two of the main divisions of the nerve, but very rarely all three at the same time. In severe cases the pain may radiate from one division to another, and even into other nerve tracts.

The *symptoms* are those of neuralgia generally, but vary to a certain extent according to the branch affected. The vaso-motor and trophic disturbances already described are here most common, and spasmodic movements of the face are frequent in a variety of neuralgia, which has been called "epileptiform tic." This occurs in the degenerative period of life, and especially in those who have a very decided family history of insanity. It is characterized by the suddenness and intensity of the pain and its resistance to all forms of treatment, so that it generally persists for the remainder of the patient's life, which it renders almost unbearable.

Neuralgia of the Ophthalmic Division is generally referred to the supra-orbital branch, and has been called "brow ague," on account of its once frequent dependence upon malaria. Tender points may be found in some of the following situations:—A little above the supra-orbital notch, in the upper eyelid, at the junction of the nasal bone with the cartilage (long nasal branch), at some indefinite point within the orbit, and at the inner angle of the orbit (trochlear branch). The spontaneous pain is frequently very severe and exaggerated by the least muscular exertion of the neighbouring parts, so that the act of chewing, sneezing, coughing, or blowing the nose is attended with the greatest distress. The skin is often hyperalgesic, and the patient becomes unable to bear the simple pressure of his hat. Congestion of the conjunctiva, photophobia, and lachrymation not infrequently occur, and much more rarely blepharo-spasm and transient paralysis of the third nerve. Intense pain in the eye or at the back of the eyeball may be experienced alone, or in conjunction with neuralgia of the parts around. When alone, it is usually binocular and dependent to a certain extent upon some error of refraction, and especially hypermetropia. When forming part of a wide-spread neuralgia, it is, as a rule, monocular, and is sometimes associated with amblyopia and constriction of the field of vision. The paroxysms of migraine are often accompanied with a neuralgic condition of this division of the trigeminal nerve.

Neuralgia of the Superior Maxillary Division.—This nerve is much less frequently the seat of pain, which tends to be more concentrated and fixed in one of its branches than in the case of the ophthalmic division. The foci may be found where the infra-orbital nerve emerges from its canal, on the malar bone, at some indefinite point in the gum of the upper jaw, and rarely in the palate or upper lip. The paroxysms of pain are sometimes accompanied with an increased secretion from the mucous membrane of the nose and from the parotid gland.

Neuralgia of the Inferior Maxillary Division generally extends over a considerable area, and painful points may be found in the course of the auriculo-temporal nerve, a little in front of the ear, at the site of emergence of the inferior dental nerve, and rarely at the side of the tongue or lower lip. Another tender point may be present a little above

the parietal eminence, where an inosculation of various branches takes place; this and the supra-orbital are by far the most frequent foci in trigeminal neuralgia. Auditory hyperæsthesia may occur when the ear is involved in the pain.

Cervico-occipital Neuralgia occurs in the area supplied by the posterior branches of the first four spinal nerves, and of these the great occipital (arising from the second) is most frequently affected. Foci may be found on any of the branches of the cervical plexus, but are most commonly situated a little above the parietal eminence and midway between the mastoid process and the spine. The pain is often bilateral, and may radiate over the back of the neck and scalp, which it renders extremely sensitive to pressure, into the territory of the fifth nerve. It is often due to exposure to cold.

Cervico-Brachial Neuralgia.—The nerves here implicated are the posterior branches of the four lower cervical nerves and those of the brachial plexus. Tender points may be looked for in the axilla, at the inferior angle of the scapula, at the posterior border of the deltoid, in the bend of the elbow, on the outer side of the upper arm about three inches above the elbow, at the "funny bone," where the ulnar nerve passes in front of the wrist, or where the radial nerve becomes superficial on the lower and outer part of the forearm. The most common situations are the axilla, shoulder, and in the course of the ulnar nerve. In these cases the pain is usually paroxysmal and spontaneous, but is greatly intensified by muscular movements.

The most frequent causes are rheumatism and nerve injuries, which are capable of producing a true neuralgia, independently of setting up a neuritis. Dental caries has been supposed the cause in some instances.

Dorso-intercostal Neuralgia affects the intercostal nerves from the third to the ninth, and especially the seventh, eighth, and ninth. Painful points are generally to be found at the intervertebral foramen near the middle line anteriorly, and midway between these two situations. The pain is generally constant, but liable to exacerbations, which may be induced by respiratory and other movements. It is frequently associated with herpes zoster. Infra-mammary pain, particularly on the left side, is of common occurrence in anemic women, and in those who have become ex-

hausted by over-lactation or menorrhagia.

Dorso-lumbar Neuralgia is less common and the symptoms are more vague, although they bear a certain general resemblance to those of the intercostal variety. The principal foci are at the intervertebral foramina, near the middle of the crista ili, in the hypogastric region, in the groin near the emergence of the spermatic cord, and in the scrotum or labium majus. This form of neuralgia is sometimes secondary to pelvic disease. Crural and obturator neuralgias, in which pain is referred to the front and inner side of the thigh respectively, are very rarely met with.

Neuralgia of the Sciatic Nerve is probably rather rare compared with peri-neuritis of that nerve; both conditions are included under the common term, sciatica (*g.v.*). The points of greatest tenderness are found a little above the sacrum near the spine, where the sciatic nerve emerges from the pelvis, at various points along the posterior aspect of the thigh, behind the head of the fibula, and on the outer and inner sides of the ankle. The neuralgic pains in these cases are referred rather to the distribution of the nerve than to it; main trunk, and there is often a history of neuralgia in other situations.

Coccydynia.—This is a term which is used to designate pain in the region of the coccyx. It occurs especially in women, and in some instances probably depends upon neuralgia of the coccygeal plexus. Pain is most commonly excited by a long-continued sitting posture and by defecation. It frequently proves very intractable.

II. VISCERAL NEURALGIA.—This is of much less frequent occurrence than the superficial variety, but is generally of greater importance on account of the difficulty frequently experienced in diagnosing it from grave organic affections.

Cardiac Neuralgia.—Pain referred to the region of the heart is often of neuralgic origin. It is sometimes the result of abuse of tobacco, and the infra-mammary pain complained of by chlorotic girls has already been noticed. Paroxysms of deep-seated neuralgic pain are sometimes accompanied by symptoms closely simulating those of angina pectoris. The diagnosis then becomes one of extreme difficulty, and is complicated by the differences of opinion, which exist in regard to the nature of angina and the cases, which should pro-

perly be included under that head. Some indeed regard it as essentially a neuralgia, but this is probably erroneous, though it is extremely likely that some cases of so-called angina are really examples of neuralgia (*see* ANGINA PECTORIS; HEART, NEUROSES OF).

Gastralgia is one of the most definite examples of visceral neuralgia. The pain may be dull, long-continued, and liable to exacerbations, or acute and lancinating. It is referred to the region of the stomach, generally darts through to the back, and may be relieved or accentuated by the taking of food. The appetite may be lost or rendered capricious during the attacks; vomiting sometimes occurs, and constipation is the rule. Such cases are occasionally closely simulated by neuralgia of one of the intercostal nerves.

Other organs are sometimes the seat of neuralgic pains, *e.g.*, the intestines, liver, kidneys, ureters, ovaries, uterus, and testicles. The all-important symptom in these cases is deep-seated pain, which is dull, heavy and constant, or acute and paroxysmal. It is unaccompanied with any evidence of organic change, but is sometimes associated with functional disorders. There is very often a history of superficial neuralgia, and the same causes contribute towards the development of both. Among women, who are the most liable to visceral neuralgias, the most important predisposing factors are hysteria and *anæmia*.

Diagnosis.—Many cases of neuralgia present no difficulty whatever. The pain is unilateral, restricted to a certain nerve-tract, paroxysmal or constant, and subject to exacerbations; there is a history of preceding attacks, and no evidence of neuritis. Such symptoms occurring in the region of the fifth nerve are almost certainly due to neuralgia; but it should not be forgotten that pain in the same region is sometimes the result of organic intra-cranial disease, which, however, usually gives rise to other symptoms, such as headache, vomiting, optic neuritis, and convulsions.

Great difficulty may be experienced in diagnosing neuralgia of the extremities from peripheral neuritis in an early stage, especially if the affected nerve, or nerves, be deeply seated and out of reach. The occurrence at a later period of patches of *anæsthesia*, wasting of muscles with the reaction of degeneration, and of swelling and tenderness of the nerve trunk when accessible, leaves no doubt that the case is one of peripheral neuritis.

The lightning pains of *tabes dorsalis* may possibly be mistaken for neuralgia. They are, however, more fugitive and migratory, and although one of the earliest symptoms, are generally associated with some other evidence of the disease, *e.g.*, the loss of the pupillary reflex, and the absence of the knee jerks.

The pain of myalgia may be distinguished by its occurring only on movement.

When the nerves of the extremities are invaded by a growth, persistent and severe pain is experienced, combined with other symptoms, sensory and motor, pointing to structural changes in their trunks. In this case, the diagnosis from neuralgia is not therefore generally difficult; but when the same condition is present in the thorax or abdomen, the diagnosis is often one of extreme uncertainty. Thus aneurysm of the descending part of the aorta may give rise to no other symptom but pain, which is generally unilateral and persistent; but in most cases some other evidence of the nature of the disease is forthcoming. Tumours of the cord, pachymeningitis and cancer of the bodies of the vertebrae may cause pain in the course of nerve-trunks; but other symptoms of these affections are generally present, pointing to the presence of organic disease.

The diagnosis of visceral neuralgia is not one to be lightly arrived at, and can only be positively made after a most careful examination has precluded the possibility of an organic lesion.

Prognosis.—This is favourable when the patient is comparatively young, has no marked neurotic predisposition, suffers from some constitutional condition which can be remedied or removed, and when the neuralgia has resulted from some over-fatigue or exhaustion, which can be prevented in the future. The slighter forms of the disease are the most amenable to treatment. When revived, or occurring for the first time during the degenerative period of life, neuralgia is apt to prove very intractable, and may resist every form of treatment. It does not tend to shorten the duration of life.

Pathology.—This has been the subject of much debate and difference of opinion. Where is the seat of the neuralgic pains? Is it in the peripheral nerve terminations, the conducting fibres, or in the ganglionic cells of the posterior roots, or in those of the central nervous system? It is impossible to discuss this much vexed question within the limits of this

article. Suffice it to say that many considerations point strongly to its central origin, and that this view is now held by many eminent authorities.

The immediate cause of the affection is probably an instability of the central ganglionic representation of certain sensory nerve-tracts, and this may depend upon an abnormal degree of irritability of the affected centres, or upon a deficiency of their inhibition. It is possible that these centres discharge spontaneously; but it seems likely that they are also excited to action by afferent stimuli from the periphery, many of which are so slight as in no way to affect consciousness.

Ætiology.—Neuralgia is often hereditary, and very frequently there is a general neurotic predisposition, a family history of insanity, epilepsy, chorea or some other neurosis. The affection is very rare up to the time of puberty, but afterwards the tendency to it rapidly increases and it becomes very common during early adult and middle life. It is frequently developed or revived at the time of the menopause and occurs with great intensity in the early period of degeneration, when the arteries are commencing to be atheromatous. After sixty its frequency diminishes. As a rule women are more frequently attacked than men. Among predisposed subjects no cause is so powerful in producing an attack as a debilitated condition, whether it result from anæmia, over-lactation, menorrhagia, sexual excess, mental or physical over-work, worry, or from any other cause. In many such patients the slightest deviation from their normal standard of health is marked by the occurrence of neuralgia. It may also arise from alcoholism, lithæmia and lead poisoning, but in all these cases it is necessary to exclude the presence of peripheral neuritis before making a positive diagnosis. Malaria is a potent cause of neuralgia, though an infrequent one in this country. Tobacco-smoking sometimes excites an attack in people who are very susceptible to its influence. The disease is often reflex in origin and dependent upon an irritation of the sensory terminations, frequently of some other nerve; the most common illustration of this is neuralgia of some branch of the fifth nerve excited by dental caries, but the same result may ensue from such a remote cause as injury to the ulnar nerve. Herpes zoster is, except in the young, usually accompanied by neuralgia in the immediate neighbourhood of the

eruption, and this may anticipate the development of the rash by a few days. The pain is often very severe and in the old may prove very intractable and persistent. Among other occasional causes may be mentioned rheumatism, rheumatoid arthritis, hysteria, nerve traumatism and probably secondary syphilis. Of the direct exciting causes, none are so powerful as exposure to cold.

Treatment.—The indications for treatment are (1) the removal of the cause and (2) the relief of the pain.

Little need be said about the former of these beyond insisting upon the importance of the recognition and removal or treatment of the causal influence. The diet should generally be liberal, containing a fair proportion of fat, and a small amount of alcohol at mealtimes is often distinctly beneficial. Complete mental rest is necessary, especially in those whose neuralgia depends upon overwork or worry. Fresh air and moderate exercise should also be indulged in. Carious teeth should be looked for and extracted, particularly in cases of neuralgia of the fifth nerve. Rheumatism, gout, malaria and syphilis must each be treated with appropriate drugs. Iron, to which cod-liver oil may be added, is valuable not only in anæmic states, but even when there is no evidence of a deficiency of hæmoglobin. Arsenic is useful when the neuralgia is due to malaria or a cachectic condition, and also in cases of pain referred to the heart. The liquor sodæ arseniatis, in doses of ℥iij-℥viii, is often better tolerated than Fowler's solution. Quinine is most efficacious in malarial neuralgia, and should be given, in a full dose of gr. v-xx, a little before the time of the expected attack. In smaller doses of gr. ij-ijj it is sometimes beneficial in other cases, particularly when the pain is in the region of the ophthalmic division of the fifth. Nux vomica or liquor strychninæ is a valuable adjunct in many cases of neuralgia. Phosphorus has been highly recommended, and its administration is sometimes attended with marked success. It is best prescribed in capsules, or combined with cod-liver oil in the proportion of gr. j to ʒjss, of which ʒj is taken every four hours. Stimulants are often serviceable in relieving the pain, and of these the chief is alcohol. It is a dangerous remedy to prescribe, and should only be recommended when the patient seems possessed of sufficient self-control to resist taking it to excess. It must be given medicinally, in fixed quantities,

to be taken only at mealtimes. Other stimulants recommended are sulphuric ether and valerian.

For the relief of the pain, no drug is so potent as opium or morphine. Great care must be exercised in their administration, lest the opium habit be developed. Morphine is best given hypodermically, but in no case should the patient be trusted with the performance of the operation. Very small doses (gr. $\frac{1}{10}$ – $\frac{1}{8}$) have frequently the desired effect, and should be raised very gradually when necessary. Given in this way, morphine sometimes not only relieves the pain, but ultimately cures the neuralgia. Belladonna is of most value in the treatment of pelvic neuralgia, and may be given by the mouth in doses of gr. $\frac{1}{8}$ – $\frac{1}{2}$ of the extract. The hypodermic injection of atropine (gr. $\frac{1}{120}$ – $\frac{1}{60}$) is more powerful, and is advantageously combined with morphine in some cases. Cannabis indica, in doses of gr. $\frac{1}{4}$ –1 of the extract, is often beneficial in the slighter forms of the disease, and sometimes also relieves the pain of severe cases. The injection of gr. $\frac{1}{2}$ –1 of cocaine is often attended with good results.

Among other drugs recommended are gelseminum (℥xv of the tincture, frequently repeated), butyl chloral (in doses of gr. v–x or even gr. xx), and aconite (℥v–x of the tincture) in cases of trigeminal neuralgia; muriate of ammonia (gr. x–xx) in intercostal and hepatic neuralgias; bromide of potassium, in 5ss doses, when there is great restlessness and irritability and antipyrine.

Local applications are often of service in relieving neuralgic pain. One of the most successful of these is counter-irritation, which is generally applied by means of flying blisters, about the size of a florin, over the painful points or by the side of the spine.

Electricity proves very beneficial in the treatment of some cases, and the continuous current is that most generally useful. It is intended only to act as a sedative, and therefore the current should only be sufficiently strong to cause a tingling and burning sensation. Sponges moistened with warm salt water should be used as electrodes, and placed in such a manner as to bring the affected nerve within the circuit. The direction of the current may be neglected. One of the sponges should be applied successively to the different painful points, but should not be raised from the skin until the strength of the current has been lowered to zero. Each application should

last about ten minutes, and may be frequently repeated when relief is afforded. A strong current of faradism or voltaism is sometimes employed as a counter-irritant.

Other local applications are the liniments of aconite, belladonna and chloroform, singly or combined; menthol, which may be used alone or mixed with equal parts of chloral hydrate and camphor; the oleates of morphine and atropine, and the ointments of aconitine and veratrine. All these are at times of value in relieving the pain, but often prove quite useless. In a certain number of cases medicinal measures entirely fail, and the propriety of surgical interference has to be considered.

The operations of nerve-stretching and excision of a portion of the affected nerve are sometimes attended with relief, which, however, occasionally proves but temporary. Meckel's ganglion has been removed with good result in some cases of neuralgia of the second division of the fifth nerve.

WM. GAY.

NEURASTHENIA. — Literally, a loss of strength in the nervous system.

This term is now very generally employed to designate a morbid condition of the nervous system, which may manifest itself by a great variety of symptoms.

Its use has been objected to on the ground that it implies a theory, viz., that the underlying condition is one of exhaustion or asthenia, whereas, for aught that is certainly known, it may be one of excessive action or defective inhibition. Whilst admitting the objection, it may be urged that if the action be excessive it is certainly not healthy, and that, if by exhaustion or asthenia only "loss of tone" is implied, there is not much danger that such a theory will be disproved as knowledge advances.

Perhaps the best equivalent in our own language for "neurasthenia" is "nervous break-down."

The various symptoms which constitute this morbid condition have been long known and accurately described, but attention has of late been specially drawn to the subject by the marked success which has attended the adoption of a certain method of treatment, first advocated by Dr. Weir Mitchell, of Philadelphia, and generally known by his name—success which has been especially noticeable from the fact that hitherto such cases had been a veritable reproach to medicine, owing to their absolutely intractable character.

Those who have had most practical experience in dealing with these cases are disposed to restrict the terms "neurasthenia" and "neurasthenic," to a condition which is for the most part characterized by a clinical history somewhat of the following character :—

The patient is usually a woman, but the condition has been met with in men. The family history is generally "neurotic," and the history of the patient previous to the onset of the symptoms is not uncommonly marked by the occurrence of various neurotic manifestations. Then an event commonly happens—it may be an illness of a definite kind (not infrequently it is some uterine affection), or a disappointment, a fright, dyspeptic troubles, or some cause of pain—which forms the starting-point for a prolonged period of ill-health, during which the original affection is quite overshadowed by the appearance of a great variety of pure neuroses. The patient becomes, as time goes on, more and more a chronic invalid, passing most of her time in bed or on a sofa, and either remaining indoors for years or perhaps going out occasionally in a bath-chair. Dyspeptic troubles often predominate, and there may be complete loss of appetite and a professed inability to take more than a ridiculously small quantity of food, attended, as such a condition must necessarily be, by extreme emaciation and anaemia. Pain or sleeplessness usually leads sooner or later to a resort to chloral or morphine, to which drugs many of these patients become absolute slaves. There is generally a marked craving for sympathy and desire to attract attention, whilst emotional and hysterical manifestations are very common.

It is not unusual to find that such cases have been seen by nearly all the leading physicians in some particular line of practice, which will vary with the organ which appears to be specially at fault, and that little or no benefit has followed the adoption of many different plans of treatment.

In another class of case there is, instead of emaciation, an excessive formation of subcutaneous fat combined with anaemia, the mental condition being very similar to that above described.

The following description of a case under the care of Dr. Lauder Brunton and Dr. William Playfair will, perhaps, convey more clearly an idea of the class first described :—

The patient was a man thirty-three years of age, considerably over 6 feet

in height, and once very strong and muscular. His illness commenced at the age of twenty-seven, when much exposed on a ranche in America. The following is his own account of its onset and course :—"About five or six years ago I began to suffer greatly from indigestion, which reduced my strength very much, and brought on a very severe pain in the right side of the stomach, from back to front, which all the doctors seemed to agree to be neuralgia. I have the pain daily, almost hourly, and it amounts to intolerable agony. I suddenly collapsed about a year ago, and was in bed most of last year. I have now got into a regular weak state, get very bad nights' rest, can take next to no food, and very often bring up what I do take. I am simply devoid of muscle, and am nothing but skin and bone. I weighed the other day 8 stone 5 lb. pounds; I consider my proper weight to be 12 stone 10 lb."

At Dr. Brunton's request, Dr. William Playfair, who has had large experience of the treatment by Weir Mitchell's method of similar cases in women, took charge of this patient.

In eight weeks his cure was complete. In Dr. Brunton's words,* "His muscles, which had almost entirely disappeared, have not only become of a normal size, but they are as hard as pieces of wood, and from being a simple skeleton he is now a well-developed man." Photographs taken before the commencement of treatment and after it was finished show in the most striking and remarkable way the astonishing results attained. This patient, when last heard of, remained in good health.

Treatment.—As already stated, the only mode of treatment of these cases which has been attended by success is that devised by Dr. Weir Mitchell, which will be found described in detail under the heading of *MASSAGE (INCLUDING THE WEIR MITCHELL TREATMENT)*.

In the cases marked by anaemia and an excessive formation of fat, a preliminary period of semi-starvation is recommended before the usual treatment by excessive feeding is begun.

J. K. FOWLER.

NEURASTHENIA SPINALIS.

—Weakness or exhaustion of the spinal nervous system. A functional neurosis of the spinal nervous system, first described under the above name by Drs. Beard and Rockwell in 1871.

* "Disorders of Digestion," p. 79.

The condition is most commonly met with in youths and adults between the ages of twenty and thirty years, and is chiefly characterized by sensations of numbness and formication, with muscular fatigue and weakness. The subjects of the affection usually believe themselves to be suffering from some organic disease of the spinal cord. Sensations of stiffness, weariness and pain are commonly complained of, and the condition is not unfrequently associated with hypochondriasis and insomnia.

Various causes of the affection have been assigned, including all those commonly credited with producing the various neuroses, such as overstrain and sexual excesses. Erb considers that the spinal centres are in a state of exhaustion.

The condition may last for a considerable period—as long as two years; but it is doubtful whether it ever passes on to organic disease.

Treatment.—Every endeavour should be made to discover the underlying cause of the affection. Massage and electrical treatment are likely to afford relief.

NEURITIS (Peripheral Neuritis; Multiple Peripheral Neuritis).—An inflammation of a nerve.

Neuritis, to which the word peripheral is generally, though somewhat unnecessarily, prefixed, may result from poisoning by alcohol, lead, arsenic, and bisulphide of carbon. It may occur as a sequel to typhoid and typhus fevers, variola, dengue and intermittent fever, and perhaps plays a part in the causation of diphtheritic paralysis. It is sometimes due to syphilis, diabetes and tabes dorsalis, and is probably an essential factor in anæsthetic leprosy and beri-beri. Now and then cases are met with which seem to be due to over-fatigue, exposure to damp and cold, or no cause may be discoverable; all such cases are termed idiopathic.

Symptoms.—Sometimes a single nerve is picked out, but more commonly the affection is a widespread one, and several nerves of both upper and lower extremities are symmetrically attacked.

The onset of multiple peripheral neuritis is generally rather rapid, sometimes apparently sudden, though, on inquiry, one can generally elicit a history of pins and needles, shooting pains, numbness or tingling of the legs and arms, dating from some weeks or months previously. In those rare cases in which one is able to follow the case from its

commencement, the temperature may be found raised, even to 103° or 104.5° F., but it soon declines to normal. The pulse is usually accelerated and rarely under 120, though in one case described it was only 48. The complaint is usually of paralysis, which is, as a rule, symmetrical, spreading from the periphery towards the trunk and falling with much greater severity upon the extensors than the flexors. Hence it is that one of the earliest, and at the same time one of the most characteristic, of the symptoms is dropping of the hands and feet. The latter gives to the gait a high-stepping character, because the patient has great trouble in clearing the ground with his toes, which he endeavours to overcome by increasing the flexion of the thigh on the abdomen and of the leg on the thigh.

At a later stage the dorsum of the foot lies almost in a straight line with the front of the leg; the toes are flexed, and the great toe is curved downwards and tucked under the second toe. Adaptive shortening of the flexor muscles and formation of adhesions between the tendons and their sheaths may now give rise to deformities—*e.g.*, talipes equinus or equino-varus, contractures of the wrists, fingers and toes.

But meanwhile the paralysis, again attacking the extensors the more severely, has spread and affected the muscles of the thigh and upper arm, so that the patient lies in bed with his thigh flexed on his abdomen, the leg on the thigh, and the forearm on the upper arm. If, further, the muscles of the trunk and diaphragm be attacked, a fatal result generally ensues. The facial muscles are very rarely paralysed, but the ocular not infrequently, especially the external recti.

There is rapid wasting of the muscles, and their faradic excitability is either lost or diminished. The galvanic formula may be retained, but diminished and with slow contractions; or more usually the reaction of degeneration is obtained. The mechanical excitability of the muscles is sometimes normal or even exaggerated, but in the later stages is probably always lost.

Muscular spasms and tremors are extremely rare, but have been described. Occasionally there is loss of muscular sense, and in such cases the gait becomes ataxic, and much unsteadiness results from closing the eyes and putting the feet together.

The knee-jerks are absent as a rule, but in some few cases have been retained and in fewer still exaggerated. The

plantar reflex is generally diminished, delayed or gone; the cremasteric and abdominal, normal or diminished. The organic reflexes of the bladder and rectum are rarely affected, except as the result of great mental hebetude.

Various paræsthesiæ are complained of, and lancinating pains may give rise to much suffering. Hyperæsthesia of the skin is not uncommon, but gives place ultimately to anæsthesia. A hyperæsthetic condition of the muscles, so that a slight pinch causes intense pain, is a very important and extremely common symptom of alcoholic paralysis. The transmission of pain, temperature and tactile sensations is diminished. Very often the nerve trunks are found to be considerably thickened and tender to the touch, and, when the arms are affected, a painful spot may be sometimes found a little internal to the upper angle of the scapula.

Vaso-motor and trophic disorders are common, and include redness and œdema of the hands and feet, local or general perspirations, glossy skin, papulous, herpetic and bullous eruptions, perforating ulcers of the feet, affections of nails, and sometimes local asphyxia and even gangrene. Most important of all in this respect is the fact that bed-sores are extremely rare. Many affections of the eye have been described, but only two, inequality of pupils and weakness of the external recti, are at all common. The rest, nystagmus, dilatation of pupils, amblyopia, central scotoma, contraction of the field of vision, optic neuritis and atrophy, are more or less rare.

Some mental symptoms are present in most cases of alcoholic paralysis. They include insomnia, loss of memory (especially for recent events), want of power of attention and concentration, and emotional disturbances. Sometimes there is active delirium, with illusions and hallucinations, and occasionally delusions, which are narrated with much circumstantial detail and appearance of truth.

Such are the general symptoms of multiple peripheral neuritis, but considerable variety of grouping obtains according to their causation. In alcoholic paralysis the chief features are the mental symptoms, the muscular hyperæsthesia and the greater incidence of the paralysis upon the lower extremities. In lead paralysis the forearms are first and chiefly affected, the supinator longus escapes, and sensory symptoms are conspicuous by their absence. In some

cases of alcoholic and arsenical origin, ataxic symptoms predominate over the paralytic, and tabes dorsalis is closely simulated.

Diagnosis.—Multiple peripheral neuritis may be diagnosed from polio-myelitis by the presence of marked sensory phenomena, the proneness of the extensors to be first and chiefly affected, and by the grouping of the muscular lesions, which correspond roughly with the distribution of certain nerves, and not with the arrangement of the functionally related centres in the spinal cord.

Multiple peripheral neuritis differs from tabes dorsalis in that there is no Argyll Robertson pupil phenomenon and no affection of the bladder, but, on the other hand, there is generally a paralysis with the reaction of degeneration, and the lightning pains play an altogether insignificant part as compared with the analgesia, anæsthesia, and muscular hyperæsthesia.

From Landry's paralysis (acute ascending paralysis) peripheral neuritis is sufficiently marked off by the presence of wasting and degenerative electrical reactions, the marked sensory disturbances, and by the progress of the paralysis, which, as we have seen, does not attack first the legs, then the trunk, and lastly the arms.

Prognosis.—In alcoholic paralysis much depends upon how far the patient can be induced to give up the exciting cause. But under any circumstances the prognosis should be sufficiently guarded, as a fatal result is by no means infrequent. It is sometimes due to complications—*e.g.*, chronic Bright's disease and pneumonia—but most generally to respiratory paralysis.

In peripheral neuritis due to most other causes a favourable opinion can generally be expressed, and a complete cure anticipated. Sometimes, however, although the paralysis ceases to spread, the nerves fail to regenerate, and permanent contractures result.

Pathological Anatomy.—Frequently nothing abnormal is discovered until the nerves are subjected to microscopical examination, when the changes are found to be entirely parenchymatous. The medullary sheath, at first slightly swollen, is broken up into fragments, between which finely granular protoplasm and new nuclei are seen. The axis cylinder may be similarly broken up or normal. At a later stage the sheath of Schwann contains nothing but a mass of globules—the remains of the medullary sheath—

protoplasm and nuclei. The axis cylinder has disappeared, or is represented only by a fine thread. Later still, variations are found in the size of the fibres, owing to the débris contained in the sheath of Schwann having been absorbed in parts. Finally, all that remains of the medullary sheath and axis cylinder is absorbed, and nothing persists but the shrunken sheath of Schwann, with perhaps a little granular matter and nuclei less numerous than before.

In other cases the nerves are plainly enlarged and inflamed. Microscopically, the vessels are found engorged, the connective-tissue fibres and cells are greatly increased, and the nerve strands are in a similar condition to that already described, except that there is a large amount of fatty deposit, probably due to the distended vessels being unable to carry away the degenerated medullary sheath.

In extremely rare cases a segmentary neuritis exists, in which an alternation of normal and degenerated zones occurs. Such has been described in lead poisoning and diphtheritic paralysis, atrophy and fatty degeneration of muscles accompanying these changes in the nerve fibres. Usually, but at a varying time, regeneration of the nerve commences. Whether this is effected by a process of growth from the unaffected part of the nerve, or by the evolution of a new axis cylinder and medullary sheath from the degenerated mass contained within the sheath of Schwann, is still an open question, and keenly contested.

Treatment.—The general lines of treatment are often sufficiently indicated by a recognition of the cause. In the severer cases a water-bed is desirable, on account of the more equable support it affords and the comfort it gives the patient.

Salicylate of soda may be given during the initial pyrexia, and also in those cases which seem to be of rheumatic origin. Morphine is often urgently called for to allay the exquisite pains and hyperæsthesia; while, locally, hot or cold douches may be used, or lint steeped in chloroform may be pressed for a minute or two over the most painful points, or the limbs may be swathed in cotton-wool. The food must be light and easily assimilated, and in those cases in which there is much gastric disturbance nutrient enemata may be necessary. In cases due to the abuse of ardent spirits it may not be advisable at once to cut off the alcohol entirely, but it should be gradually diminished, and stopped as

soon as possible. When the acute stage of the disease has passed, strychnine or arsenic often proves useful. The patient should be encouraged to cautiously use the muscles of the affected limbs, and a properly conducted course of massage is of the greatest value at this time. Electricity also finds here one of its most beneficial applications; by its use the muscles are exercised, and their function and nutrition maintained until the nerves have had time to regenerate. One pole is put over the trunk of the nerve, and the other over the muscle, and the current is slowly interrupted. Contractions which will not respond to a long-continued massage must be treated by tenotomy, and adhesions of joints and tendons forcibly broken down.

WM. GAY.

NEUROMIMESIS.—The mimicry of organic disease by functional neuroses.

Of the various organic affections which may be simulated in functional disorders of the nervous system none is more common than disease of some joint. The position of the limb, the rigidity of neighbouring muscles, and the character of the pain are faithfully copied, but the administration of an anæsthetic generally demonstrates the true nature of the case. The pain, although intense when movement is attempted, is not, as in true joint disease, increased by pressing together the diseased articular surfaces, and other neurotic symptoms are commonly present in association with the simulated joint affection.

Treatment.—This should be conducted on the lines indicated in the article on HYSTERIA (*q.v.*). Local appliances are especially to be avoided, and the patient must be encouraged to use the limb.

NEUROSIS.—A convenient term, under which are grouped together a great variety of widely differing affections having this only in common—viz., that they are all referable to some derangement of the nervous system. The nature of the derangement is unknown. There must be no organic lesion of any part recognizable after death, either by the naked eye or by the aid of the microscope. Hysteria, neurasthenia, epilepsy, chorea, Graves's disease, neuralgia, spasmodic tic are a few of the more common neuroses. Improved methods of investigation have already done much to reduce the number, and will doubtless continue to further reduce it in the future. (*See*

HEART, NEUROSES OF; HYSTERIA; LARYNX, NEUROSES OF; NEURASTHENIA.)

NOSTALGIA (Home-sickness).—A variety of melancholia chiefly met with in young soldiers on duty abroad, and characterized by an intense longing to return home. It is chiefly seen in those coming from mountainous districts of moist climates. Great exaltation of the imaginative faculty is the first warning, accompanied, it may be, by constipation and a sense of oppression and weariness. Febrile symptoms are sometimes observed, and a gradual decline of mental and bodily power may be followed by death from exhaustion. The subjects of this disorder sometimes commit suicide. (See MELANCHOLIA.)

NYMPHOMANIA.—A condition of increased sexual excitement in the female sex, corresponding to satyriasis in males.

The *symptoms* may vary from mere extravagancy in dress, and a prurient tendency in conversation, to solicitation, suggestive attitudes, exposure of person, and masturbation. Nymphomania must be distinguished from erotomania—a disorder in which amatory conceptions predominate, but which finds neither the object nor the gratification of the desire in sexual congress. It is a disorder of the imaginative faculty, and the affection is frequently fixed upon a person of the

same sex. Pure nymphomania is a rare condition, and is allied to hysteria and hypochondriasis, but similar symptoms are not uncommon in both acute and chronic mania. The cause may be local, such as ascarides, hæmorrhoids, or pruritus ani et pudendi, or uterine disease. Foreign bodies may be found in the vagina.

NYSTAGMUS is a name given to certain rhythmical involuntary movements of the eyeballs. It is usually present in both eyes, and to the same degree. In the most common form the movements are purely horizontal, *i.e.*, from side to side, but sometimes they are rotatory. Usually, but not always, the movements are rapid. It is met with in certain local affections of the eyes, also in coal-miners who work in stooping or lying positions with dim lights, and in certain diseases of the nerve centres, *e.g.*, disseminated sclerosis and hereditary locomotor ataxy (Friedreich's disease), in which affections it differs from the ordinary form in appearing only when the patient attempts to fix his eyes upon some object. It also occurs in meningitis, thrombosis of cerebral sinuses, tumour cerebri, and in cases of hæmorrhage and softening, but is often seen apart from any other disease as a result of ophthalmia neonatorum, and in some cases it is believed to be congenital. It is common also in albinism.

O

OBESITY (Corpulence; Polysarcia).—An excessive development of fat throughout the body.

The exact degree of fatness which constitutes obesity cannot be rigidly defined; no hard-and-fast line can be drawn between the merely stout and the obese. The condition is most common in those who are past their prime, and especially amongst women at and after the climacteric; but it may be met with at all ages and in both sexes. Sometimes it is congenital, or appears very soon after birth, but in the latter case it does not generally persist for more than a year or two. Heredity certainly plays a part in its production, and the influence of the nervous system in its causation is undoubted. Corpulence is common among the gouty and diabetic.

The main exciting cause of obesity is

the ingestion of more food than is required for the due maintenance of nutrition, though it is undeniable that a great many large eaters never become corpulent, and some stout people are remarkable for the smallness of their appetites. Alcoholic drinks, especially champagne, port, burgundy, and malt liquors, have a marked effect in the production of adipose tissue. With excess of food should also be mentioned the lack of active exercise, as there is no doubt that the latter has a powerful effect in warding off the consequences of over-feeding. The taking of insufficient exercise may, in the first instance, be the result of mere laziness, but is afterwards due to physical inability consequent on the corpulent state.

The part played by the different articles of diet in the production of the fat has

been the subject of much discussion, but it is now generally accepted that no fat is produced directly from the carbohydrates, but that, when these are associated with an abundant supply of albumen, they cause fat to be separated and deposited from the albumen. The explanation of this is that the carbohydrates are very rapidly converted by combustion in the body into carbonic acid and water, and protect a portion of the albumen from total decomposition, and thus what survives is the fat. Ebstein has shown that when fats are given as food they are not nearly so liable to produce fat as are the carbohydrates, for, being less readily converted into carbonic acid and water, they do not interfere nearly so much with the decomposition of the albumen, and hence there is less probability of a residue of fat.

It must be understood that obesity has nothing to do with fatty degeneration, and that, as a rule, the viscera remain more or less free from disease, although often disturbed in their functions by mechanical causes; thus, the heart is often hampered by the layer of fat that accumulates on its surface. It is unnecessary to dwell on the symptoms of obesity further than to remark that in children the fat is mostly subcutaneous, and in older persons tends to be deposited in the deeper structures.

Treatment.—Ebstein's treatment is entirely based upon the physiological principles above referred to, his object being, in the first place, to effect a considerable reduction in the total quantity of food taken, without, however, starving the patient, and, in the second place, to select a diet which the patient will be able to adhere to for the rest of his life. The carbohydrates are absolutely forbidden, sugar, sweets and potatoes being the most important of this class; bread he limits to the smallest possible quantity, whilst he by no means forbids his patients to eat fat, and has often found that even those who formerly disliked fat could take it with relish and with relief to their dyspeptic symptoms. He allows all kinds of meat and vegetables, especially the leguminous kinds, with tea, coffee and light wines. The following is the diet-table of one of his patients:—

Breakfast.—One large cup of black tea, about $\frac{1}{2}$ pint, without milk or sugar; 2 ounces of white or brown bread toasted, with plenty of butter.

Dinner (at midday).—Soup, often with marrow; from 4 to 6 $\frac{1}{2}$ ounces of roast or boiled meat, vegetables (leguminous)

and cabbages; for second course a salad or some stewed fruit without sugar; two or three glasses of light white wine; immediately after dinner a large cup of black tea without milk or sugar, and a little fresh fruit is also allowed.

Supper.—In winter almost invariably, and in summer occasionally, a large cup of black tea without sugar or milk; an egg or a little fat roast meat, or both, or some ham with its fat, Bologna sausage, smoked or fresh fish; about 1 ounce of white bread well buttered; occasionally a small quantity of cheese and some fresh fruit.

The method which was successful in the case of the late Mr. Banting, and which now bears his name, excluded almost all fats, but gave a much larger allowance of albuminous food, and all other diets have been based on the same idea—viz., as far as possible to exclude the carbohydrates and fats.

Exercise and cold bathing are important elements of the treatment, and should be encouraged by every means. The medicinal treatment is of much less value; iron is useful, especially in cases where there is much anæmia, and iodine and the alkalies have been supposed to have a beneficial effect; the fucus vesiculosus, which has been much lauded, perhaps owes any virtues which it may possess to iodine. A purgative treatment, except on a very mild scale, cannot be recommended.

JOHN ABERCROMBIE.

ŒSOPHAGUS, DISEASES OF

THE.—**Cancer.**—Cancer as a rule affects the upper or the lower end of the œsophagus, rarely the middle. Epithelioma is the most common form at the upper end, scirrhus at the lower. The encephaloid form also occurs. The growth may infiltrate the walls of the tube or form a distinct tumour, in either case causing difficulty in swallowing solid food. Ulceration is frequent, and in some cases goes on to complete perforation.

Symptoms.—The leading symptom is a gradually increasing obstruction to the passage of food, the localization of which is obvious to the patient himself. At the outset, solid and lumpy food only is obstructed; later, even pulpy substances cannot be passed; and, finally, the channel may become impervious to liquids. In the earlier stages, the obstructed food may pass after a while; if the passage be wholly impeded, it is regurgitated into the mouth. Regurgitation from obstruc-

tion high up in the tube is almost immediate; if the growth be low down, the impeded matters may accumulate, distending the tube, their return may be delayed for many hours, and the process may closely simulate gastric vomiting. The alkaline reaction of the returned matters, and the maceration and decomposition, instead of digestion, of the food, furnish a means of distinction. Pain is usually felt in greater or less degree at the seat of the growth, if it be in the neck; in the interscapular region, if it be in the thoracic portion of the tube. In either case it will probably be aggravated by attempts to swallow, especially solid food. It sometimes shoots into the shoulders or the sides of the chest. A sense of fulness or oppression in the chest, or actual dyspnoea, may occur from pressure of the growth on surrounding parts.

As the disease progresses, the ejected matters contain much mucus, and sometimes blood.

Rapid loss of flesh and strength occurs, and the usual signs of the cancerous cachexia are manifest. Thirst is often a troublesome symptom.

Diagnosis.—The diagnosis of all forms of obstruction of the œsophagus is discussed at the end of the article.

The *course* of the disease is fairly rapid, life being seldom prolonged more than eighteen months from the first appearance of the symptoms. The posterior wall of the trachea may be infiltrated and perforated, such cases sometimes proving fatal by the supervention of gangrenous pneumonia. Perforation into the pleura may set up acute pleurisy.

Treatment in the early stages consists in excluding hard and lumpy articles from the dietary, and enjoining slow eating and careful mastication. As obstruction advances, the diet will need to be gradually reduced to liquid food. At this point rectal alimentation had better be commenced. Tonics are often of service; also cod-liver oil if it can be taken; small doses of morphine may be needed to relieve pain. If the growth have ulcerated, cocaine, in the form of a lozenge or tablet, may be of use in relieving pain and spasm. Thirst, if present, is best assuaged by acid lozenges.

When obstruction becomes total, or threatens shortly to become so, the choice must be taken between maintaining life by means of rectal alimentation or resorting to an operative procedure.

The operative procedure which offers the greatest advantages is Mr. Symonds'

method of passing through the midst of the growth, by means of a bougie, a short tube, to the upper end of which is attached a small funnel. The tube, further retained in position by a silk thread passing out through the mouth, is allowed to remain *in situ* for several days, or even for a fortnight at a time, and affords a sufficient channel for the passage of fluid food taken in the ordinary way.

Benefit is in many cases obtained by the passage of a small bougie through the growth, creating a temporary channel, or by the similar use of a gum catheter, through which fluids can be poured past the stricture; but it must be remembered that every passage of an instrument through a malignant growth is attended with a risk of perforation.

The operations of œsophagostomy in the case of a growth high up, or of gastrostomy in the case of one low down, offer other alternatives in surgical procedure, if the risk of perforation or other cause be held to prohibit any kind of intubation.

Fibrous Stricture is usually the result of syphilitic disease; more rarely, it occurs from cicatrization of wounds or simple ulcers. It may exist at any level of the tube.

The *symptoms* are the same as those of cancerous stricture, except that acute pain and ejection of blood are rarely present unless ulceration has taken place above the stricture; wasting is less rapid, and the special marks of the cancerous cachexia are wanting.

The œsophagus becomes dilated and pouched above the stricture, and sometimes ulcerated from the irritation of the obstructed contents.

The *prognosis* is more favourable than in the case of malignant stricture. The progress of the affection is towards complete obstruction, but the result may be averted, or its consequences avoided, by operative measures, the success of which enables life to be prolonged.

Treatment.—The dietetic regulations described under CANCER being enjoined, the systematic passage of bougies must be commenced, with the object of maintaining the existing degree of patency of the tube and, if possible, of increasing it. A bougie should be passed weekly at least, and attempts cautiously made to increase the size of the instrument from time to time. If pain follow the passage, its frequency must be lessened, and attempts at dilatation suspended; and if there be reason to suspect ulceration about the seat of stricture, the œsophagus

must be left quiet for a while, and rectal alimentation resorted to, in order to allow the ulcer to heal. A powder of 10 grains of subnitrate of bismuth, placed on the tongue daily and slowly swallowed, may assist the healing of the ulcer, and a small quantity (from $\frac{1}{2}$ grain) of a morphine salt may be added if there be much pain or irritation. When the symptoms of ulceration have subsided, the use of the bougie may be carefully resumed.

Should the use of the bougie fail of its object, œsophagostomy or gastrostomy, according to the seat of the stricture, will afford a chance of prolonging life.

Ulceration.—Except as a consequence of malignant disease or fibroid stricture, ulceration is rarely met with. Severe localized pain, greatly increased by attempts to swallow, and the ejection of mucus and blood, are its special symptoms. Perforation is the chief danger to be apprehended.

Treatment.—Rest may be given to the part by suspending deglutition and feeding per rectum. Powders of bismuth, with morphine if necessary, may be given as described above. The use of a bougie is attended with some risk of perforation.

Spasm (*Œsophagismus*).—More or less spasm attends all organic diseases, and especially ulceration of the œsophagus; but it may exist as a result of temporary irritation from hot or cold drinks, from irritating articles of food, or from the habitual use of spirits; it may be caused by pressure on the œsophageal nerves, or reflexly by affections of neighbouring organs, or may occur as the result of a purely nervous condition, especially in hysterical women and hypochondriacal men. The spasm may be so slight as to produce only a trifling inconvenience and delay in swallowing, or so severe as to amount to complete obstruction. It is unattended with pain, and the patient is only conscious of its existence during attempts to swallow. It sometimes yields to repeated acts of deglutition. It is occasionally accompanied by spasm of the cervical or thoracic muscles.

Treatment must be directed to the cause. If ulceration be discovered, it must be dealt with as described above. If errors in diet of a nature capable of producing spasm be detected, they must be amended. The hysterical or hypochondriacal condition must be attended to on general principles. In these last cases the systematic use of the bougie is often followed by marked improvement, a

result possibly mental rather than physical.

THE DIAGNOSIS OF ŒSOPHAGEAL AFFECTIONS.—Difficulty in swallowing is the symptom which almost invariably attracts our attention to an affection of the œsophagus. "The food sticks," is an expression commonly used by the patient. Regurgitation ("the food returns") is a frequent accompaniment. In stricture of the lower end of the œsophagus the patient's perception of obstruction may be less distinct, and regurgitation, described as *vomiting*, may be the chief or only symptom detailed. The criteria of œsophageal regurgitation are the reaction of the ejecta, which is alkaline, and the absence of the effects of gastric digestion in the articles of food brought back, which are merely sodden and partly decomposed. The dysphagia being thus localized in the œsophagus, the distinction between organic and spasmodic obstruction must be made. The gradual onset of the symptoms, their constant character and localization, and the comparative degrees of immunity found in attempting to swallow food of varying degrees of fluidity, are indicative of the former; sudden onset, paroxysmal character, shifting of situation, relief afforded by repeated efforts of deglutition, and special susceptibilities to particular articles of diet, apart from their solidity or fluidity, suggest the latter.

The presence of much mucus in the ejecta points to organic stricture; blood indicates either cancer or ulceration.

Some clue to the seat and degree of obstruction may be obtained by observing the patient as he takes food or drink, and by auscultating, while he is drinking, the left side of the spine, from the neck to the lower dorsal region. The rapid gurgle heard over the healthy œsophagus is checked at the seat of stricture, or replaced by a slow, dribbling murmur.

The presence or absence of hysterical or hypochondriacal manifestations, of evidences of syphilis and of the cancerous cachexia must be taken into account, as well as the patient's family history.

A severe, sharp, and narrowly localized pain, increased by deglutition, is the special symptom of ulceration; a deep-seated and radiating pain, that of malignant disease.

The neck and thorax must next be carefully examined for signs of dilatation of the œsophagus, as well as for morbid growths. This having been done, and the

absence of an aneurysm as far as possible ascertained, a well-oiled bougie or œsophageal tube may be carefully passed. If it meet with no obstruction, the occurrence of any localized pain in its passage, as indicative of an ulcer, should be noted. If an obstruction be experienced, the instrument should not at once be withdrawn, but by gentle persistent pressure it should be made out whether the hindrance to its passage is permanent or temporary (*i.e.*, spasmodic), partial or complete. The length of tube passed will give a rough idea of the seat of disease. Any matters brought away on the tip of the instrument should be examined microscopically for cancer cells, and also for blood and pus. The possibility of the obstruction being due to the tube passing into a diverticulum from an otherwise healthy œsophagus should not be altogether overlooked.

ISAMBARD OWEN.

OLD AGE.—The period of life in which the degenerative changes that set in after middle age become obvious.

This period does not correspond to any definite term of years. Its time of commencement is matter of inherited and individual idiosyncrasy, modified by external circumstances. It is particularly hastened by want, confinement, hardship and mental anxiety, by exposure to nitrous or mercurial fumes, and by the habitual use of morphine. Some persons may be said to be old at forty, or even earlier; others can hardly be so regarded at seventy.

The following are the more marked anatomical and physiological changes of this period of life. The bones become lighter and more brittle, without reduction in size, owing to absorption of the cancellous tissue, and, later, of the compact portions from within outwards. Fractures are in consequence more readily produced, especially in the spongy portions of the bones, and noticeably in the neck and trochanteric region of the femur. The cartilaginous parts of the skeleton are thinned, producing a slight loss of height. The alveolar processes of the jaws are absorbed, causing the teeth to loosen and drop out, and the angle of the lower jaw is enlarged. The face is thus shortened and the chin thrown into increased prominence. The voluntary muscles waste, causing a loss of athletic and respiratory power, a hesitating and staccato articulation, and an increased difficulty in maintaining the erect posture. The resulting stoop

of the back may cause a further change in the shape of the vertebrae. The cardiac muscle shares in the general wasting. The heart's beat becomes weakened and often intermittent, but its rate is not materially altered. The involuntary muscles also diminish, lessening the powers of digestion, inducing constipation, detracting from the power of circulatory and ophthalmic accommodation, and diminishing the expulsive force of the bladder. A general atrophy of elastic tissue renders the skin wrinkled and less extensible, augments the circulatory difficulty, permits of passive dilatation of the lung vesicles, and hinders the expulsion of mucus from the air sacs and bronchi, while dwindling of the gastric and intestinal glands further lessens the digestive powers. Adipose tissue is absorbed and the cutis is thinned; the cuticle and its appendages become friable and the roots of the scalp-hairs undergo atrophy, while the colour of the hair, which usually begins to be discharged in middle life, is still further lost. The lungs, the spleen, the lymphatic glands, the uterus and the ovaries undergo more or less atrophy, and the functional powers of the testes diminish or cease. They may be retained in some degree to an extreme old age. The brain and spinal cord shrink in size, reflex action becomes sluggish, the power of mental concentration and the memory for recent events markedly lessen. The fluids of the eye undergo partial absorption, lengthening the focal distance, and thus correcting myopia, if present, or inducing presbyopia in the healthy eye.

The above changes may be regarded as normal to the advanced stage of life, but the old are very subject to other degenerative alterations of tissue, which may more properly be considered *morbid*. The walls of the arteries are very liable to fibroid thickening, atheroma and calcification, by which the passage of blood is impeded. Thrombosis and embolism and a dry form of gangrene ("senile gangrene") are not infrequent results of the state of the vessels, and the risk of cerebral hæmorrhage is always present. The valves of the heart are often atheromatous or calcified, and increase the circulatory trouble. The costal cartilages in many cases calcify and become rigid, so that respiratory movements are impeded. A ring of degeneration ("arcus senilis") is often seen near the margin of the cornea, and cataract is common. The atrophy of the brain may be carried to the point of actual dementia; that

of the lungs may extend to serious emphysema. Deafness and paralysis agitans are common, and the wasting of the heart muscle becomes a source of serious danger. The joints are liable to the changes known as rheumatoid arthritis, though this lesion more commonly commences in middle life. Cirrhosis is seldom delayed to old age, but granular degeneration of the kidney not seldom commences in it. A form of glycosuria unaccompanied by special symptoms or special danger to life is often met with. The prostate is liable to fibroid enlargement, causing retention of urine and the train of results dependent on it.

Old age is to a marked degree exempt from acute rheumatism, enteric fever, diphtheria and tubercular diseases. Acute affections generally are less common than in earlier life, and, when they occur, are apt to assume an asthenic or an insidious form, and readily lapse into chronic maladies. Few aged people escape chronic rheumatism in some shape or another. Gout, though its onset is most usual in middle life, may make its first appearance at any age. Cancer is common in advanced life, but runs a slower course than when it appears at an earlier period, and in extreme old age has been known to dry up and wither. The aged are especially subject to catarrhs of the air passages, which are prone to persist and extend and to set up a form of lobular pneumonia.

Wounds in the old are liable to slough, but, apart from this risk, heal even more readily than in middle life. Fractures, except those about the neck of the femur, repair with facility.

A fatal issue may occur in old age from general enfeeblement of the vital functions without predominant lesion of any one organ. Cerebral hæmorrhage and cardiac failure are frequent modes of death, but bronchial catarrh, leading on to lobular pneumonia, is responsible for the largest mortality at this time of life.

Professor Humphry has lately shown, as the result of an extended inquiry, that longevity is, to a large extent, hereditary. Women have a greater tendency than men to long life, which is not necessarily forfeited by repeated parturition. A robust frame, a bodily and mental stature above the average, the power of sound sleep and of speedy recovery after fatigue, good reproductive power, and long retention of the hair of the scalp are the criteria of the capacity for prolonged life. Serious illnesses, as might be expected, are calculated to lessen the

prospect. The very aged are seldom found to be the offspring of immature marriages or to have contracted such themselves. The elder children of a large family appear to have an advantage over the younger.

The habits of life which, according to the same authority, most conduce to length of years may almost be summed up in the phrase, "temperance in all things." Moderate and continuous activity of mind and body, moderate and regular hours of sleep, a somewhat spare diet, little or no indulgence in alcoholic liquors, and in particular a guarded use of flesh food, are the most salient points. It is noticeable also that the very old have seldom been in the habit of resorting much to drugs during life.

In the *treatment* of aged persons, the failing powers of digestion, of repair and of vaso-motor accommodation must be constantly kept in mind.

The need of regular and sufficient hours of sleep, and of a period of rest after any unusual demand upon the brain, muscles or heart, must be duly impressed upon the patient.

The enfeebled digestive powers require a restriction of the habitual amount of food, and, in many cases, a prolongation of the intervals between meals, and between the last meal and the hour of retiring to rest. With this restricted dietary it may be advisable to have nourishment ready for administration during the night in case the patient should be awake, and to give some light refreshment, a cup of milk with tea or coffee, or one of beef-tea, immediately on waking in the morning.

The dietary of the elderly should consist in less degree of meat and in larger degree of milk and farinaceous matters than that of the young or middle-aged. The stimulus of much flesh food is neither needed by the habits nor compatible with the diminished capacity for muscular and cardiac effort of old age, while the powers of nitrogenous elimination may be readily overtaxed. Milk, owing to the diminished acidity of the gastric secretion, is better borne by the old than by the middle-aged. Fatty matters, on the other hand, are less easily tolerated, and should be taken with caution. The teeth should always be looked to, and, if they are insufficient for mastication, either artificial ones supplied or food given in such a condition as to be independent of them. Severe dyspeptic symptoms often arise from imperfect mastication in the aged.

Malted and pre-digested aliments may be required to supplement the diet as age advances, but it is remarkable upon how little food the very old contrive to support life.

Though the popular idea that old people require alcoholic liquors "to keep their strength up" is not borne out by exact observation, these liquors are of considerable service as stimulants to the failing appetite and digestion in advanced old age. White wines, as Graves, Bucellas, Marsala, and Sherry, seem to be more appreciated by the very old than the red varieties, and brandy is the most valuable form of distilled spirit (*see* ALCOHOL; ALCOHOLIC LIQUORS). Alcohol serves another useful purpose in old age in combating restlessness and inducing an inclination for necessary repose and sleep.

The reduction of the power of vascular accommodation renders the aged very susceptible to the influence of changes of temperature, which must be guarded against by the use of sufficient or even superfluous clothing, the under-garments being of flannel, and by the practice of carrying extra wraps to be used in case of emergency. Care must be taken of the head and extremities as well as of the trunk. A cardigan jacket, with close-fitting sleeves, and a light silk cap to be carried in the pocket, are useful additions to the equipment of old age, and the thickness of the foot-gear should always engage our attention. The liability of the aged to bronchitis should dictate caution in breathing cold or damp air, and the onset of catarrh of any kind should never be neglected.

The condition of the arterial walls should not be overlooked, and, if a tendency to degeneration be observed, the patient should receive a special caution against sudden or severe muscular exertion, heavy meals, and neglect of the state of the bowels (*see* CONSTIPATION).

Finally, we must never forget that the life of the aged, even when they appear to present striking examples of robust health, is held on but a frail tenure. Shocks and disturbances that would pass unheeded in earlier life may precipitate an impending and irrevocable catastrophe in an individual seemingly vigorous and well.

ISAMBARD OWEN.

OLFACTORY NERVE, DISEASES OF.—Alterations in the sense of smell may be considered under (1) Loss

of smell due to peripheral causes. (2) Subjective sensations of smell produced by central changes in the brain. Besides these two conditions, hyperæsthesia of smell, occurring in hysteria and insanity, and perverted sensations of smell have been described, but they are not of sufficient importance to require a special notice.

1. **Loss of Smell** is caused—(a) by diseases which affect the nasal cavity, such as acute or chronic catarrh of the nose, polypus obstructing the nasal passage, paralysis of the fifth nerve, producing dryness of the nasal mucous membrane—this last condition is also brought about in hemianæsthesia involving the mucous membranes of one-half of the face, due to lesions of the posterior part of the opposite internal capsule—and also occasionally by a complete paralysis of the facial nerve, which prevents the nostrils being opened in the act of sniffing. (b) By lesions involving the olfactory nerve itself, from caries of the bones due to simple meningitis or syphilis, or from abscess; the olfactory bulb or tract is also liable to be compressed or destroyed by tumours in the anterior fossa of the skull, and also to be torn by falls or blows on the head. The loss of smell may be complete or partial, and may involve one or both sides of the nose. In testing the nerve, aromatic substances such as oil of cloves, and not pungent bodies like ammonia, which act on the sensory nerves of the nasal cavity, should be used.

Prognosis in loss of smell is favourable in cases due to local causes, but in cases where the olfactory nerve has been destroyed by tumours or lacerated by injury the prognosis is necessarily unfavourable.

The *treatment* of loss of smell is that for the disease causing it. The constant current, with the negative pole inside the nasal cavity, is said to have done good in some cases.

2. **Subjective Sensations of Smell** have been observed, as warnings before some epileptic fits. They are usually described as of an unpleasant nature, such as "chloride of lime," "burning rags," or "dirty water." In some of the cases the sense of smell has not been affected, and, in those in which an autopsy has been made, a tumour has been found in the hippocampal lobule in the anterior end of the temporo-sphenoidal lobe of the same side—the part assigned by Broca and Ferrier to the sense of smell. (Cases reported by Sander and others,

and one by Dr. Hughlings Jackson and the writer, in *Med. Soc. Proc.*, vol. xii.)

C. E. BEEVOR.

OOPHORITIS (Inflammation of the Ovaries).—It is believed that the ovaries are subject to acute and chronic inflammation. Our knowledge of acute oophoritis is almost entirely derived from post-mortem examinations; chronic oophoritis, on the other hand, is a condition inferred from clinical phenomena.

The first stage is believed to be one of *hyperæmia*. This is physiological during menstruation, sexual intercourse, and pregnancy. Menstruation is often accompanied by ovarian pain; sexual excesses produce similar pain, and in pregnancy ovarian pain is common. It has been supposed that ovarian congestion may lead to hæmorrhage into Graafian follicles, interfering with their natural maturation and bursting, and thus entail sterility; but of this there is no proof. Nor is there any evidence to show that cystic disease of the ovaries is at all dependent on their congestion.

Hæmorrhage may take place into the follicles or into the stroma. How to draw the line between the normal hæmorrhage which accompanies the bursting of a Graafian follicle and a hæmorrhage slightly in excess of that, we do not know. Nor do we know why some follicles into which there has been hæmorrhage burst, and others do not; nor what are the symptoms, if any, which distended but unruptured follicles cause. There are rare cases in which the ovary is found enlarged and ruptured, in which fatal hæmorrhage has occurred. We know nothing definite about the pathology of such cases; but analogy would make us suspect them to have been due to twisting of the pedicle of a small cystoma.

Hæmorrhage into the stroma takes place in diseases in which there is a tendency to hæmorrhage, such as purpura, scurvy, typhus, septicæmia, &c. The hæmorrhage may be confined to the production of small points of effused blood, or it may be so great that the organ resembles a sponge soaked in blood. These large hæmorrhages are rare, and are probably due to obstruction to the return of blood from the ovary.

Small hæmorrhages into the ovary are probably absorbed without leaving any trace behind. Large ones may lead to complete destruction of the parenchyma

and to suppuration, the organ being converted into a brownish pulp.

Hæmorrhage into the ovary, either follicles or stroma, is not known to produce any symptoms unless rupture take place. If there be any, they are usually overshadowed by the symptoms proper to the disease which has caused the hæmorrhage, or by those which are consequent on rupture; so that it has generally been discovered unexpectedly on post-mortem examination. Hæmatoceles have been suspected to be due to this cause, but no case has been published in which such a diagnosis has been made and verified.

More advanced changes due to *oophoritis* have been described. These are of two kinds: *Parenchymatous* or *Follicular*, and *Interstitial*. They seldom exist separately, and both forms are usually accompanied by some inflammation of the surrounding peritoneum.

In **Follicular Inflammation**, the contents of the follicles become first turbid, then purulent. When extensive, the interstitial tissue becomes also affected.

Follicular oophoritis is said to be not rare in the acute exanthemata, in cholera, relapsing fever, septicæmia, arsenic and phosphorus poisoning. Occurring in these conditions, it has no special symptoms, and cannot be recognized clinically. Occasionally, cases are seen of persistent ovarian pain following one of the acute exanthemata, and possibly due to acute inflammation of the ovary during the height of the disease; but a connection of such pain with persistent change in the ovary has not yet been shown.

Interstitial Oophoritis has been described as presenting three forms or degrees—(a) serous, in which the ovary is infiltrated with serous fluid; (b) suppurative or hæmorrhagic, in which there are either yellow lines running from the hilus, or these lines have coalesced, forming small cavities containing pus; and in the tissue between these purulent collections are small capillary apoplexies; (c) necrotic. In the worst and most acute cases the organ is converted into a brown pulp, its structure being no longer recognizable.

Interstitial oophoritis may arise by the extension of follicular inflammation. Its most common cause is labour. It is then usually part of general septicæmia or pyæmia. But it may be a primary disease, existing by itself; this, however, is exceedingly rare.

Suppression of the menses, and gonor-

rhœa, are described as causes of oophoritis. There is no evidence that either of these conditions leads to any change in the substance of the ovary, although they may lead to inflammation of its peritoneal covering—i.e., peri-oophoritis.

It is believed that oophoritis may lead to the production of large abscesses of the ovary. But in cases of large ovarian abscesses it is possible and probable that they may have been suppurated cysts.

When well-marked changes, such as suppuration and disintegration, are seen, there can be no doubt of their pathological nature. But such conditions as hyperæmia, slight hæmorrhages, atrophy of follicles, thickening of the albuginea, cicatrices on the surface, are all accompaniments or consequences of the natural ripening and bursting of follicles; and we do not yet know how to draw the line between physiological and pathological changes of this kind. It has been supposed that follicular inflammation may lead to shrinking and obliteration of follicles, and to thickening of the surrounding stroma, and the formation of cysts; but of this there is no proof.

Hypertrophy of the Ovary has been described as a result of oophoritis, leading to overgrowth of the stroma with destruction of the follicles, the organ becoming enlarged, it may be to the size of the fist, but retaining its natural shape. Some might call this the production of a tumour. The connection between either hypertrophy of the ovary or solid ovarian tumours and previous inflammation has not yet been demonstrated.

Cirrhosis of the Ovary.—Destruction of the follicles, with shrinking of the stroma and puckering of the surface, has been described as a result of inflammation. A condition similar, but, it is said, less advanced, occurs in women who have had many children. We have as yet no criteria by which to distinguish between a cirrhotic ovary, the product of inflammation, and one which was originally small, and has become smaller as the result of age.

Diagnosis.—Acute oophoritis may be suspected if, in one of the diseases which are apt to be complicated by it, there be much tenderness per vaginam or per rectum in the situation of one or both ovaries. But no case has been reported in which it has been diagnosed, and the diagnosis verified. All the forms of disease which have been described are rare, even in the experience of expert morbid anatomists; and

the descriptions even in the best standard works on gynecology are based on very few cases. Until we can diagnose the affection it is unnecessary to discuss treatment.

Peri-oophoritis, or inflammation of the peritoneum covering and around the ovary, is fairly common. It may be acute, sub acute, or chronic. It leads to the formation of adhesions. These may be simply a few thin filaments, or the ovary may be imbedded in dense fibrous tissue. The ovary may be displaced and fixed in its altered position.

The most common cause of peri-oophoritis is inflammation of the tubes, either catarrhal, as from suppression of menses, or gonorrhœal. If the tubal disease persist, there may be repeated attacks of peri-oophoritis. The symptoms are those of slight perimetritis, and the signs those of perimetritis limited to the situation of the ovary: viz., a fixed tender lump at the side of and behind the uterus. Its treatment is that of perimetritis.

Chronic Oophoritis and Ovarian Pain.—Some authorities on the diseases of women teach that chronic oophoritis is very common, others seldom if ever mention it. The explanation of the apparently contradictory teaching is, that there is a group of symptoms very commonly met with, the anatomical condition underlying which is unknown. Some think that this group of symptoms warrants the inference that inflammation is present, and they call it oophoritis; others do not, and they call it ovarian pain. There is no conclusive evidence either one way or the other. The symptoms are, persistent burning, aching, pain and tenderness, lasting for months or years, varying in severity, sometimes intermitting, usually presenting a monthly exacerbation. The site of the pain is pointed out by the patient as a spot about two inches internal to the anterior superior iliac spine.

Those who think this group of symptoms justifies the inference that inflammation is present, point to its persistence and its characters, which are unlike neuralgic pain, and to its relief by treatment like that which benefits pelvic inflammation. Against this view is the fact, that no kind of chronic inflammation of the ovary has been demonstrated, either by post-mortem examination or by abdominal section, to exist in these cases. There is no doubt that symptoms like these are produced by peri-oophoritis, but in some of the worst cases of chronic ovarian pain, the uterus and ovaries

are quite movable and non-adherent. Further, removal of the ovaries does not quickly cure these patients, if it cures them at all.

There is a physical sign described by the older authors as evidence of oophoritis—viz., the occurrence, with pain and tenderness in the ovaries, of swelling, which increases, and then diminishes and disappears, the symptoms undergoing similar changes. This combination of signs and symptoms is not uncommon. But morbid anatomists and abdominal surgeons are alike in knowing little or nothing of such swollen ovaries; while they agree also in the opinion that distension of the tubes is common. It is highly probable that in these cases, assumed to be instances of inflamed and swollen ovaries, inflammation and dilatation of the tubes is the real condition.

The tenderness is ascertained by examining bimanually. The best way to feel the ovary is to put the patient on her back, to stand on the side corresponding to the ovary that is to be examined, and use for external examination the hand of that side. Then, if the patient be not too fat, or the abdominal walls too resistant, the uterine appendages can be traced outwards from the upper corner of the uterus, and the ovary arrived at, and seized between the hands.

This chronic ovarian pain is relieved by lying down, but not removed. It is aggravated by alcohol; indeed, in some cases produced by it; and this class of cases can be cured by stopping the alcohol. It is aggravated by constipation, and is lessened by tonics. It is more often in the left side, because the left side is weaker than the right as to resistance to pain as well as in muscular power.

Its most common cause is parturition. It may be consequent on dysmenorrhoea of long standing. Most chronic diseases of the uterus are accompanied by pain having this character. Morbid sexual excitement and chronic alcoholism are exciting causes. It occurs chiefly in nervous and anæmic subjects, and is associated with atonic dyspepsia, disturbed sleep, headaches, and symptoms of hysteria and nervous exhaustion.

The *treatment* is to find out and remedy any uterine disease that may be present; to administer tonics; to give such advice as may lead to the correction of anything unhealthy in the patient's mode of life; and to regulate the bowels. Alcohol

should be forbidden, unless it be clear that a small dose with meals enables the patient to digest more food. The patient should be kept recumbent while in pain, and counter-irritation used to the lower part of the abdomen, the best form being flying blisters. If the patient be free from pain while recumbent, but cannot walk without pain, support of the parts by a vaginal pessary will be found beneficial.

Prolapse of the Ovary means that the ovary is displaced so that it lies behind the uterus, in Douglas's pouch.

One or both ovaries may be so displaced, and yet be neither tender nor painful. In that case there will be no symptoms of any kind.

The ovaries, so displaced, may be tender, but not painful. In such a case there will be no suffering unless the ovaries are pressed on. The patient will then complain of pain on passing a hard motion, and of pain in sexual intercourse. The pain is of a burning aching character, and is often described as lasting an hour or so after the occasion which produced it. The treatment is to keep the motions soft with laxatives, and support the ovary, and protect it from contact by a thick india-rubber ring pessary in the vagina.

The displaced ovaries may be both tender and painful. If so, beside the symptoms above mentioned, there will be the symptoms of so-called chronic oophoritis above described.

The treatment follows from what has already been said, with the addition that a thick india-rubber ring pessary will be of marked utility. G. E. HERMAN.

OPHTHALMOPLEGIA (*Externa and Interna*).—**Ophthalmoplegia Externa**.—A progressive paralysis of the external muscles of the eyeballs, usually symmetrical, and affecting muscles associated in their action.

The term was originally applied to a condition which has since been found to be due to a degenerative change affecting the nuclei of origin of the ocular nerves. The name *ophthalmoplegia externa* is, however, frequently used to denote more or less complete palsy of the ocular muscles arising from other causes, among which may be mentioned tumours and syphilitic thickening at the base of the brain and in the orbits. The external ocular paralysis is often accompanied by *ophthalmoplegia interna*, or palsy of the internal muscles of the eye; but these conditions may occur separately.

Symptoms.—In progressive ophthalmo-

plegia externa of nuclear origin the paralysis commonly affects first the levator muscles of both upper eyelids, either simultaneously or in rapid succession. With this there is associated paralysis of the superior recti. After the lapse of time, other muscles which have a combined action are involved, such as the internal recti, or the external rectus on one side and the internal rectus on the opposite side. Occasionally, the muscles are attacked more or less irregularly, and without regard to their associated actions. When the affection is advanced, the drooping of the eyelids gives a drowsy aspect to the patient: the eyeballs are fixed, or practically so, and the patient in his endeavours to view objects out of the straight line of vision, moves his head in the required direction in a characteristic way. Occasionally, there is some protrusion of the eyeballs, though this is never extreme.

Ophthalmoplegia externa is a disease of slow course, and its duration may be as long as twenty years. The condition may exist alone, though commonly other nervous symptoms are combined with it. It occurs sometimes in association with optic nerve atrophy, or with paralysis of various cranial nerves, and it may supervene in bulbar paralysis, progressive muscular atrophy, general paralysis, and more particularly in locomotor ataxy; sometimes, and especially in the last-named disease, progressive paralysis of the external ocular muscles may occur at a very early period. Dr. Bristowe has recorded two cases in which ophthalmoplegia externa was probably of functional origin (*Brain*, Oct. 1885).

Ophthalmoplegia Interna.—This term was suggested by Mr. Hutchinson for a slow and progressive paralysis of all the internal muscles of the eyeballs. When the affection is complete, the pupils are fixed, contracting neither on exposure to light nor during efforts at accommodation; loss of accommodation from paralysis of the ciliary muscle is also present, as shown by the failure of vision for near objects.

Diagnosis.—Ophthalmoplegia may result from aneurysms, tumours or thickenings involving the nerves at the base of the brain. The existence of these conditions may be manifest from other symptoms, such as headache and vomiting. In intra-cranial growths the paralysis is usually more rapid than in ophthalmoplegia of nuclear origin, and

there is usually much irregularity in the march of the paralysis. Disease of the nuclei may be inferred when either ophthalmoplegia externa or interna exists separately, or when paralysis attacks the external ocular muscles according to their physiological grouping.

Morbid Anatomy and Pathology.—In a fatal case of Mr. Hutchinson's, in which there was paralysis of both external and internal muscles, Dr. Gowers found degeneration and atrophy of the nuclei of the third, fourth, and sixth nerves, the change resembling what is seen in progressive muscular atrophy.

Although there is little positive evidence respecting the pathological nature of the two forms of ophthalmoplegia, there are certain anatomical points which throw light on these conditions, and which may be, therefore, suitably referred to here.

In the first place, there is good reason to believe that the nucleus of the third nerve is made up of several centres having distinctive functions, and that these centres may undergo separate degenerative changes. The centre for the ciliary muscle is the most anterior, lying just in front of that which subserves the reflex action of the iris. The rest of the third nerve nucleus is concerned with the movements of the eyeballs, and there is little doubt that the centres for muscles which are associated in their action lie close together.

It may be mentioned here that the internal rectus has a double innervation. When associated with the opposite external rectus in lateral movements, it is controlled by the nucleus of the opposite sixth nerve, and hence in ophthalmoplegia externa it sometimes happens that, while there is loss of power of the internal rectus in its associated action with the opposite external rectus, the muscle acts well with its fellow in convergence.

Many of the clinical features of ophthalmoplegia, its progressive tendency, and the various combinations which occur, are intelligible in the light of these facts. It is quite conceivable that ophthalmoplegia interna may depend, as Mr. Hutchinson believes, on disease of the ciliary ganglion; but it is highly probable, from its association with external ocular palsy, that in many cases the affection is due either to disease of the nucleus or of the trunk of the nerve.

Etiology.—According to Mr. Hutchinson, syphilis is the usual cause of this disorder. Little, however, can be said on the ætiology of this affection, especially

in view of the frequent association of ophthalmoplegia with other disorders of the nervous system.

Treatment.—Iodide of potassium and mercury are mentioned favourably by Mr. Hutchinson. In most cases drugs have been ineffectual. W. B. HADDEN.

OPHTHALMOSCOPE.—In the year 1851 Helmholtz invented the ophthalmoscope, an instrument consisting of three superimposed pieces of plain glass set at an angle in a frame. With this simple appliance in front of his own eye, Helmholtz was enabled to reflect the light from a lamp into the pupil of the observed eye, and study the details of the hitherto unseen living fundus oculi. Previous to this invention the pupil had always maintained its characteristic black appearance, in spite of all attempts to see into it, on account of the fact that rays of light issue from the eye only to return to their source along the same path. Since the observer's pupil is not a source of light, he can never receive any rays from the interior of an eye.

A mirror with a central perforation, or sight hole, which soon replaced Helmholtz's original instrument, overcomes this difficulty, as it enables the observer to throw light into a pupil, and to receive some of the reflected rays, through the sight hole, into his own eye, where they form a picture of the observed fundus. This manner of examining the eye is known as the direct method, in contra-distinction to the indirect method, introduced by Ruete, in which a large concave mirror and a strong convex lens are employed.

Both methods are essential to the thorough examination of an eye, and can be conducted with greater ease if the physician uses an instrument possessing the latest mechanical improvements, such as Moreton's modification of Mr. John Couper's refraction ophthalmoscope. It consists of a body and two mirrors, each with a central hole. The body contains a large series of convex and concave spherical lenses, which can be brought by the rotation of a wheel successively in front of the sight hole. Of the two mirrors, the smaller, highly concave and set at an angle, can be rotated around its own centre; it is used in conjunction with the series of lenses for the direct method, whilst the larger and less concave is used, together with a convex lens of about 3 inches focus, in the indirect method.

Direct Method.—The examination is made in a darkened room by means of an artificial light. When the patient is in bed the light should be placed on the pillow on the side opposite to the eye to be examined. The ophthalmoscope is held erect in the right hand, and close in front of the observer's right eye when a right eye is to be examined, and *vice versa* for the left. The apex of the wedge formed by the small tilted mirror must be directed vertically upwards, and the light will then fall into the eye to be examined, as the observer, who stands opposite to the lamp, stoops over the patient.

When the patient can sit up in bed or in a chair, the light should be placed on a level with, but behind and to one side of, the eye to be examined. The observer sits beside the patient, opposite to the light, and holds the ophthalmoscope erect and close to his own eye, with the apex of the wedge formed by the small mirror directed towards the root of his nose. He can now bring the mirror so close to the observed eye as almost to touch it, and still have room to move the wheel without his hand coming in contact with the patient's face. The light will now fall on the eye, and as long as the small shadow which corresponds to the sight hole in the mirror is on the pupil, the fundus will remain illuminated and visible. If both physician and patient have normal (emmetropic) eyes, and neither accommodate, the details of the fundus should appear quite sharp and clear; if, on the other hand, either the physician or the patient have some abnormality of refraction (ametropia), then the series of lenses in the body of the instrument will have to be moved in sequence in front of the sight hole until the fundus details are clearly seen.

The lens which produces this effect will indicate the amount of the ametropia either of the one or both eyes engaged in the observation. It is, therefore, absolutely necessary for the observer to know the amount and nature of his own error of refraction, if he has any, and if it is one of any great amount it is well to have the correcting glass set in the disc provided for such extra lenses in Moreton's instrument.

Thus corrected, the physician does not require to make any allowance for his own error, and the lens found to give the clearest image of the fundus represents the patient's defect. The direct method thus serves two purposes—viz., to obtain a very magnified view of the fundus,

and also to find the glass the patient should wear to correct his ametropia.

Indirect Method.—The light may be placed on either side of the patient's head. The observer is seated in front of and at about his own arm's length from the patient. The ophthalmoscope, held by the right hand in front of the right eye, throws the light upon the examined eye by means of the large mirror. In the left hand the large convex lens (13 D) is held about 3 inches from the patient's eye. The rays reflected from the back of the examined eye pass through and are brought to a focus at or near the principal focus of this lens, where they form an inverted image of the fundus. This aerial image, situated between the lens and the ophthalmoscope, is seen by the observer through the sight hole of the mirror, and as it is situated at about the ordinary reading distance from the eye, he must either accommodate for it, or, what is better and less fatiguing, look at it through a convex lens of 4 dioptries placed behind the sight hole.

Whilst examining the right eye it is well to direct the patient to look at the tip of the extended little finger of the hand holding the mirror, when the optic disc will come under observation. To see the disc of the left eye, the patient is directed to look at the observer's left ear, and when the yellow spot is to be examined he must look at the centre of the observer's forehead. In some patients the pupils are too small to allow of sufficient light being thrown into the eye; it is then necessary to dilate them by applying a mydriatic to the conjunctiva. In homatropine and in cocaine we have two drugs, which, either separately, or, better still, in combination in a 2 per cent. solution, accomplish this perfectly, without the effect lasting so long as when atropine and some similar drugs are employed. As the paralysis of the accommodation which accompanies the dilatation is very inconvenient, it is always well to apply a drop of eserine solution, 1 per cent., at the end of the examination, so as to neutralize the mydriatic, and thus avoid an attack of glaucoma, which occasionally supervenes when the pupil is left widely dilated.

The erect image, as seen by the direct method, magnifies the fundus about fourteen times; it is, therefore, useful for seeing minute changes; whilst the inverted image, seen by the indirect method, only magnifies the fundus about four times, consequently a larger area is

seen at once, and the topography of a disease can be better appreciated. Since this latter method allows more light to enter the eye, it is more serviceable where the media are not clear, but both methods should be practised in almost every case, as each is capable of showing something that is not to be seen by the other.

Before proceeding to examine the eye in either of these ways, the physician, standing about 4 feet in front of the patient, should throw the light by means of the large concave mirror on to the pupil—the lamp being so placed as to leave the patient's face in the shade. On rotating the mirror around an imaginary vertical axis, he will notice that a part of the fundus is not illuminated, and as he moves the light from side to side across the patient's eye this shadow will be observed to move either in the same or in the opposite direction to the light.

The mirror must next be rotated around an imaginary horizontal axis so that the light may be moved across the eye in a vertical direction. If the shadow move in the same direction as the light, the eye is myopic, and a concave lens will be required to see the fundus by the direct method; if it moves in the opposite direction, the eye is either hypermetropic or emmetropic, and the fundus details will be seen more clearly through a convex lens in the former case, but no lens will be necessary in the latter. If the shadow be of different intensity or moves in opposite directions in the two meridians, then astigmatism is present. By this method, known as "retinoscopy," not only the quality but also, by the placing of trial glasses in front of the patient's eye, the quantity of the refractive error can be ascertained.

Should the fundus reflex be obstructed by a fixed shadow whilst this examination is being conducted, an opacity in one or more of the clear media must be looked for by the oblique examination. To do this the lamp is placed 2 or 3 feet to one side and slightly in front of the patient's face, the rays of light are then brought to a focus by means of the large lens, in succession on the cornea and on the surfaces of the lens and on the vitreous; by this means the position and nature of the opacity can be studied.

The chief objects to be observed in a healthy eye are the round or oval pink optic disc with its central white excavation or physiological cup, varying in shape and size, and the emerging vessels, readily recognized from their difference in colour, size, and tortuosity as arteries

and veins, the latter being darker, larger and more tortuous. The retina is invisible except for its just mentioned vessels and the slight pigmentation at the yellow spot. The red back ground of the fundus is formed by the vessels of the choroid covered by its own and by the retinal pigment, both of which vary according to the lighter or darker complexion of the individual. In the negro the fundus is nearly grey, whilst in the albino every branch of every vessel is clearly seen, and the light which streams through the sclerotic and iris, as well as through the pupil, thus gives rise to the characteristic pink eye.

These varieties of the healthy eye will soon become familiar to the observer who makes a practice even of examining only the eyes of those patients who come under his observation complaining of headache. Before long his reward will come in the discovery of an unsuspected optic neuritis or retinal hæmorrhage.

W. LANG.

OPISTHOTONOS.—An arching backwards of the trunk and head so that, in the dorsal decubitus, only the head and heels touch the bed. This condition is met with in tetanus, strychnine poisoning, hydrophobia, cerebro-spinal fever and some other diseases, and is due to a spasmodic contraction of the muscles of the neck, back and legs. In rare instances the muscles in front of the spine are affected. *Emprosthotonos* is the term used to describe the condition in which the patient's body is arched forwards, and *pleurosthotonos* when it is bent to one side or the other.

OPIUM, Poisoning by.—The *symptoms* of poisoning by opium and its alkaloid, morphine, or their compounds, do not materially differ. The main feature is a gradual and increasing stupor. At first, especially when morphine has been used, there may be a short stage of excitement with headache and dryness of the mouth, but in any case within half an hour of taking the poison drowsiness followed by stupor makes its appearance. The patient can be roused and made to answer questions, but when left to himself he at once lapses into stupor, and after a time he cannot be roused so easily, or perhaps at all. At this stage the pupils are contracted and insensible to light, the pulse, which was at first small and frequent, becomes fuller and less frequent, the breathing is slow and somewhat stertorous, the counte-

nance of a dusky pallor, and the skin clammy or bathed in perspiration. The breath may exhale an odour of opium. In cases that are proceeding to a fatal termination, the muscular relaxation becomes complete, the pulse is irregular, the breathing becomes slower and more stertorous, the intervals between each respiration becoming more prolonged. The duskiuess gives place to lividity, and the patient dies asphyxiated, the pupils sometimes becoming widely dilated towards the last. This latter sign is very unfavourable. Sometimes the patient, even after several hours of coma, rallies up to a certain point, but then relapses into a state of unconsciousness, and dies.

Vomiting is not an uncommon symptom in an early stage where a large quantity of opium has been taken by the mouth, and in a few cases convulsions have been present. It is possible that the convulsions in such cases are of an uræmic nature, for it is noteworthy that, in fatal cases, the urine has frequently been found to be highly albuminous when drawn off or examined after death, although the patient was not the subject of any form of kidney disease.

Diagnosis.—In the absence of any history of the mode of appearance of the symptoms, it will sometimes be difficult, if not impossible, to make a certain diagnosis of opium poisoning. Hæmorrhage into the pons Varolii may produce the complete muscular relaxation, the stertorous breathing, the lividity and the contraction of the pupils that are seen in the later stages of opium poisoning; and if the patient were past middle life, and presented evidence of advanced arterial disease, it would hardly be safe without any history to treat him as for opium poisoning in the presence of these symptoms. Hæmorrhage into other parts of the brain would probably be accompanied by unequal pupils or by flaccidity on one side of the body more marked than the other, or by unilateral convulsion or spasm. In alcoholism the most reliable signs would be a flushed rather than a livid countenance, and the pupils would probably be dilated. In uræmia convulsion is usually a prominent feature, coma a secondary one. In the status epilepticus the pupils are dilated. In any case where there is the slightest doubt the urine should be examined, the possibility of diabetes being borne in mind; the urine will probably be albuminous; a low specific gravity points to uræmia and granular kidneys, if high, the coma might be due to opium poisoning.

The ophthalmoscope might be of aid in a doubtful case by revealing the existence of albuminuric retinitis, but it must not be forgotten that the person might be the subject of chronic renal mischief, and yet be suffering from opium poisoning.

Post-mortem Appearances.—The viscera may be congested, but, unless the smell of opium were recognisable, the cause of death could only be surmised on negative grounds.

Treatment.—The stomach should be at once washed out; if an instrument be not at hand, emetics, such as mustard (a tablespoonful of the powder in water), or gr. xx of sulphate of zinc in water, or ipecacuanha (gr. xx of the powder in water), may be given. The patient must be roused by flapping with a wet towel, by shouting at him, and later on by walking him about if he show signs of returning stupor. Ammonia may be applied to the nostrils, and hot strong coffee may be given with the same object. The hypodermic injection of sulphate of atropine gr. $\frac{1}{10}$ – $\frac{1}{20}$ (the true physiological antidote) should never be omitted, though it must be confessed it very often fails to produce any effect. Artificial respiration should be employed if necessary. In cases of poisoning by morphine injection, the stomach pump and emetics will of course be of no avail. The importance of giving the patient rest and nourishment when a certain stage of improvement has been reached can hardly be over-estimated; many patients die after having been sufficiently roused to give their names, &c., and sometimes even after having been able to walk, and it is highly probable that such relapse is due to exhaustion.

Chronic Poisoning.—Opium when chewed or smoked in moderation probably does not do more harm than tobacco under similar circumstances, but when used to excess it produces dyspepsia, emaciation, a yellowish tint of skin and a stooping, shuffling gait; pains in the long bones are frequently complained of. In some persons the habit may be abruptly broken off; in others only a gradual change can be borne. The abuse of morphine by hypodermic injection gives rise to a train of symptoms which is detailed elsewhere (*see MORPHINOMANIA*).

OPTIC NERVE AND TRACT, DISEASES OF.—The diseases peculiar to the optic disc are congestion, inflammation and atrophy.

Congestion of the Disc.—So variable are the appearances of the healthy disc that it is extremely difficult to diagnose with certainty the slight changes which occur in the course of congestion. Indeed, unless they occur under observation, it is almost impossible in some cases to come to a definite conclusion. The colour of the disc is increased, and it has a softer and rather velvety appearance. The physiological cup participates in these changes, and, when small, may be entirely lost to view. The outline of the disc is ill-defined in its whole extent. Such a condition may ensue as the result of injuries to the eye, in retro-ocular affections of the nerve, and in the course of toxic amblyopia due to tobacco, &c. Complete resolution may occur, if so the disc regains its normal appearance and no permanent affection of sight results; frequently, however, atrophic changes take place, the disc gradually becomes paler, with ultimately a considerable loss of sight.

Tobacco Amblyopia occurs generally in men about or beyond the middle age, with usually a history of some degree of alcoholism and of nerve exhaustion proceeding from one cause or another. The amount of tobacco necessary to induce amblyopia varies with the idiosyncrasy of the individual. It may be either smoked or chewed, and is generally of a strong variety, *e.g.*, twist or shag. There is a gradual, but extensive, loss of sight, equal in the two eyes, and specially affecting the centre of the fields of vision. There may be no other symptom complained of, and, except perhaps for some sluggishness of the pupils, the eyes may appear quite normal. Sometimes, however, there is congestion of the discs. In all cases there is a central scotoma for red and green. This is best obtained by making the patient fix some object with his eyes, and moving before him small squares of cardboard of a red and green colour. It will be found that he is completely colour blind for these colours in an oval area bounded on one side by the blind spot and on the other by the fixation point, but that outside this region he readily names them correctly. If the indulgence in tobacco be persisted in, the disc eventually becomes universally pale, and an extensive and irrecoverable loss of sight occurs.

The *diagnosis* should never be difficult if the above characters of the disease be borne in mind.

The *prognosis* is good in recent cases if the patient be content to submit to the treatment; but if the condition be of

long standing, and especially if atrophic changes be detected in the discs, little or no improvement results, although absolute blindness seldom, if ever, occurs.

Pathology.—The anatomical basis of the disease is an axial neuritis of the optic nerve. A condition very similar to tobacco amblyopia sometimes occurs as an hereditary defect, in bisulphide of carbon poisoning, and perhaps also in some cases of diabetes.

Treatment consists in the absolute avoidance of tobacco, a careful limitation of alcohol, and the administration of nuxvomica or strychnine internally. Of these the first is by far the most important indication, and it will generally be found that it is easier for the patient to give up tobacco entirely than to limit himself to one or perhaps two pipes in the course of the day.

Optic Neuritis (Papillitis).—Inflammation of the optic nerve may exist alone or participate in a retinitis of albuminuric origin (neuro-retinitis). The present article deals only with the former condition. It cannot be too much insisted that, at any rate in the earlier stages, there may be no visual disturbance at all. Hence the immense importance of making an ophthalmoscopic examination in all suspicious cases of headache, vomiting or convulsions. In the later stages some diminution of sight nearly always occurs, and may go on to complete blindness. The visual defect is often not at all proportionate to the intra-ocular changes. Some of the worst cases are those in which the evidence of neuritis is comparatively slight, and, on the other hand, almost complete vision may be retained with considerable swelling of the disc. When the defect of sight is considerable, there is usually a constriction of the field of vision, and frequently some deficiency of colour sensation.

Ophthalmoscopic Appearances.—In the earliest stage, in addition to congestion of the disc, there is a cloudiness of the margin, which thus loses its definition and appears striated. The veins are rather enlarged, and, as they pass over the edge of the disc, may be seen to curve, and at this place they lose their light streak and appear darker, being, in fact, foreshortened. This is evidence of swelling of the disc, for vessels curving on a flat surface retain their light streak and are of a uniform colour. In addition to this the parallax movement may be seen. This is obtained by moving the head from side to side, when the vessels of the disc will appear to move in front

of the choroid behind. At a later period the swelling increases both in depth and extent, so that the disc may seem two or three times its normal size. The veins further increase in size, become tortuous and kinked, and are in places lost in the swelling. The arteries may be smaller than normal, and are lost to view much more frequently than the veins. Hæmorrhages and flake-like spots may sometimes be seen on the surface of the disc. Optic neuritis rarely terminates in complete recovery. More often some evidence of previous inflammation is present. The disc may be pale, the arteries contracted, or white lines may be seen to run along some of the vessels. Very often, however, complete atrophy results. The disc has a staring white appearance, and its outline may be irregular; the physiological cup is filled in and the arteries contracted. Some cases of post-papillitic atrophy show no signs of previous inflammation.

Diagnosis.—From what is known in regard to the normal variations of the appearance of the disc, it will be understood that the diagnosis of optic neuritis may be extremely difficult in its earliest stages. Of all things it is necessary not to mistake a hypermetropic haze for a neuritis of organic origin. An easily appreciable swelling of the disc is conclusive proof of the existence of neuritis, and if hypermetropia can be eliminated, so also is the concurrence of deep coloration of the disc, haziness and radial striation of its margin, so that the outline is lost in the whole extent. Optic neuritis, the result of brain disease, may be accompanied by the formation of white spots in the retina and even in the region of the macula lutea, thus closely simulating albuminuric neuro-retinitis.

Prognosis.—No definite opinion in regard to the probable effect upon sight can be formed until the swelling begins to subside. During this process sight may actually improve, but very often contraction of the vessels ensues and vision may become greatly diminished or even lost.

Ætiology.—The most frequent cause of optic neuritis is disease of the brain, whether inflammatory or neoplastic. It also results from albuminuria (generally as a part of neuro-retinitis), lead poisoning, anæmia, the exanthemata and sudden suppression of menstruation. Cases, for which no appreciable cause is found, sometimes occur and are called idiopathic. Unilateral neuritis is generally due to orbital disease but may

rarely also be found in cases of brain tumour.

The occurrence of optic neuritis in the course of meningitis is easily explained by the spread of the inflammation from the affected area, down the optic nerve to its intra-ocular termination (*descending neuritis*). Not so easy is the explanation, when it is due to some distant cerebral tumour. In these cases there is often considerable swelling, which Von Graefe considered of mechanical origin. He held that increased cranial pressure compressed the cavernous sinus and in this way dammed back the return of the blood from the eye; he further believed that this condition was accentuated by rigidity of the scleral ring. This theory was upset by the discovery of a free communication of the orbital vein with the facial, which would thus act as an overflow. Surrounding the optic nerve is a space (the subvaginal), in direct connection with the subdural space. Any increase of intra-cranial pressure, or of subarachnoid fluid would thus tend to distend this space with fluid; a condition which is found in many cases of optic neuritis and is greatest just behind the globe. The simple pressure thus induced upon the optic nerve is considered by some sufficient to explain the occurrence of optic neuritis; others invoke the aid of pathogenic germs, carried to the disc by the fluid. The mechanical theorists carefully distinguish between cases of descending neuritis resulting from meningitis and those occurring in the course of distant cerebral affections. The latter they call "stauungs papilla" or Anglicè "*choked disc*." These views still retain many adherents, but many objections to them have been pointed out and observers have sought in other directions for a mode of causation. Hughlings Jackson believes optic neuritis to be the result of vaso-motor changes set up by the irritation, due to the presence of a tumour which acts as a foreign body. This cannot be looked upon as a very satisfactory solution of the difficulty. Comparatively recent microscopic researches seem to show that in many, and perhaps in all, cases inflammatory changes are present in the whole course of the optic nerve. It is therefore supposed that interstitial inflammatory changes, or a slight meningitis occurs in the region of a tumour, spreads, affects the optic nerve, and by a descending neuritis at length reaches the disc. Why the optic nerve should be specially picked out in this process, and why cases of gross meningitis are fre-

quently unaccompanied by optic neuritis, are questions not easily answered on this theory. The subject is full of difficulty and the reader is referred to Gowers' *Ophthalmoscopy* for a masterly inquiry into the whole question.

Perineuritis is a term which has been applied to cases in which the periphery of the disc is alone inflamed; it was first described by Bouchut, who erroneously believed that it only occurred in cases of meningitis. It will be noticed that descending neuritis, choked disc and perineuritis, are in the present article grouped together under the one head of optic neuritis.

Treatment.—This is directed towards the disease of which neuritis is only a symptom. Recently Brudenell Carter has incised the optic sheath with an encouraging amount of success in some cases of great swelling of the disc.

Optic Atrophy.—This may be primary or follow upon some previously existing inflammation, *e.g.*, optic neuritis, neuro-retinitis and chorio-retinitis; it is also a sequel of embolism of the central artery.

The *symptoms* are, diminution of sight, contraction of the field of vision, which shows concentric or sector-like defects, and colour-blindness, which is sometimes the first thing noticed by patients who have much to do with colours. Green and red are seen over a smaller area of the retina than yellow or blue and are the first to be affected. Vision for yellow is usually the next to be lost and that for blue ultimately follows. The perception of white still remains, but the field is variously contracted.

Ophthalmoscopic Appearances.—Typical cases of primary and post-papillitic atrophy differ so markedly in appearance that it is possible at once to say to which class a given case belongs. Intermediate cases however occur, whose origin it is quite impossible to determine with any certainty. The appearances of post-papillitic atrophy have been already described (*vide supra*). In primary atrophy the disc is grey, its outline sharply defined, the physiological cup retained, the stippling at its base more distinct than usual, the arteries normal or only slightly contracted.

The *diagnosis* of atrophy may be as difficult in some cases as it is extremely easy in others. It is important to remember that a bright light makes even a fairly tinted disc look almost white, and hence a subdued light should always be employed in the examination of doubtful cases of atrophy. Nor must it be

forgotten that a large physiological cup may make the outer half of the disc appear as pale as in atrophy; a deficiency of colour therefore in this position is only of value when the physiological cup is small.

The *prognosis* in cases of primary atrophy is invariably bad, but a certain amount of improvement in sight sometimes occurs during the transition from papillitis to atrophy.

Ætiology.—The causes of secondary atrophy have been already considered. Those of the primary variety are mainly certain diseases of the spinal cord, and especially tabes dorsalis, in which disease the optic atrophy may anticipate the development of the ataxia by many years. Both discs are ultimately affected, but one may precede the other by several months. Atrophy also occurs in some cases of general paralysis of the insane, and rarely in disseminated and lateral sclerosis. Sometimes the disease is hereditary, and affects the male members of a family soon after puberty. Hydrocephalus is occasionally the cause of atrophy through pressure of a distended third ventricle upon the chiasma. It may also result from other local cerebral lesions—*e.g.*, meningitis and exostoses. As a monocular affection it is found in various diseases of the orbit. In a fair proportion of cases no adequate cause can be discovered; some of these no doubt develop tabes dorsalis, and others have been ascribed to syphilis, sexual excess, menstrual disturbance and diabetes.

It has been proposed by Charcot and others to distinguish, not only pathologically, but clinically, between an atrophy resulting from primary degeneration of nerve fibres and one in which these suffer secondarily to an interstitial inflammation. The present state of our knowledge hardly seems to warrant such a nice distinction. In some cases of primary atrophy the nerve is shrunken, and its constituents are wasted equally, connective tissue and nerve fibres alike. In others the nerve may be only slightly diminished in size, and marked increase of the connective elements is found microscopically, as well as wasting of the nerve fibres, and in an early stage the products of their degeneration are present. Sometimes areas of gelatinous-looking material, surrounding an artery, are found throughout the course of the nerve; the intervening tissue shows degeneration of nerve fibres, but only slight increase of connective tissue.

The *treatment* resolves itself into that

of the cause, if any be found. In primary atrophy, nervine tonics, nitrate of silver, and the interrupted current have been recommended, but their use is not often attended with much success.

Retro-ocular Affections of the Optic Nerve and Tract.—The optic nerves gain the intra-cranial cavity by the optic foramina, and, meeting soon after at the chiasma, undergo a partial decussation. The fibres supplying the temporal halves of the retina continue their course, keeping to the outer side of the chiasma, and forming the outer part of the tract of the same side. The nasal fibres, however, the more numerous, entirely cross over at the chiasma to the opposite tract. In this manner each tract contains fibres representing the temporal half of one retina and the nasal half of the other, and a lesion occurring in its course would cause a corresponding defect of vision (lateral or homonymous hemianopia). It is probable that the region of the macula lutea, where vision is most acute, is represented in both tracts. Proceeding backwards across the crura cerebri the tracts reach the posterior part of the optic thalamus, where they divide into two. The larger outer part goes to the thalamus, external corpus geniculatum, and anterior quadrigeminal body, from each of which fibres pass to the posterior part of the internal capsule, and thence to the occipital lobes by the optic radiation. The inner portion of the tract reaches the internal corpus geniculatum, and through that is probably connected with the posterior corpus quadrigeminum.

The ultimate destination of the fibres of the optic radiation is still the subject of keen controversy. Charcot holds that the fibres which pass to the corpora quadrigemina are those which have not yet decussated, and that these having united with those which have already crossed over at the chiasma, they proceed together to their destination in the cortex. According to this theory, therefore, the cortical visual centre represents the entire vision of the opposite eye, and all cases of lateral hemianopia must be explained by a lesion of the tract, either primary or the result of pressure from neighbouring regions. By this means a ready explanation is afforded of cases of functional hemianæsthesia accompanied by crossed amblyopia, and of similar symptoms of organic origin. Nevertheless, the bulk of clinical and experimental evidence tells strongly against this view. There can now be little doubt that the

occipital lobe is a half vision centre, representing the tract of the same side and corresponding halves of the retinae. A lesion in this situation would then cause lateral hemianopia. The angular gyrus is believed to be a still higher centre, combining the functions of the occipital lobes in such a manner that it represents the vision of the opposite eye to a great extent and that of the eye on the same side in a much slighter degree. Experiments upon monkeys in this region by different observers have given very contradictory results, and it has been by no means definitely proved that the angular gyrus possesses the functions here attributed to it.

Symptoms.—If any part of the nerve from the eye to the chiasma be damaged, the sight of that eye alone is affected. The pupillary reflex is sluggish, and congestion of the disc, optic neuritis, or a slowly developing atrophy may be seen ophthalmoscopically, according as the disease is inflammatory or implicates the nerve by pressure. In orbital cellulitis the motor nerves may also be affected, and they frequently recover, but irreparable damage is generally done to the optic nerve.

A lesion limited to the central portion of the chiasma affects only the decussating fibres, which supply the nasal halves of the retinae. For this reason the patient cannot see towards the temporal sides of the field of vision (temporal hemianopia). The converse condition, nasal hemianopia, is caused by a symmetrical lesion of the outer parts of the chiasma. Both affections are extremely rare. If they depend on a progressive disease, the area of vision may be still further diminished as more fibres become involved, until complete blindness occurs.

Lesion of the optic tract causes homonymous hemianopia, in which vision is lost either to the right or left, according as one or other tract is implicated. The dividing line may pass through the fixation point, but more generally it deviates to the extent of a few degrees, and then leaves the central vision intact or only slightly impaired. Usually the line of demarcation between normal vision and absolute blindness is sharply defined, but there may be an intervening zone of diminished sight. The dividing line is sometimes rather oblique and in very rare cases horizontal. The visual defect occasionally appears as a quadrant in each field; this, in some cases, represents the limit of improvement of a previous lateral

hemianopia, and in others is itself the original defect. The functions of the external geniculate body are still doubtful, but hemianopia sometimes results from disease of the posterior extremity of the optic thalamus, of the posterior part of the internal capsule, or of the occipital lobe, especially in the region of the cuneus. What clinical evidence there is supports the contention that the angular gyrus is the cortical representation of the opposite eye chiefly and of that on the same side slightly. A lesion in this region would therefore cause a marked concentric contraction of the opposite field and a slighter contraction of that of the same side. There is sometimes a contraction of the remaining half-fields in cases of hemianopia; this has been explained by supposing that the angular gyrus is subsequently invaded by a lesion originating in the occipital lobe. Hemianopia is accompanied by hemiplegia in about half the cases, by hemianæsthesia more rarely, and occasionally by defects of speech. It is also a common symptom of migraine.

Colour vision is lost proportionally with that for white in hemianopia, but sometimes hemi-achromatopsia occurs, i.e., practically a colour hemianopia, leaving the field for white intact. In this curious condition all coloured objects seen on the affected side appear grey. Such an affection conclusively points to the existence of a separate centre for colour vision.

Diagnosis.—Unilateral defect of sight, accompanied by optic neuritis or atrophy and paralysis of ocular muscles, is indicative of an orbital affection. Temporal and nasal hemianopia are characteristic of affections of the chiasma. Lateral hemianopia may result from disease of the fibres of the optic tracts in any part of their course from the chiasma to their ultimate distribution in the occipital cortex. In order to arrive at any conclusion as to the seat of the disease, other localizing symptoms, e.g., hemiplegia, hemianæsthesia and convulsions, have to be considered.

Prognosis.—This is grave as regards sight when the optic nerve is affected secondarily to some orbital mischief. Recovery from hemianopia of central origin occasionally occurs to a certain extent, but most frequently the defect remains unchanged. The chiasma and tracts are generally affected by a progressive disease, and therefore no improvement can be anticipated. The

prognosis as regards life must be founded upon a consideration of the probable seat and nature of the lesion.

Etiology.—The optic nerve may be implicated in the course of an orbital cellulitis, by pressure of an aneurysm of the ophthalmic or internal carotid artery, by hæmorrhage into its sheath, fracture of the optic canal, or thickening of its periosteum, caries of the sphenoid bone, or by a tumour originating in the bone or pituitary body. A retro-bulbar neuritis seems sometimes to be rheumatic in origin, and to result from cold. The chiasma may be affected by tumours in its neighbourhood, hydrocephalus, or chronic inflammation of the dura mater. The tract may be invaded by tumours on the inner side of the temporo-sphenoidal lobe, or arising from the base of the skull. The cerebral course of the fibres may be involved in softening, hæmorrhages, or neoplasms.

Treatment.—This depends entirely upon the nature of the original disease, of which the visual defect is a symptom.

WM. GAY.

OXALIC ACID, Poisoning by.—

—The *symptoms* produced by oxalic acid taken in a concentrated form are those of an irritant poison, and consist of a burning, sour, acid taste in the mouth, which is perceived immediately, followed by burning in the throat, gullet, and stomach, grumous and blood-stained vomit, and cramps in the limbs. The patient may die from collapse in less than half an hour. When taken in a less concentrated form there may be tetanic spasms, and when still more dilute, the patient may pass quietly into a somnolent state from which he never arouses.

In non-fatal cases there will be varying degrees of inflammation of the mouth, throat, and stomach, as well as cramps and numbness of the limbs, loss of voice, dyspnoea, and a dull red mottling of the skin in circular patches. The binoxalate of potash produces the same symptoms as the acid itself. A sudden indisposition, with symptoms of irritant poisoning, followed by speedy collapse, is characteristic of oxalic acid poisoning.

Post-mortem appearances.—The mucous membrane of the mouth and throat is whitened, the stomach contains a dark, mucous, gelatinous fluid, its mucous membrane is soft and in places abraded, the intestines are more or less congested and contracted.

Treatment.—The stomach-pump and emetics are contra-indicated, but warm

water in sufficient quantity to ensure speedy vomiting may be administered; the proper antidote is a saccharated solution of lime, a drachm of which should be given immediately and repeated frequently. Failing this, magnesia or chalk, mixed into a paste with milk, may be given. A dose of castor oil (ʒj) should be given to clear the bowels.

OXALURIA.—A persistent and copious deposit of oxalate of lime from the urine.

Oxalate of lime is a normal constituent of the urine. It is very frequently deposited as isolated crystals when the urine is slightly acid or even faintly alkaline. The crystals are always small, sometimes exceedingly minute, and occur in two forms. Their most common shape is that of an octahedron, presenting itself in various aspects; but they may also appear as dumb-bells or ovoids. The latter forms are due to the different views which are obtained when a bi-concave disc, the real shape of the crystal, rolls over in the fluid. From the analogy of other salts it seems probable that the formation of disc-like crystals is determined by the presence in the urine of some viscid substance, such as mucus. The two forms of crystal are identical in composition.

When the deposit exceeds what may be a normal amount, its naked-eye appearances are characteristic. Shortly after the urine is voided, a white mucus-like cloud is seen, which gradually settles at the bottom of the urine-glass. The upper layer of the deposit forms a wavy film-like membrane, sharply separating the deposit from the supernatant urine. On the sides of the glass, too, there are seen fine lines of crystals running in all directions.

A deposit of oxalate of lime does not disappear when the urine is heated; it is insoluble in acetic acid, alcohol and ether, but soluble in the mineral acids.

Oxalic acid is a result of the disintegration of organic substances in the body. It represents a lesser degree of oxidation than carbonic acid, which is one of the final terms of tissue metamorphosis. In the laboratory uric acid can readily be made to yield oxalic acid, and it has been suggested that the same reaction occurs in the urine; that, in fact, amorphous urates, by their decomposition, constitute the sole source of the oxalic acid of the urine. It is interesting to note, in connection with this, that the

urine of gouty subjects, which habitually deposits uric acid on standing, not infrequently for a time deposits oxalate of lime. It must not be concluded, however, that this is caused by a decomposition of the uric acid. It is much more probably due to a variation in the acidity of the urine, which favours the precipitation of oxalic acid, but not that of uric acid. The oxalic acid of the urine exists almost entirely as the lime salt, and this, sparingly soluble in water, is nevertheless somewhat freely soluble in a solution of the acid phosphate of sodium. Such a solution, however, when neutralized, deposits the lime salt in octahedral crystals. Probably the same phenomena take place in the urine. An excess of alkaline bases in the blood favours the excretion of oxalic acid, and the more lime there is present the more oxalate of lime will be deposited.

Oxalic acid administered in the food has been found to appear in the urine. It has therefore been thought, though probably on insufficient grounds, that such vegetables as rhubarb and sorrel, when taken with the food, may cause a deposit of oxalate of lime in the urinary passages.

There is no method of estimating oxalic acid in the urine which can be made use of for clinical purposes.

Clinical Significance.—The main interest of the presence of oxalate of lime in the urine attaches to the possibility of its deposition while the urine is still in the urinary passages, thus forming a calculus (*see* RENAL CALCULUS). But it has been maintained that the persistent presence of more than normal quantities of oxalate of lime as a deposit in the voided urine is associated with a definite group of symptoms. Those supposed to be suffering from the so-called **Oxalic Acid Diathesis** complain of hypochondriasis and nervous depression. They also have vague nervous symptoms, such as tingling in the limbs, anæsthesia of irregular distribution, depression of spirits, irritability of temper, headache, loss of memory, and pain in the back, while with these symptoms there may be disinclination for exertion, irritability of bladder, flatulence and other symptoms

of atonic dyspepsia. But this clinical picture may be present without the occurrence of oxalate deposit in the urine, and the deposit may co-exist with various diseases unattended by the symptoms above mentioned. Further, the occurrence of deposit of oxalate of lime in the urine is no proof that this substance is present in abnormal quantity, and, as has already been stated, there is no reliable clinical method for the quantitative determination of oxalate of lime in the urine. The deposit is due probably to an alteration in the acidity of the urine, and both this and the assemblage of symptoms described may be produced by the same causes. These causes have been fully investigated by Beneke, who showed that they lead to an impeded metamorphosis of nitrogenous substances, and consist of excessive use of nitrogenous matters and also of carbohydrates as food, together with anæmia, insufficient fresh air, and hindrances to the respiration and circulation. A definite oxalic acid diathesis, however, must now be assumed to be non-existent. The occurrence of oxaluria as an occasional phase of the gouty diathesis has already been mentioned.

Treatment.—The treatment of deposit of oxalate of lime within the urinary passages is discussed under the head of RENAL CALCULUS. The other conditions which occur in association with oxaluria demand treatment directed to a general stimulation of the metabolic processes. The diet should be arranged so as to provide for a due proportion between the nitrogenous and other food stuffs. Digestion should be assisted; in the majority of cases the atonic state of the stomach demands the administration of the mineral acids, but in other cases, where there may chance to be irritative dyspepsia, alkalies and bismuth are called for. Due exercise in the open air should be prescribed, and, if possible, change of scene and removal to a bracing climate. Not infrequently domestic worries are at the same time interfering with the general health, and the patient should be warned to avoid them if possible.

ROBERT MAGUIRE.

P

PALPATION.—The use of the hands in physical examination, so as to obtain information through the medium of the sense of touch.

CHEST.—In the article on FREMITUS (*q.v.*) the normal conditions and the significance of alterations of the various kinds of fremitus are fully described.

HEART.—The right hand should be placed flat upon the chest over the precordial region, first about the apex and then at the base; at the same time the point of the left thumb should be placed upon the right carotid artery in the superior triangle of the neck, on a level with the thyroid cartilage (just internal to the sterno-mastoid muscle). It is of importance to practise this combined palpation of the heart and the carotid pulse in order (1) to time any thrill which may be present; (2) to ascertain the relation of the apex beat to the carotid pulse, whether, as under normal conditions, the two are practically synchronous ($\frac{1}{10}$ second interval), or whether, as occasionally happens in cases of aortic regurgitation, they alternate, or whether the carotid pulse is delayed; (3) to ascertain that every beat of the heart is represented in the carotid pulse. This latter point will be further confirmed on auscultation, if, as recommended in the article on that subject (*q.v.*), the thumb be still retained upon the carotid pulse.

The position of the cardiac apex, which may or may not have already been observed on inspection, will be more definitely ascertained by palpation. It may be here stated that the importance in all cases of fixing this point accurately cannot be over-estimated, as *the position of the cardiac apex is the key to the diagnosis of nearly all affections of the chest and heart.*

The character of the impulse, whether forcible and thrusting, as in hypertrophy, or sudden, short and tapping, as in dilatation, will also be ascertained.

The force of the ventricular systole can be best estimated by pressing the point of the thumb between the ribs over the apex beat. It must be noticed also whether the impulse is due chiefly to the contraction of the left or right ventricle.

The presence of any abnormal bulging

will be noted, and especially whether or no it be a pulsating swelling.

ABDOMEN.—During the act of palpation of the abdomen the patient should lie upon the back with the legs fully extended, and the shoulders slightly raised. If the abdominal walls be rigid, it is rarely of any use to make the patient flex the thighs upon the abdomen, as a rule, the effect of so doing is to render the muscles more tense than before; it may, however, be of service when the psoas muscles are in a state of undue tension. Rigidity of the abdominal wall may often be overcome by making the patient take a succession of deep inspirations, the chest being as much as possible emptied of air between each act. At first slight resistance is maintained as the abdominal walls rise owing to the descent of the diaphragm; but immediately expiration begins the hand is quickly pressed downward as far as possible, and is maintained in its position. Greater resistance is then offered to the rise during the next inspiration, whilst with the following expiration the hand is pressed still further downwards. In this way it is generally possible to overcome rigidity, unless it be due to inflammation of the underlying peritoneum. If there be no rigidity, the fingers of one or both hands (the fingers being slightly flexed and in contact) should be employed in palpation, quick movements of flexion being constantly made, by which means any fluid in the cavity is suddenly displaced, and a solid organ or tumour, if lying near to the surface, is easily felt.

When it is desired to ascertain the lower limits of an organ, such as the liver or spleen, the hand should invariably be placed on the abdominal wall below the margin of the organ, and *gradually moved upwards*, never in the opposite direction. A marked difference in the resistance is almost always noted as soon as the organ is reached, even if its margin be not distinctly felt. In "mapping out" any organ it is approached in this way from all sides; and the spot where the edge is felt is marked with ink or an aniline pencil.

In the case of an abdominal tumour it is very important to place the whole hand flat upon the abdomen over the

tumour, in order to ascertain its consistence, outline, and degree of mobility.

In the article on **FLUCTUATION**, the method of ascertaining the presence of fluid in the peritoneal cavity is fully described.

Pain may be complained of on palpation, when due to hyperæsthesia of the surface the slightest touch may cause intense suffering, whereas if the patient's attention be distracted by conversation, deep pressure may be made without so much as attracting attention to the spot.

J. K. FOWLER.

PALPITATION is usually a subjective symptom, the patient complaining that he feels the beating of his heart. The action of the heart may be found to be tumultuous or only forcible, or nothing abnormal may be detected as regards the force, frequency, or regularity of its action. It is usually present at some period in organic disease of the heart, and may then be a symptom of failure of compensation or of degeneration of the cardiac walls. In functional affections of the heart, as seen in Graves's disease, or in hysteria, it may be constant or occur in paroxysms, whilst in a considerable number of the cases in which it is present it is dependent upon indigestion. Gout, nervous exhaustion, venereal excesses, the abuse of alcohol, tea, coffee, and tobacco are also common exciting causes of this condition. When due to valvular disease it is generally increased on exertion, whilst in other cases it may be relieved by moderate exercise, and in gastric cases it is often worst when the patient is in bed. Even in cases of heart disease it is often dependent on the condition of the stomach, and will be relieved by treatment directed accordingly. (*See also* **HEART, DISEASES OF MUSCULAR WALLS, and HEART, NEUROSES OF.**)

PANCREAS, DISEASES OF.—

Diseases of this organ are uncommon, and are often unrecognized.

The following conditions are here described:

1. **Obstruction of the Pancreatic Duct.**
2. **Cancer of the Pancreas.**
3. **Acute Pancreatitis.**
4. **Pancreatic Hæmorrhage.**
5. **The Celiac Affection of Children.**

1. **Obstruction of the Pancreatic Duct.**—*Symptoms.*—The absence of pancreatic juice from the intestines, owing

to complete obstruction of the pancreatic duct, produces a condition of the feces which is characteristic; the stools are copious, loose, putrescent, greasy and stone- or clay-coloured. The presence of fat in the stools has long been recognized, but the significance of the pale colour has been only recently pointed out by Dr. T. J. Walker.

Beyond this condition of the stools there appears to be no constant symptom; epigastric pain may be slight, of short duration, or absent; glycosuria has been observed in some cases, and there may be considerable emaciation and debility. On the other hand, complete obstruction is not incompatible with long life, the patient continuing to pass the characteristic stools for many years. In a few cases the obstruction has been followed by the formation of large cysts, which have been mistaken for ovarian cysts. Such a cyst, if of moderate size, presents a rounded elastic or fluctuating tumour beneath the right costal border; pulsation may be transmitted from the abdominal aorta, and a blowing murmur may be heard over it from pressure on the same vessel. Percussion may be sub-tympanic owing to interposition of intestine. In other cases the cyst presses forward under the right lobe of the liver, and the physical signs are then very obscure.

Pathology.—In man the pancreatic juice is conducted into the duodenum by a single main duct—the duct of Wirsung—but small supplementary ducts draining a few acini may open independently into the intestine. For the last inch or more of its course the duct of Wirsung is in intimate relation with the ductus communis choledochus, and opens with it by a common orifice about three inches below the pylorus. The action of the pancreatic juice on the chyme is three-fold—(1) it transforms starch into sugar and dextrin; (2) it acts upon albuminous bodies, producing in the first place soluble peptones, in some portion the peptones are further converted into leucin and tyrosin, and finally a number of bodies belonging to the aromatic series are formed, among these are phenol, indol and skatol, the characteristic odour of the feces being mainly due to the two last-named bodies; (3) it emulsifies and assists in the saponification of fats. The pancreatic juice decomposes neutral fats into fatty acids and glycerine; the fatty acids thus set free combine with the alkalies of the pancreatic juice and the alkaline bases

of the bile salts to form soaps, and the liberated bile salts continue the process of saponification by saponifying neutral fats which may be present in the intestines. Recent researches show that the presence of bile also renders the pancreatic digestion of starches and albumens more rapid and complete; the two secretions therefore are in their function intimately related, and in some degree complementary to each other.

The colour of the fæces is mainly due to altered bile-pigments, of which the most constant and important appears to be stercobilin, nearly related to urobilin, which is the chief urinary pigment.

If owing to obstruction of the pancreatic duct the secretion of the gland be no longer poured into the intestine, the above facts would lead us to expect that the fats, which are unaffected by salivary or peptic digestion, failing to be emulsified or saponified in the intestines, would be found unaltered in the fæces, and that nutrition would suffer owing to imperfect digestion of starchy and albuminous foods. The absence of bile pigments from the intestines would explain more or less completely the pale colour of the stools. It remains therefore to account for the sudden disappearance of bile. That this is not due to arrest of secretion appears to be proved by the fact that jaundice may be entirely absent or may be present temporarily, showing that the liver has not ceased to form bile, an hypothesis which it would be, on general grounds, impossible to accept. The only remaining hypotheses are that the bile pigments and its derivatives are re-absorbed in, probably, the small intestine, or destroyed; it is known that stercobilin "accompanied by imperfectly changed biliary pigments is taken up by the branches of the portal vein and carried into the liver, where it is probably again changed by the action of a ferment into a chromogen" (McMunn), whereas there appears to be no analogy for the other alternative. Claude Bernard found that destruction of the pancreas produced symptoms exactly parallel, and made the observation that the bile alone only gave a light yellow colour to the fæces, whereas when the pancreatic juice was also present the colour was a distinct brown. "The pancreatic juice," he concludes, "therefore contributes indirectly to the coloration of the fæces."

Morbid Anatomy.—Obstruction of the pancreatic duct may be due to impacted calculus, to cicatricial contraction after ulceration, or to pressure by a tumour or

enlarged glands. The calculi may be spherical, oval or branched, single or multiple; they are composed of carbonate of lime, or of a mixture of carbonate, phosphate and oxalate. The duct and its branches become dilated, and the gland tissue undergoes a process of fatty degeneration with some accompanying fibrous overgrowth. The dilated branches of the duct may form sacculi; one or more of these sacculi may become much enlarged, forming a distinct cyst, which may attain large dimensions so as to be capable of containing several litres of fluid; the walls of these large cysts are lined by friable phosphatic concretions, and the fluid contained in them is frequently of a chocolate colour owing to hæmorrhage.

Treatment.—This has hitherto been mainly symptomatic; benefit is believed to have been derived from the administration of pancreatin.

Large cysts have been successfully treated by laparotomy performed in two stages. The first stage consists in producing adhesive inflammation between the cyst and the abdominal wall, thus closing the peritoneal cavity; the second in opening and draining the cyst with antiseptic precautions.

2. Cancer of the Pancreas is either secondary to growths in the stomach, gall-bladder, liver, or duodenum, or, more rarely, primary; in either case it usually begins in the head of the gland, and is commonly of the scirrhus variety.

Symptoms.—Emaciation is generally an early symptom, and is very rapid in its progress. There may be deep-seated burning pain in the epigastrium, with occasional exacerbations of a neuralgic character; the pain is relieved by relaxing the abdominal muscles; it is not aggravated by food, nor relieved by pressure. A pancreatic tumour presents at the right edge of the epigastrium just below the ribs, but often it pushes the edge of the liver in front of it, in which case a distinct tumour may not be apparent; in either case the percussion note is not absolutely dull. Pressure on, or secondary involvement of, the common bile duct generally ensues sooner or later, and then jaundice is extreme and persistent. Ascites from pressure on the portal vein, anasarca from pressure on the vena cava, or both conditions, frequently occur. Dyspeptic symptoms are often severe, and nausea and vomiting cause much distress; constipation is the rule.

The *diagnosis* is often difficult; rapid

emaciation, with fatty stools, deep-seated epigastric pain, and a tumour in that situation not freely movable. make the diagnosis highly probable in the absence of jaundice, but all the symptoms may be produced by a growth in the hilum of the liver. As in either case the prognosis is hopeless, the differential diagnosis is not of much clinical importance, and is often impossible; the tumour of cancer of the stomach is more movable, hæmatemesis is generally present, and vomiting occurs early in the disease; cancer of the transverse colon is, at some period of the case, generally more movable, there is hæmorrhage from the bowel, pain aggravated some hours after food, and often chronic obstruction; in cancer of the gall-bladder the tumour is more superficial, defined, and rapid in growth, and there are attacks of biliary colic; a merely distended gall-bladder may be recognized by its pyriform shape and fluctuation, while a bladder containing gall-stones is, though hard, nearly painless. Aneurysm of the aorta or celiac axis may be confounded with malignant disease of the pancreas, but in the latter case the pulsation is not distensible, and disappears when the patient is placed on his elbows and knees; in addition, the course of the symptoms is entirely different. Cancer must also be distinguished from *cyst* of the pancreas; the latter may be produced by pressure or by calculi impacted in the duct. Such cysts are occasionally met with, and have been cured by incision and drainage; but it must be remembered that they may be produced by the pressure of malignant disease of the pancreas itself or of the liver.

In a certain proportion of cases of diabetes the pancreas has been found to be the seat of fatty degeneration; calculi and cancer have also been met with, and an attempt has been made (Lancereaux) to constitute a special variety of diabetes in which there is degenerative disease of the pancreas, accompanied by, perhaps in all cases, disease of the celiac plexus. This is said to be characterized by a rapid course, diarrhœa and greasy stools, containing scraps of undigested nitrogenous food.

3. **Acute Pancreatitis.**—The pancreas is liable to become acutely inflamed, probably by extension from the duodenum.

Symptoms.—These generally commence quite suddenly, severe epigastric pain followed by nausea, vomiting, tenderness in the epigastrium, and tympanitic swelling in the same region being the

most prominent; there is marked prostration, and death may be due to collapse.

Diagnosis.—This is very difficult. The condition must be distinguished from irritant poisoning, and from perforation of the stomach and duodenum, chiefly by the history. Diarrhœa is often present, and serves to distinguish pancreatitis from intestinal obstruction, with which, if constipation exist, it is otherwise very liable to be confounded.

The morbid appearances vary with the stage and intensity of the inflammation; three forms have been described (Fitz)—hæmorrhagic, suppurative, and gangrenous. When suppuration occurs the pus may find its way into the stomach, the duodenum or the great omentum.

Hæmorrhagic Pancreatitis appears to be the most acute form of inflammation; it usually leads to death in two to four days, but if the patient survive, the whole gland may slough, and eventually find its way into the intestine and be discharged per anum. *Gangrenous Pancreatitis* may also be due to ulceration and perforation of the gastro-intestinal or biliary tracts.

In cases of acute pancreatitis it is usual to find in the sub-peritoneal tissue of the omentum, mesentery and pancreas scattered areas of fat necrosis, which vary in size from a pin's head to a hen's egg.

No *treatment* is known to have any effect on this rare disease.

4. **Pancreatic Hæmorrhage** is a rare cause of sudden death. The patient is seized by sudden collapse which may, or may not be preceded by abdominal pain, death may occur within half an hour or less. After death diffuse hæmorrhage or multiple circumscribed extravasations are found in the pancreas, in the surrounding sub-peritoneal tissue, the omentum, the mesentery, and the perinephric fat. The sudden collapse appears to be produced reflexly through the medium of the sympathetic nerve.

Etiology.—The causation of this hæmorrhage is obscure; it may possibly be due to rupture of small aneurysms, analogous to those which are frequently the cause of fatal hæmoptysis, but none have been found in any case.

5. The "**Celiac Affection of Children.**"—There is a disorder not very rarely observed in children under the age of five years, which may be mentioned here since it is most probably due to a temporary suspension of the functions of the pancreas. It is character-

ized by the passage of large, loose, white or greyish, frothy and intensely fetid motions once, twice, or thrice a day. The appetite is poor, the abdomen large and doughy; the child suffers from abdominal pain, and gradually becomes anæmic and debilitated without much emaciation. Intercurrent attacks of watery diarrhoea are frequent, and contribute to produce a degree of exhaustion which may end in death. No lesion of the pancreas or its duct has been found post mortem, but it is doubtful whether sufficient attention has been given to this point.

Treatment.—Cows' milk should be replaced by goats' or asses' milk, or by a mixture of cream and scalded whey. The principal meal should consist of raw meat freed from fat, pounded and rubbed through a hair sieve; one to four table-spoonfuls may be given according to the age of the child, mixed with sifted sugar, or fruit jelly with a pinch of salt. If this be not well taken it may be replaced by the juice extracted from raw meat by dilute hydrochloric acid. Malted food with well-cooked rusks and some butter may also be allowed. The general hygienic surroundings should be inquired into, and the trunk and limbs should be clothed in woollen garments. As to drugs papaine is often useful; it is best given in powder shortly after milk has been taken (papain gr. j, sodii, gr. ij, saccharin, gr. $\frac{1}{12}$); pancreatic milk also would appear to be indicated.

Intercurrent attacks of watery diarrhoea are best controlled by large doses of bismuth combined with a few drops of tincture of opium or the compound tincture of camphor, or in powder with pulv. kino co. DAWSON WILLIAMS.

PARACENTESIS means literally a piercing or pricking through. The name was applied by Galen to the operation of tapping in cases of dropsy or of couching for cataract, and it is now in medical language synonymous with the English word "tapping," the object being the removal of fluid.

In former times the operation of tapping was much more restricted than it now is, the larger cavities of the body only being dealt with. But since the introduction into medical practice of improved instruments, it has been employed very freely both as a means of diagnosis and treatment. In illustration of this it is only necessary to refer to the tapping of joints distended with effusion, of hydatid cysts, abscesses of the liver

and the like. In this article it will be considered only as regards the thorax, abdomen and cranium.

Paracentesis may be performed with a simple trocar and cannula; but it is best, in the case of the pleura and pericardium at least, to use an aspirator, to guard against the entrance of air.

Paracentesis Thoracis or Thoracocentesis may be very well effected by means of a large syringe having such a stop-cock arrangement that when the tap is turned in the direction of the long axis of the syringe the way is open towards the chest; when at a right angle to this the way is closed towards the chest and opened towards the outside; and when turned half-way between these points the stop-cock is air-tight for the production of a vacuum. The syringe is composed partly of glass, so that it may be at once seen whether fluid flows into it, and it has an air-tight piston, which, when pulled out, is fixed by a turn of the handle. It is connected to the cannula by an india-rubber tube, from about the middle of which another tube, protected by a metal tap, passes at a right angle. When the apparatus is used, the vacuum being made in the syringe, the tap opening the way from the chest is turned on and the syringe soon nearly fills. The tap to which the other tube is attached being then opened, the fluid flows into a vessel placed on the floor until a sufficient quantity has been removed, the tube acting partly after the manner of a siphon. Or a Potain's aspirator may be used, in which the vacuum is created in a bottle which may be graduated so that the quantity of fluid removed may be read off as it flows.

Cases of aspirating apparatus are provided with trocars and cannulae of various sizes, and it is best to use one of small diameter, say from $\frac{1}{32}$ to $\frac{1}{16}$ inch. The idea that small cannulae are more apt to become plugged by fibrinous masses than those of larger calibre is erroneous, the converse being more nearly correct. If plugging does occur, the trocar, or, what is better, a blunt-ended stilette, must be passed through to clear the tube.

One or two preliminary precautions must be attended to. In the first place, it need hardly be said that the puncturing instrument, and indeed all the apparatus, must be scrupulously clean. To this end some strong hot antiseptic solution should be used, and, in addition, the trocar and cannula should be rubbed over with carbolized oil and passed through the flame of a spirit-lamp. In the second

place, the whole apparatus should be put together and tested to see that every part of it is air-tight. It should also be seen that the collar of the cannula fits closely round the neck of the trocar; otherwise, unnecessary pain may be caused in making the puncture; and when the instrument enters the chest, it may carry the parietal pleura or a lining of lymph before it, and so fail to reach the fluid at all.

Before the operation is performed, it is well to freeze the skin, so as to diminish, if not abolish, the pain of the prick. This may be most conveniently done with a small piece of ice cut flat with a knife, the flat surface measuring about an inch square. The ice is dipped in salt, held in the corner of a towel or handkerchief, and applied firmly for half a minute or less to the spot which has been chosen for the puncture. When the ice is removed, the skin will be found frozen and insensitive, and, having been wiped free from salt and moisture, it is ready for the operation. As to the place for puncture, there is considerable latitude of choice, but none is better than the sixth or seventh interspace on the left, and the sixth on the right side in the mid-axillary line. A spot posterior to this is often selected—namely, in the seventh or eighth interspace, just outside the inferior angle of the scapula. There is, however, this objection to it, that although fluid may be undoubtedly present, it is not always reached. The reason of this, as long ago suggested by Fraentzel, probably is that the cannula becomes blocked by flakes of coagulated fibrin adhering to the thoracic wall. A dull percussion note must, of course, be found at the spot selected.

In making the puncture the operator should press the tip of the forefinger of the left hand firmly into the intercostal space, and plunge the trocar, at a right angle to the surface, quickly through the chest-wall alongside his finger, causing it to enter the interspace close to the upper border of the rib, so as to keep as far as possible from the line of the intercostal vessels and nerve. The skin should be drawn aside a little when anything but a fine instrument is used for the puncture.

It is very desirable to draw off the fluid slowly (hence the importance of a *small* cannula), so as to allow the lung an opportunity of gradual re-expansion. If this precaution be attended to, syncope need not be feared, and it does not much matter whether the patient be sitting up

in bed or lying down. When severe cough is set up, or a feeling of tightness in the chest is complained of, or blood-staining appears, the removal of fluid should be stopped, the cannula withdrawn, and the wound covered with a pledget of cotton-wool dipped in collodion and kept in its place by strapping.

It is a good plan to make a preliminary incision through the skin before using the trocar, especially when the skin cannot be rendered anæsthetic by freezing, or when it is necessary to employ a trocar and cannula of somewhat large size. If, on emergency, an aspirator cannot be got, and an ordinary small trocar and cannula have to be used, a piece of goldbeater's skin must be tied to form a valve round the end, or some other similar arrangement made to prevent the passage of air into the chest. In the case of nervous persons and children, it is well to use a general anæsthetic, and chloroform is best suited for the purpose. The freezing of the skin is then, of course, unnecessary.

Paracentesis Abdominis may be performed with an ordinary full-sized trocar and cannula, but the plan introduced by Dr. Southey, of using a very small instrument (capillary, so called), by means of which the fluid is very slowly removed and the risk of syncope obviated, is much to be preferred.

The best spot for puncture is in the middle line, half-way between the pubes and umbilicus, care being taken that the bladder is empty and an undoubtedly dull note on percussion obtained at this point. The instrument is pushed with a stabbing motion through the parietes into the peritoneal sac, the trocar is withdrawn, and a fine india-rubber tube affixed to the end of the cannula, and also fastened by a strip of plaster to the skin to prevent kinking or displacement. This tube is long enough to pass over the side of the bed to a vessel placed on the floor, into which the fluid gradually runs. From four to six hours generally suffice to get all the fluid away. When the flow has ceased, the cannula is withdrawn and the wound closed, as in the case of the thorax. With the larger instrument and more rapid emptying of the peritoneum, a bandage or binder should be used, and gradually tightened, to give support to the abdominal wall as the fluid diminishes, and so avert the risk of syncope. When the small cannula is used this is unnecessary, but a binder should be applied after the

operation, and should be left on for some days.

Paracentesis Capitis is occasionally practised for the removal of effusion in cases of chronic hydrocephalus, but very rarely indeed with any substantial benefit. For the operation a very fine trocar and cannula or hollow needle should be used, and the puncture should be made in the neighbourhood of the anterior fontanelle to one side of the middle line so as not to wound the longitudinal sinus. It is generally recommended to remove only a small quantity of fluid at a time, and to counteract the diminished internal pressure by the application of an elastic bandage. The aspirator must not be used in this operation.

Paracentesis Pericardii.—A state of affairs calling for puncture of the pericardial sac is much less frequent than in the case of the pleura or peritoneum; nevertheless, the operation has been occasionally performed with great advantage. The aspirator should be used with a very small trocar and cannula or hollow needle. The best spot at which to make the puncture will vary somewhat with circumstances. Generally speaking, it will be found to be the fourth interspace, right or left, as close as possible to the sternal border. In this situation the thoracic wall will be pierced to the inside of the internal mammary vessels. A lower interspace should not be chosen unless the puncture be made an inch or more from the border of the sternum. It is not safe to puncture close to the sternum in the fifth space, as one or other of the internal mammary vessels or a branch may be pierced.

If the presence of pus be suspected, it is best to make the puncture well outside the vessels, say $1\frac{1}{2}$ inch from the border of the sternum, so that the cannula may serve as a guide to the knife by which a free incision may subsequently have to be made. If the trocar or needle should have been introduced close to the sternal margin, it could not be properly made use of in this way, inasmuch as an incision of sufficient length outwards would divide the internal mammary vessels, and troublesome hæmorrhage would result. In this case the left side of the chest should be chosen for the operation.

Paracentesis Pulmonis.—This is done as an exploratory operation merely, preliminary to free incision for abscess or for opening up a gangrenous or bronchiectatic cavity. The trocar and cannula are used as in the operation for the re-

moval of pleural effusion; and, if the focus of disease be reached, which may be judged by the character of the discharge coming through the tube, or, in absence of this, by the foetid smell, the cannula is utilized as a guide for the knife, and a free incision made into the lung substance.

DAVID W. FINLAY.

PARALYSIS, ACUTE ASCENDING (Landry's Paralysis).—A disease characterized by motor paralysis, beginning in the lower limbs, and spreading rapidly upwards so as to involve the trunk, upper extremities and, finally, the parts innervated by the medulla oblongata.

The disease was first described by Landry in 1859.

The affected muscles retain their normal bulk, and exhibit no change in their electrical reactions. The pathological nature of the disease is obscure.

Symptoms.—Before the onset of the characteristic symptoms, slight pyrexia, pains in the back and limbs, numbness and formication of the extremities are occasionally experienced for a few days. The paralysis, with rare exceptions, begins in the lower limbs, attacking first the muscles which move the toes and ankles. In a day or two, or even in a few hours, the paralysis of the lower extremities may be absolute. While the weakness is progressing in the legs the muscles of the trunk become invaded, so that there is inability to sit up; coughing, defæcation and such-like acts become enfeebled, and respiration is embarrassed. The arms are then implicated, the weakness usually extending upwards from the hands and rapidly increasing in intensity, so that in a brief space the upper limbs may become quite motionless. Finally, the diaphragm and muscles of the neck are attacked, as well as those of the tongue, soft palate and face; deglutition becomes difficult, articulation embarrassed and dyspnœa urgent.

The paralysed muscles, though flaccid do not waste, and the electrical reactions of both muscles and nerves are unchanged. The cutaneous and tendon reflexes disappear early. Various subjective disorders of sensation are often present, but there is rarely any actual anaesthesia. The nutrition of the skin is unimpaired, there is no tendency to the formation of bed-sores, the general health is good, and the mental state is unaffected. There is frequently some difficulty in voiding the urine and fæces from

paralysis of the abdominal muscles, but paralysis of the sphincters never occurs. Pyrexia is absent, except occasionally in the initial stage, when there may be some slight fever. In exceptional cases diplopia, paralysis of accommodation and inequality of pupils have been described. An acute increase in the size of the spleen has been occasionally noted.

In a few instances the paralysis has taken a descending course, the arms or the muscles supplied from the medulla oblongata being first involved.

Course.—The majority of cases are fatal within a week, but death may be delayed for three or four weeks. In about a third of the cases recovery has been recorded, arrest taking place at any stage of the disease. Convalescence is slow, complete power often not being regained for two or three months. The parts last involved are the first to show signs of amendment.

Diagnosis.—Acute ascending paralysis has some features in common with acute anterior poliomyelitis. In the latter, however, there is rapid muscular wasting with the reaction of degeneration, and the paralysis has no progressive tendency. The normal electrical reactions and the absence of muscular atrophy in Landry's paralysis serve to distinguish it from all acute affections of the spinal anterior grey matter. In diphtheritic paralysis the soft palate and power of accommodation are first implicated, and there is loss of sensation.

Prognosis.—The danger to life is very great, even in the more chronic cases. A favourable opinion may be entertained when distinct return of power has begun to take place.

Morbid Anatomy and Pathology.—No constant or adequate changes have been discovered in the various parts of the nervous system. Slight inflammatory lesions in the grey matter of the cord and some degenerative changes in the anterior roots have been noted in a few cases, but these alterations seem to be quite exceptional. The absence of muscular wasting and the normal electrical reactions in all cases of acute ascending paralysis are against the view that the seat of the disease is in the anterior cornua. It has been suggested that this affection is due to some toxic effect. This view has lately received confirmation from an interesting case reported by Dr. Bristowe and Mr. Horsley at the Clinical Society on November 9, 1888. The facts of this case strongly suggest that acute ascend-

ing paralysis is sometimes the paralytic variety of rabies.

Ætiology.—Very little is known as to causation. The disease has been ascribed to cold, and occasionally is said to follow an acute affection, such as small-pox and typhoid fever. By some the disease has been attributed to syphilis. Males are more frequently attacked than females, and the onset occurs chiefly between the ages of twenty and forty.

Treatment.—The use of the hot or vapour bath and the application of counter-irritants along the spine have been recommended. Dr. Gowers suggests salicylate of soda, and, in addition, speaks favourably of ergotine given subcutaneously. In convalescence the constant current and tonics may prove of service.

W. B. HADDEN.

PARALYSIS AGITANS (Shaking Palsy; Parkinson's Disease).—This disease was first described by Parkinson, in 1817, with great accuracy of detail.

Symptoms.—Although tremor is the most prominent feature, and the one which has given the name to the disease, there are other symptoms which are so marked as to enable the observer to diagnose the case irrespective of the shaking, which in some cases is exceedingly slight.

In the early stages tremor usually begins in one hand, and consists in a rapid to and fro movement of the thumb and forefinger, which are moved over each other as in the act of rolling a pill; this movement is accompanied by flexion and extension of the wrist; in other cases these joints do not move, but there is a rapid pronation and supination of the forearm. The movements of the upper limb are usually followed by movements in the lower limb of the same side—the hemiplegic type—rarely of the arm or leg of the opposite side. If the disease take the usual course, after some months the other arm begins to shake, and this is followed later by movements in the other leg. Even in the early stages the hand has a characteristic attitude: the phalangeal joints are extended while the metacarpo-phalangeal joints are flexed; the thumb is applied to the forefinger and becomes hyper-extended, giving the appearance of a hand holding a pen. The movements cease during sleep, and are usually diminished or stopped by performing a voluntary movement with the hand, so much so that some cases with marked shaking can thread a needle.

One of the earliest symptoms is a

characteristic appearance of the face and carriage of the individual. There is a lack of expression about the features, and, in speaking, the lips move without the rest of the face showing any expression; there is also a characteristic fixed look about the upper part of the face; in addition, it is noticeable, in walking, that the whole body moves as one piece, and this is especially obvious when the patient turns round. It is important to note that the symptoms referable to the face and trunk are present bilaterally, when, perhaps, only one arm may be affected by tremor. The speech is already monotonous, but not as yet high-pitched. A slight stiffness at the back of the neck, which prevents the patient from looking upwards with comfort, may be complained of. The gait may not be altered, or may be somewhat slow and deliberate.

The symptoms of the early stages have been given in detail, as, when the disease is well marked, its characters are so evident that a mistake can hardly be made.

When this later stage is reached, there is tremor of all four limbs, rarely shaking of the head and tremor of the chin and tongue, the movements being synchronous. The attitude is still more characteristic: the patient stoops, the head is carried forwards, the elbows are carried away from the trunk and flexed, the wrist directed towards the ulnar border and the hand in the writing position.

The gait is typical, and consists in taking very short rapid steps; when pulled backwards till he is almost over-balanced, the patient takes short rapid steps backwards to endeavour to get behind his centre of gravity, but, as he is unable to do this, his movements get faster and faster, and he would eventually fall if not prevented; this is called "retropulsion." The same thing occurs in walking forward, but it is developed later than the backward movement. He appears now as if his whole body were solidified, and has great difficulty in rising from a chair or in looking upwards; but the movements of the eyes always escape tremor and fixity, and this the writer thinks is best shown by making the patient suddenly look to his right or left, when the eyes will turn at once, but the head follows slowly in an appreciable time after the eyes, instead of the two movements being together. The movements of the hands are slow, both in beginning an action and in performing it. The speech is monotonous and high-

pitched. In bed the patient is very restless and requires to be continually shifted into another position, and there is a great feeling of heat, so that only a slight amount of bed-covering can be borne. Although the disease is called "paralysis agitans," there is no diminution of muscular power, as tested by the dynamometer, till the latest stages. The writing is characteristic, the down-strokes being fairly well made, while the up-strokes consist of fine wavy lines. No alteration in the knee-jerks has been observed.

The duration of the initial stage is two or three years, and, when the disease is fully developed, it may last twenty or thirty years, till in the last stage when the patient is confined to his bed completely helpless, general exhaustion sets in, with mental obscurity and involuntary passing of excreta, and, with the occurrence of bed-sores, death ensues.

It must be mentioned that in rare cases all the symptoms of the disease may be developed without any tremor. The writer has now a case under his care in which for seven years all the symptoms have existed, but without any shaking in the limbs, and only in the last six months has slight tremor appeared in the chin and tongue.

Diagnosis in well-marked cases is not difficult. When the disease appears in advanced life it has to be diagnosed from senile tremors, but these begin usually in both hands simultaneously, and there are not the fixed look and the rigidity of paralysis agitans, and shaking of the head is more common in the former disease. Disseminated sclerosis is a disease of youth; the movements only come on with voluntary effort, and nystagmus is common; it cannot, therefore, be easily confounded with paralysis agitans.

Prognosis is unfavourable, although some cases improve for a time, but, when the disease is well marked, recovery can hardly be hoped for.

Pathology.—This is at present unknown, but, in the opinion of the writer, the most probable site of the lesion is the cerebrum, either in the cortex or more likely still in the basal ganglia.

Ætiology.—Paralysis agitans is a disease of middle life, usually not beginning before forty, though undoubted cases have been observed at thirty, or even younger. It affects both sexes, but men more commonly than women. As causes of the disease, mental worry and anxiety have been given, and the shaking has been observed to follow directly after some

severe mental shock. In other cases the tremors have been first observed in the hand in which a needle was evidently imbedded. Exposure to damp cold is also considered to be a cause. The onset is usually insidious, but after a sudden shock it may begin suddenly.

Treatment.—Improvement has been obtained in early cases by the use of liquor arsenicalis, cannabis indica, and morphine (Gowers); other drugs have been tried, but in most cases have failed to do any good. Galvanism has appeared to modify the tremor when applied without interruption of the current, but it has not much effect in checking the disease. Statical electricity has been tried, but without any good results. The patient should live quietly and as much as possible away from all worry and anxiety, and he should be careful to avoid all exhaustion.

C. E. BEEVOR.

PARAMETRITIS (Pelvic Cellulitis).—Inflammation of the cellular tissue about the uterus. It is also called *pelvic cellulitis*. This latter term is objected to, because cellulitis, having its origin about the uterus, may spread beyond the pelvis, and inflammation of cellular tissue in the pelvis may be unconnected with the uterus.

Parametritis arises more especially from injury to the cervix uteri and vagina. It is met with chiefly after labour. It may also follow abortion, or operations on the cervix. It is by some, and with much reason, regarded as essentially a lymphangitis due to the entrance through wounds of the cervix or vagina of phlogogenic matters which are then stopped by the lymphatic glands, and so prevented from getting further into the system. Parametritis often accompanies perimetritis, the one disease arising by extension from the other.

Symptoms.—These are much the same as those of any other inflammation in the lower abdomen, being, in brief, fever and pelvic pain. Parametritis cannot by the symptoms be distinguished from perimetritis. Taking all cases together, the pain in the early stages of parametritis is rather less than at the corresponding period of perimetritis; and gastro-intestinal disturbance, *e.g.*, vomiting, is less than in the peritoneal affection.

Signs.—These depend upon the seat of the inflammation, the stage at which it is seen, and its course. The most common form of puerperal parametritis is the inguinal. The inflammation gene-

rally begins in the cellular tissue which laterally adjoins the cervix uteri. It may remain limited to this part. If it spread further, its most usual course is to follow the round ligament to the inguinal region. The inflammation presents two stages, first that of "phlegmon," or inflammatory œdema, then that of abscess. In many cases it does not go beyond the stage of phlegmon, the disease then ending by absorption of the inflammatory exudation. In cases which terminate thus, the inflammation seldom extends beyond the pelvis and the inguinal region. In such cases we often find that while there is a swelling in one inguinal region, no exudation can be felt per vaginam. Nevertheless, the known ætiology of the disease leads to the inference that the inflammation began in the neighbourhood of the cervix, and that the products underwent absorption there before attention was directed to the inguinal swelling.

Puerperal parametritis tends to the inguinal region more often than parametritis apart from pregnancy, because at the full term of pregnancy the peritoneum leaves the uterus high up at the sides, so that there is then below it plenty of loose cellular tissue about the brim of the pelvis and the inguinal regions. Inflammation of the cellular tissue within the pelvis, and of the pelvic peritoneum, both produce a hard swelling in the pelvis. But while the induration produced by thickening of the peritoneum is bilateral, joins the uterus high up, retreats towards the sides of the pelvis out of reach of the examining finger, and dips down lowest behind, the parametric phlegmon is usually on one side only, and is in continuity with the uterus as low down as the insertion of the vagina, and thence slopes off towards the wall of the pelvic outlet. In inguinal, or as it is often called, "iliac," parametritis, there is a swelling on one side of the lower abdomen, lying close beneath the abdominal walls, feeling as if continuous with Poupart's ligament. The dimensions of this swelling present a remarkable similarity in different cases. Its upper outline is a curve starting from a little below the anterior superior iliac spine, reaching its highest level an inch or so internal to this point, where it may extend a little above it, and then descending till it sinks below the pelvic brim $\frac{1}{2}$ inch or less beyond the middle line. The inner part of this swelling is usually formed by the body of the uterus. As the absorption of the swelling progresses,

its boundaries get less defined, and its upper limit becomes lower. The swelling, after it has become definite, is hard and non-fluctuating. If it end in absorption, the patient is usually well in three or four weeks' time. There is sometimes retraction of the thigh, from the cellular tissue around the psoas muscle being affected. The course of these cases is rather longer, and in them there is generally, but not always, suppuration. When this takes place, it is marked by persistence of hectic fever, together with bulging, softening, and pointing of the swelling. In cases of suppuration with much retraction of the thigh, the pus usually extends under the psoas muscle, between it and the pelvic brim. The usual place for suppurative parametritis to burst is where the round ligament leaves the abdomen, viz., a little above the middle of Poupart's ligament. When the pus has been discharged, fever usually ceases, appetite returns and the patient's condition rapidly improves.

Course.—There are many variations in the course of suppurative parametritis. What determines these variations we do not know. Whilst, speaking generally, the abscess points and the pus is discharged as in abscesses elsewhere, there are some cases in which hectic fever persists for weeks and yet no sign of pointing appears; nevertheless, an exploratory puncture with the aspirator-needle lets out pus, the matter seeming as if bound down by some structures which prevent it coming to the surface. In other cases the abscess bulges, and appears as if about to point and burst, but after a time the swelling diminishes, and ceases to be tense, and, if opened, the matter does not flow unless forced out by pressure.

The abscess does not always follow the course of the round ligament, and burst in the inguinal region. It may pass under Poupart's ligament, and point in the thigh, or spread along the psoas muscle to the cellular tissue which surrounds the kidneys, and form a perinephritic abscess. It may extend downwards, and open by the side of the anus, or burst into the bowel, either colon or rectum; it may also creep round the uterus and involve the cellular tissue between the uterus and bladder. In this situation it may form a communication with the vagina, or the bladder, or it may follow the urachus and present at the umbilicus or at some point in the middle line between the pubes and umbilicus. Again, the pus may travel backwards through the sacro-sciatic notch,

and open by the side of the sacrum. It may follow the obturator tendon to the thigh, and come to the surface near the trochanter. In three cases seen by the writer the cellular tissue between the bladder and the symphysis pubis was affected. There may be more than one abscess, or the same abscess may open, in more than one place. Even after the abscess has been opened by the surgeon another opening may be formed spontaneously elsewhere. An abscess may open into the bowel as well as externally, and fæces or intestinal gases escape into the abscess cavity. Usually, however, although pus flows from the abscess into the bowel, fæces do not pass into the abscess cavity. As a rule, the communication with the bowel soon closes spontaneously, or, at least, the passage of gas and fæces into the abscess does not continue long. In the formation of a pelvic abscess, vessels of some size may be opened and hæmorrhage take place, and such hæmorrhage may be fatal.

Prognosis.—This is, as a rule, favourable. It differs from the prognosis in perimetritis in this, that there is not in parametritis a tendency to relapse. If the inflammation end in absorption, the patient soon gets well, and remains well. If suppuration take place, the patient remains very ill, with hectic fever, wasting, &c., until the abscess bursts, and then, as a rule, rapid amendment follows. The patient may die from hæmorrhage, or from exhaustion from the long discharging of a sinus, or from some other disease brought about by the long-continued suppuration; but this is rare.

Treatment.—There is no drug that will certainly produce absorption or prevent suppuration. While there is any pyrexia, the patient should be kept in bed; appetite should be helped by tonic medicines, and the strength maintained and nutrition favoured by easily digested food. To aid absorption and lessen inflammation, the skin of the abdomen may be painted with lin. iodi. Sedative local applications may be used, if necessary, to relieve pain. When suppuration has occurred, if the patient be free from pain, the abscess may be allowed to burst. But if there be much pain, it is better to open the abscess by a free incision, and insert a drainage-tube. In some cases, especially those in which the suppuration extends under the psoas muscle, it may be that the abscess will not heal until the parts are kept at absolute rest by fixing the limb, which can be done by enveloping the pelvis and the thigh on

the affected side in a plaster-of-Paris case.

Erysipelas Malignum Internum, so-called (Virchow).—The inflammation of cellular tissue that has so far been spoken of may be described as "sub-acute." After delivery there is sometimes seen an acute, suppurative, rapidly spreading inflammation of cellular tissue, beginning in the pelvis, and resembling the so-called "phlegmonous erysipelas" which is seen in the subcutaneous cellular tissue. It is this disease which Virchow has described as one form of puerperal fever, and to which he has applied the name "erysipelas malignum internum" (thereby causing his authority to be adduced in support of the view that there is identity between cutaneous erysipelas and puerperal fever). This disease differs widely from erysipelas of the skin. It is usually rapidly fatal, and is generally associated with an unhealthy condition of wounds of the genital passage received in parturition, and with general pyæmia. It is to be prevented by the use of antiseptics at the time of delivery.

Cases have been recorded of a rare form of cellulitis dependent upon sloughing of the cellular tissue in the pelvis, like that which occurs when urine is extravasated, but occurring without any injury or disease of the urinary organs. It is usually fatal, but may take a chronic course and end in recovery. A similar disease has been observed in the scrotum of the male. Nothing is known about its ætiology or pathology. The treatment is to open the abscesses and let out the sloughs.

G. E. HERMAN.

PARAPLEGIA.—The term "paraplegia" was formerly applied to all forms of paralysis of spinal origin, and also to those which are now known to depend on disease of the peripheral nerves. With the advance of our knowledge the use of the word has become more restricted, until at the present time the term is chiefly employed to denote those spinal affections the pathological nature of which cannot be definitely determined during life. The number of such affections is still considerable, for it is a matter of great, often insuperable, difficulty to forecast during life the exact anatomical conditions of a spinal paralysis. But, although a precise pathological diagnosis is often impossible, it is usually justifiable to ascribe certain clinical states to lesion of well-defined parts of the spinal cord. An acute paralysis (provided this be clearly not

due to affection of a definite nerve) accompanied by marked wasting of the muscles, with qualitative change in the electrical reactions, without impairment of sensation and without implication of the bladder and rectum, may be referred with confidence to disease of the anterior grey matter of the cord, or, more definitely, to the large multipolar cells.

Again, a slow paraplegia, with rigidity of the muscles and exaggeration of the tendon reflexes, is due to degeneration of the lateral columns, or rather of the pyramidal tracts which occupy the main part of these columns. Spasmodic paraplegia is a convenient clinical term for such a condition, and lateral sclerosis is commonly used to denote its anatomical cause.

It may, however, be observed, parenthetically, that a spasmodic paraplegia practically undistinguishable from that found in organic disease of the cord may be present in such conditions as hysteria, and may even result from prolonged over-use of the muscles, and that under such circumstances there is reason to believe that there is no coarse disease of the spinal cord. In most instances there is no doubt that spasmodic paraplegia is accompanied by degeneration of the lateral columns, but the difficulty is to determine on what such a degeneration depends. This is a matter of the greatest importance, for prognosis and treatment will be alike influenced by a knowledge of the underlying pathological conditions. Is the spasmodic paraplegia due to secondary degeneration in the lateral columns from the pressure on the cord of a tumour or aneurysm or of inflammatory products (as in Pott's disease), or to a localized patch of softening? Or, again, is it part of a diffuse change in the nervous centres, such as is present in disseminated sclerosis, general paralysis of the insane and amyotrophic lateral sclerosis? Finally, is the clinical condition to be ascribed to a primary degeneration of the pyramidal tracts? Such are the problems which present themselves, and it must be allowed that not unfrequently the true nature of the affection remains undecided. To denote a clinical state, the term spasmodic paraplegia, may, therefore, be justifiably employed, but the various underlying pathological causes should be borne in mind.

Another form of paraplegia is characterized by loss of motor power with flaccidity and diffuse wasting of the muscles and qualitative changes in their electrical reactions, absence of the re-

flexes, together with loss of sensation, want of control over the sphincters of the bladder and rectum, and a tendency to the rapid formation of bed-sores. Such a condition may occur suddenly as a primary affection, or may supervene acutely in various chronic affections of the cord. As a primary state, a paralysis with these characters is usually ascribed to acute myelitis (often loosely termed "softening"); but here again there is a divergence of opinion as to the true nature of the morbid change. That there is a destructive alteration of the grey matter of the cord is undoubted, but it is by no means clear whether this depends on primary inflammation, or on degenerative processes, or on initial vascular changes such as thrombosis, or, lastly, on the presence of some infective agency.

Disease of the posterior columns of the cord, or, more precisely, of the external part of those columns or the posterior-root zones, gives rise to the condition now known under the name of locomotor ataxy or tabes dorsalis. In this affection motor power is retained, but there is inability to co-ordinate the voluntary muscles. It is not necessary to recapitulate here the chief points in the symptomatology of this disease, as a full account of the condition and of its diagnostic features is given elsewhere. Under the heading of "Paraplegia" it is convenient to describe here two forms of paralysis. The first is characterized by combined inco-ordination and weakness, and is known under the name of "ataxic paraplegia." The second, which embraces several clinical types, although having a similar causation and anatomical nature, has been described under various terms, such as "birth palsy," "infantile spasmodic paralysis," "bilateral spastic hemiplegia," and "spastic diplegia."

Ataxic Paraplegia.—This disease, which is slowly progressive, is marked by the co-existence of weakness and inco-ordination, affecting first, and sometimes exclusively, the lower limbs. In the early period the ataxy is the predominant feature, and the unsteadiness and irregular gait are such as are seen in ordinary tabes dorsalis. Even in the early stage exaggeration of the knee-jerk and the presence of clonus mark off the affection from tabes, in which the knee-jerk is lost from the beginning.

With the progress of the disease the lower limbs slowly become weaker, rigidity supervenes, and a condition of

spasmodic paraplegia with some degree of inco-ordination is established. The arms may suffer in the same way as the legs, but sometimes they remain unaffected. It is important to bear in mind, as distinguishing points from tabes, that lightning pains are of the rarest occurrence, that anaesthesia and hyperaesthesia are almost invariably absent, and that throughout the disease there is marked increase in the tendon reactions, and very commonly clonus may be elicited. The pupils, with rare exceptions, are normal; atrophy of the optic nerves is much less common than in tabes; and the external ocular muscles are generally unaffected. Girdle-pains are uncommon; but Dr. Gowers calls attention to a dull pain in the spine, frequently in the sacral region, which is often an early symptom.

The plantar reflexes are normal or increased. Sexual power may disappear early, and there is often loss of control over the bladder and rectum, though usually this is not extreme. Impaired articulation, with irregular movements of the face, is sometimes present, and this may be associated with mental change and sometimes with general paralysis of the insane. It is important to note that cases occur which seem to constitute a link between tabes dorsalis and the typical ataxic paraplegia.

Diagnosis.—The points of distinction between this disease, tabes dorsalis and spasmodic paraplegia are evident from the foregoing description. Ataxic paraplegia resembles in many respects the hereditary ataxy of Friedreich. The main points of difference are the usual occurrence of the latter in members of the same family, the fact that the knee-jerk is commonly absent in hereditary ataxy, and that nystagmus and affection of speech are frequent. From cerebellar disease ataxic paraplegia is distinguished by the absence of headache, vomiting and optic neuritis.

Morbid Anatomy.—Both posterior and lateral columns are the seat of sclerosis. According to Dr. Gowers, the change in the posterior columns differs from that found in tabes in two respects—(1) the degeneration is usually not more marked in the lumbar region than elsewhere, and (2) the posterior-root zones are not especially affected. The sclerosis in the lateral columns is generally diffuse and more or less irregular; occasionally there is annular sclerosis, which extends into the substance of the cord in the region of the lateral columns.

Ætiology.—The causation is obscure. Dr. Gowers asserts that "a history of syphilis is as rare as it is frequent in pure tabes." Males are attacked in much larger proportion than females. The period of greatest liability is between thirty and forty. Exposure to cold, injury to the spine and sexual excesses are mentioned as antecedents.

Treatment.—Turkish baths and rubbing of the affected limbs are said to be of service. The effect of drugs is doubtful. The method of suspension (described under LOCOMOTOR ATAXY) deserves a trial.

Infantile Spasmodic Paraplegia (*Spastic Cerebral Paraplegia; Spasmodic Tabes Dorsalis; Birth Palsy*).—In this affection there is muscular rigidity of the lower limbs, usually noticed at birth or shortly after. The thighs are rigidly adducted and slightly flexed at the hips, the knees are in contact and often overlap, the heels are drawn up by the contraction of the calf-muscles, and the feet are in a position of talipes equinus or equino-varus. If progression be possible, the patient will be seen to walk on the toes, and as one or the other limb is brought forward the knees rub together and overlap. The gait is characteristic, and is known under the name of "cross-legged progression." The tendon reactions are exaggerated, but clonus is not usually to be elicited. The muscles do not undergo degenerative atrophy, and there is no change in the electrical reactions. Sensation is intact. The sphincters of the bladder and rectum are unaffected, except in cases where there is marked mental impairment. This condition of spasmodic paraplegia, which is believed by most authorities to have a primarily cerebral origin, may exist alone, though not uncommonly other symptoms are present which point to more widespread change in the brain. Some degree of awkwardness or ataxy of the hands may be evident, or there may be rigidity of the upper limbs, sometimes slight, sometimes extreme. In the latter case the arms are stiff and flexed at the various joints. When both arms and legs are affected the condition is sometimes termed "bilateral spastic hemiplegia of children," or "spastic diplegia." Sometimes there are irregular movements, most commonly affecting the upper limbs, which resemble chorea or athetosis, and hence such cases have been described under the terms "chorea spastica" and "double congenital athetosis." Irregular movements occasionally

affect the face and tongue. In some instances the paraplegic rigidity of the lower limbs is associated with rigidity of one upper extremity. Weakness of the muscles of the neck and trunk is often present, so that the child is unable to sit upright or to maintain the head in position. When the lower limbs only are affected, speech may be unimpaired; but sometimes articulation is defective, and occasionally there is total inability to talk. Mental impairment, ranging from mere dullness to marked idiocy, may be present. Extreme defects of speech and great mental impairment are most commonly present when the upper limbs are markedly affected. Convulsive attacks, which often occur immediately after birth, may persist. Among other occasional conditions, nystagmus, squint, inequality of pupils, retarded dentition, defective teeth, arching of the palate, asymmetry of the head and microcephalus may be noted.

In most cases of the conditions just described there is a history of convulsions and asphyxia at birth, and, as will be presently shown, there is reason to believe that in the majority the affection is due to damage to the brain during parturition.

Diagnosis.—When rigidity of the limbs is noticed at birth, or soon after, there can be no doubt as to the real nature of the condition. It often happens, however, that the state of the limbs does not attract attention for months, sometimes not until the period when the child should begin to walk. In a small proportion of birth palsies the condition is unilateral, and then the affection may be confounded with ordinary infantile hemiplegia. An important distinguishing point is the occurrence of an acute onset in the latter, whereas the former will be noticed at birth or very shortly after, or, when the condition does not attract notice until a later period, there is no history of an abrupt supervention of the hemiplegia.

Morbid Anatomy.—In the recorded fatal cases of bilateral spastic hemiplegia there has been found sclerosis with atrophy of the motor convolutions or a simple arrest of development, and occasionally a condition of porencephalus. It is supposed that the cortical sclerosis found in many of these cases is due to hæmorrhage into the meninges and superficial parts of the brain from prolonged pressure on the foetal head during childbirth. If the child survives, the meningeal extravasation becomes ab-

sorbed, but the cortex, which has been damaged partly by compression, partly by extravasation of blood into its substance, undergoes degenerative changes. The information regarding those cases in which the lower limbs are mainly or exclusively affected is less definite. There is reason to believe, however, that the condition is due to the causes already mentioned. The pyramidal tracts in the spinal cord have occasionally been found sclerosed, and in some instances undeveloped. It is not improbable that some cases of birth palsy are due to arrest of development, and some possibly to disease in foetal life.

Etiology.—A large proportion occurs among the first-born, and in most there is a history of prolonged labour or unnatural presentation, with convulsions and asphyxia at birth. In a few instances there is a history of premature labour.

Prognosis and Treatment.—Fortunately, there is a tendency to improvement in many of these cases of spasmodic paralysis. As voluntary control is acquired, some power of standing and of walking may be slowly gained. The prognosis is unfavourable when the arms are much affected and when there is great mental impairment. Prolonged massage of the limbs, gymnastics and education should be employed. The ordinary go-cart is a useful agent. Sometimes division of tendons and muscles is attended with benefit, but very often the result is disappointing. Drugs, except in the case of persistent convulsive attacks, and the use of electricity are without service.

W. B. HADDEN.

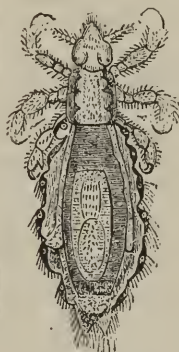

PEDICULOSIS (Phthiriasis; Lousiness).—Three kinds of lice prey upon the human skin, causing dermatitis of the regions they inhabit. The diseases thus produced are essentially confined to the neglected and uncleanly, are limited to the parts protected by clothing or by hair, and are usually proportional in severity to the number of the parasites present, although debilitated persons and those at either extremity of life are prone to suffer most severely.

Pediculus Capitis.—The insect is greyish in colour, but in dark races acquires a dark, even black, hue; it is smaller than either *P. corporis* or *P. pubis*. The male is smaller than the female (Fig. 1); it presents a head, thorax and abdomen. The head is triangular, carries a pair of jointed antennæ, minute, compound, lateral eyes, and a complicated masticatory apparatus. The body has

brownish markings on the sides; the thorax is narrow, carrying three pairs of jointed legs terminating in a claw; the abdomen is long and has seven segments, the last of which is rounded off. The penis projects from the dorsal surface, on which is also situated the anal aperture. The female exists in much greater abundance than the male; the last dorsal segment is forked; the genital opening is on the ventral surface. They are oviparous, and lay from fifty to sixty eggs, from which the young emerge after six days, and in

FIG. 2.

FIG. 1.

Female *Pediculus*

Pediculus Capitis.

twenty-seven days become sexually mature.

The ova, or nits (Fig. 2), are often present in abundance when the mature insect can only be detected with difficulty; they are most commonly found in the occipital region, and appear as white specks attached to one side of the hair-shaft, to which they are pretty firmly adherent by means of a chitinous cement substance which surrounds the hair like a tube, so that they can usually be moved with the finger along the hair; this serves to distinguish nits from loose scales. Each ovum has a lid or operculum.

Pediculus capitis in healthy persons may cause no symptoms except slight and occasional itching; indeed, the discovery of their presence is often accidental. When they are very numerous, however, and occur in cachectic persons, or in children with irritable skins and a predisposition to eczema, intensely severe weeping, pustular dermatitis may be produced as the conjoint result of the parasite and of scratching. Ulceration occurs, thick crusts and scabs form, the hairs

become matted together by gummy discharge entangling epithelium, dirt, lice and débris, constituting the condition formerly described as *plica polonica*, from its frequency among the Jewish inhabitants of Poland. The corresponding cervical lymphatic glands are almost always swollen, often suppurate and may form large abscesses. The glandular affection more frequently attracts the attention of parents than the primary cause. The pus has a special tendency to acquire infective properties, impetigo supervenes and sores appear on the face, hands and other parts of the body.

The disease is commonest in children and in young women with abundant and knotty hair.

Treatment is promptly successful, but re-infection is, for obvious reasons, very common. In children the nits are best removed by cutting the hair very short; crusts are best removed by soaking with oil and under white precipitate ointment (diluted, if necessary) the sores rapidly heal. In adults, the nits may be loosened by soaking the hair in turpentine or kerosene for twenty-four or thirty-six hours, the head being covered with a flannel mask, and then removed by frequent washing and assiduous use of a fine comb. In less severe cases nits may be destroyed by lotions of carbolic acid (1-40) or perchloride of mercury (gr. iij ad ℥viiij). After crusts have been removed, as already described, white precipitate ointment applied to the ulcerated surfaces will soon complete the cure.

Pediculus Corporis (vel vestimentorum).—*Pediculus corporis* (Fig. 3) closely resembles *pediculus capitis*, but is slightly

Male *Pediculus Corporis*.

larger, and the head is more elongated; the abdomen has eight segments, and is distinctly separated from the thorax; the antennæ, legs and claws are more developed, and its movements are much more rapid. It is greyish-white in colour, and lives entirely in the clothing, especially in the folds, only resorting to the skin for nutriment. It is possessed of a labium surrounded by a collar of hooklets which it fixes into the margin of the opening of a cutaneous—generally a sweat-gland; then it protrudes its membranous proboscis or sucking ap-

paratus into the skin and sucks up blood, at the same time causing a minute, evanescent wheal; when the proboscis is withdrawn a little blood fills the dilated follicle and coagulates to constitute the pathognomonic "hæmorrhagic speck," which may be differentiated from excoriations produced by scratching secondary pruriginous papules by its smaller size, and by not being raised above the general level of the skin. These specks are most common about the neck, shoulders and clavicular regions, then about the back, thighs, and abdomen, but the secondary lesions produced by scratching generally greatly predominate and comprise wheals in parallel lines, linear excoriations, torn papules with adherent blood clots, pustules, scabs and ecthymatous sores. In old-standing cases the skin becomes harsh, deeply pigmented, hardened and thickened (*morbus erroneum, vagabond's disease*) and the lymphatic glands enlarge. The subjective symptoms are burning, itching and creeping sensations, always worst at night, and transferred, probably by cutaneous reflexes, to other regions than those where the real origin of the disease is located.

The disease is distinctly rare in early life, but very common in advanced life, especially in the dirty and cachectic.

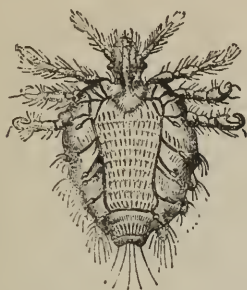

Diagnosis.—The distribution distinguishes it from scabies; the history, age of the patient, hæmorrhagic specks, and presence of pediculi or their ova on the body or in the folds of the clothing, especially of the neck-band, diagnose it from prurigo.

Treatment must be directed chiefly towards the clothing, which ought to be subjected to a dry heat of at least 220° F. for several hours, preferably in a disinfecting oven. It is well to iron all underclothing along the seams. Stavesacre ointment freely applied destroys all pediculi that may remain on the skin, and subsequent pruritus may be relieved by a lotion of liquor carbonis detergens (℥j ad ℥viiij). Good feeding and constituents, especially cod-liver oil, are of value.

Pediculus Pubis (Phthirus Inguinis; Crab-louse) resembles *P. capitis*, but is shorter, broader, and flatter (Fig. 4); the head is rounder, and has five antennæ; the thorax and abdomen are not separated by a constriction. The two posterior pairs of legs with their claws are stronger. The female lays from ten to fifteen eggs, from which the young emerge in six days, and are sexually mature in four-

teen days. The head-quarters of the parasite are in the pubic hair, where they penetrate into the hair follicles, the

FIG. 4.

Male *Pediculus Pubis*.

nits being fixed to the base of the hair-shaft. Thence they may emigrate to the hairs along the middle line of the abdomen, to the sternal region, axillæ, eyebrows, eyelashes, and beard, but almost never to the scalp. Their salivary secretion inoculated beneath the skin produces extensive bluish discoloration (*maculæ ceruleæ, taches ombrées*).

P. pubis causes itching, varying much in severity in different subjects, but always worst at night, and the consequent scratching produces a localized dermatitis similar to that described under *P. corporis*. The parasite, from its small size and close attachment to the skin, is often difficult of detection, but must always be carefully searched for in cases of eczematous rashes in the pubic region. The disease is by no means confined to the dirty or to the lower classes of society.

Treatment.—Free inunction of unguentum hydrargyri is always promptly effectual, but may cause dermatitis. Chloroform vapour, white precipitate, naphthol or stavesacre ointment are almost equally efficacious and less objectionable. It is not necessary to shave or cut the hair short. Pruritus subsequent to cure is common, and may be relieved by lotions of calamine or liquor carbonis detergens (3j ad 3vj).

Cimex Lectularius (*Acanthia Lectularia*; *Common Bed-bug*) is oval in shape and of a brown colour. The head carries a long proboscis, two jointed antennæ, and a pair of eyes; the thorax carries three pairs of three jointed legs; the abdomen consists of eight segments. The peculiarly offensive odour of the insect is due to the secretion of a gland situated on the anterior part of the meta-

thorax. The female deposits numerous operculated ova in the early spring; in three months a larva is produced, similar in every respect to the parent except in size; this becomes full-grown in three weeks. The bed-bug is nocturnal in its habits, and lives in the cracks of wood, &c. It is able to undergo long periods of inanition, and possesses remarkable olfactory powers.

Cimex attacks for preference the hands, feet, and face, causing urticarial wheals with a central puncture, which, by scratching, may be converted into papules or even pustules. The irritation which they produce is attributed to the deposition of an acrid matter in the wound which excites hyperæmia and renders the blood more accessible to the parasite.

Treatment.—Washing with Eau de Cologne or a mild carbolic or naphthol lotion relieves all symptoms. Sulphur fumigations effectually destroy the insect.

Leptus Autumnalis (*Harvest Bug*) is a comprehensive term applied to a sexual parasite larvæ of different species of the family Trombidinæ, genus Arachnidæ. They are minute, oval in shape, reddish in colour, and possess eight jointed legs, arms with hooklets, as well as a formidable rostrum. They frequent the fields, especially in autumn, and are also found on gooseberry and currant bushes, in granaries and barns. The animalcule implants its rostrum into the opening of a sebaceous gland at the base of a hair-shaft while the hooklets of the legs act as anchors. Intense irritation is set up, with the formation of urticarial wheals and minute papules; frequently the other phenomena due to severe scratching are developed. The legs, being nearest the ground and most accessible, are the parts most frequently attacked, but occasionally the whole body may participate, and considerable general disturbance ensue.

Treatment.—Diluted sulphur or naphthol ointment or weak corrosive sublimate lotion rapidly effect cure and destroy the parasite.

Pulex Irritans (*Common Flea*) is a temporary parasite, and only attacks man in the later stages of its development. It is of deep brown or black colour, and is highly active; it possesses a head bearing antennæ, eyes, and a complicated suckorial boring apparatus, a thorax bearing three pairs of powerful legs adapted to jumping, and an abdomen with nine segments. The female is about twice as large as the male; she

usually lays about twelve eggs in clothing, the cracks of wood-work, &c. These are broad, flattened at each end, and present several micropyles. In about six days a white, footless, eyeless larva with thirteen segments is developed. It feeds on organic matter and the faeces of the parent, and in eleven days forms a cocoon consisting of fine fibres of a sticky material and foreign matters. From the cocoon springs a whitish-yellow larva, similar in shape to the adult; this reaches maturity in eleven days. The average development to the adult parasitic stage occupies about twenty-eight days in summer and about forty days in winter.

Pulex produces a minute circular red spot, in the centre of which is a tiny speck which marks the spot where the boring apparatus has penetrated the skin. The actual "bite" of the creature is sometimes accompanied by a smarting sensation, and examination reveals the parasite in the very act. Some persons are habitually insensible of, and ignore, the bite and its consequences; others suffer severely, the irritation causing diffuse eczematous eruptions and sometimes even fever. Any part of the body may be attacked, but usually the face and hands escape. The flea is distributed all over the world, and apparently the only inaccessible regions are the deserts; it is especially associated with personal and domestic uncleanness.

Treatment.—The use of Goulard's extract, weak carbolic, or calamine lotion soon relieves the itching.

Dracontiasis (*Guinea Worm Disease*) is a disease of the skin, characterized by the development of deep vesicles or abscesses, due to the presence of the fully developed nematode worm, *dracunculus medinensis*.

The female worm is cylindrical, $\frac{1}{10}$ th inch in diameter and generally about 30 inches long, although occasionally much longer. The mouth is surrounded by four papillæ; it is viviparous and contains an enormous number of embryos which, escaping from man into water, lodge in a minute crustacean—cyclops—where they grow to full maturity in six weeks. They obtain entrance accidentally into the human interior, where they become impregnated, and the female passes through the tissues to lodge in the skin, generally about twelve months after they obtained entrance into the system. The characters of the male are not known; they are sup-

posed to be excreted along with the faeces. The idea formerly entertained that the worm enters the skin of the feet or legs during bathing is undoubtedly erroneous.

In the great majority of cases the worm is single and is detected in the foot, leg or thigh, where it can be felt like a bundle of soft string under the skin. When about to make its escape it gives rise to some itching and discomfort; then a small abscess-like swelling forms from which clear fluid is discharged and in which the head of the worm can be detected. In some cases very severe inflammation and suppuration may occur along the whole worm-track, with fever and much constitutional disturbance. If the worm break during extraction the embryos may penetrate into the system and cause disastrous results. The disease is endemic in India, Arabia, Mauritius, Egypt, the Gold Coast, and Guinea, and occasionally is observed in the West Indies and Brazil.

Treatment must be mainly directed towards the removal of the worm entire. The abscess cavity having been opened, very gentle traction must be made on the head of the worm and as much as can be easily extracted wound round a small stick, to which a turn or two can be given daily till the whole is extracted. Abscesses must be treated on general surgical principles.

J. J. PRINGLE.

PELIOSIS RHEUMATICA (*Purpura Rheumatica*).—A condition much more closely related to erythema exudativum than to the forms of purpura, along with which it is usually classified. It resembles the former disease as regards distribution, concomitant symptoms, tendency to relapse and to hæmorrhage, which latter is usually so marked a feature as to mask its truly erythematous nature.

The lesions are at first slightly elevated papules, from the size of a pin's head to a lentil, of a deep red colour which does not disappear on pressure and soon becomes dark purple, subsequently undergoing the changes of tint common to all blood extravasations. They are always present on the legs and feet, often clustered round painful joints, and are also common on the hands and arms, but very rare on the trunk and face. The hæmorrhagic papules may be confined to the immediate vicinity of the follicles and remain discrete, or may coalesce to form extensive, irregularly shaped patches,

round the margin of which isolated hæmorrhagic spots can generally be observed. Sometimes erythematous or urticarial rashes (*P. urticans*) are present on other parts of the body, and, more rarely, vesication occurs (*P. pemphigoides*).

Peliosis is commonest in persons from fifteen to thirty years of age, especially perhaps of the male sex. An outbreak is preceded by, or attended with, considerable lassitude, malaise and feverish disturbance, which frequently subside when the rash is fully developed. Rheumatic pains, effusion into joints, especially the knees and ankles, and œdema of the feet usually accompany it, and sometimes acid sweats occur, while endocarditis may develop during its progress. In severe cases hæmaturia has been noted. Repeated relapses of all the symptoms of the original attack almost invariably occur, prolonging the disease over several weeks, and there is a marked tendency to recurrence at regular intervals.

The disease must be considered as closely allied to articular rheumatism. The immediate cause of the rupture of capillaries and consequent hæmorrhage is unknown. The blood infiltrates the papillæ or deeper layers of the corium especially round the glands and hair follicles.

Diagnosis.—The affection must be carefully differentiated from symptomatic and idiopathic purpura, from flea-bites, hæmorrhagic syphilodermata, and hæmorrhagic iodide or bromide rash.

Treatment certainly influences the course of the disease. Absolute rest must be enjoined. The diet ought at first to be chiefly liquid with slops, but in old-standing cases more liberal and stimulating fare may be indicated, including fresh vegetables, butcher's meat and wine. Salicylates are very efficacious in relieving pain and joint symptoms. Small doses of turpentine internally and ergotin subcutaneously control the hæmorrhagic tendency, while the astringent salts of iron, especially the perchloride, arsenic and quinine are all of value.

J. J. PRINGLE.

PELLAGRA.—An endemic disease confined to the south of France, the north of Spain, the north and centre of Italy, but occasionally observed in Roumania. As its effects are most marked on the skin, especially in its earlier manifestations, it may be here considered as a "skin disease," but the central nervous and digestive systems are also profoundly

affected and its fatal issue is due to their involvement.

Pellagra is found only among the most destitute and squalid of the peasantry, and is invariably due to chronic poisoning with diseased or fermented maize, the effects of which are in many respects analogous to those induced by ergot of rye. Children are rarely affected, and women suffer more frequently than men. Attacks are especially frequent between the ages of thirty and fifty years.

The disease always begins in spring, and is preceded by or ushered in with gastro-intestinal symptoms (coated or red tongue, nausea, vomiting, epigastric tenderness, diarrhoea, &c.), resulting in great weakness, lassitude and emaciation; giddiness, various neuralgiæ and "rheumatic" pains in the limbs are also frequent prominent complaints. The portions of skin exposed to the air and light (face, neck, backs of hands and feet) become the seats of an intense, rapidly extending erythema, bright red, livid or brown in colour, with much swelling, and causing violent burning or itching. The spreading edge of the patches is much elevated and generally of deeper colour than the central portions.

In the first attack the symptoms usually subside after about three months; the skin occasionally suppurates and discharges, but more frequently cracks or merely desquamates, and recovery, apparently perfect, occurs spontaneously. Unless the patient, however, leave the district, the symptoms recur with ever-increasing intensity in each succeeding year, the rash extends over the whole body, the skin becomes completely anæsthetic and the patient succumbs in the course of a few years, in a condition of extreme marasmus. Mental disorders, especially acute mania and melancholia with suicidal tendencies very often precede the fatal termination.

Pathology.—Nothing very definite or distinctive is known of the pathology of the disease, but it is surmised—and with much probable truth—that it is due to the toxic effect on the sympathetic and pneumogastric nerves of a fatty oil and extractive matter found in decomposed and fermented maize.

Neuritis of cutaneous nerves has been demonstrated, and fatty degeneration, atrophy and peculiar deep pigmentation of almost all the internal organs is usually found.

Treatment.—No treatment is of avail unless the patient be removed from the locality and placed in good hygienic sur-

roundings. Maize as an article of diet is, of course, to be interdicted. Arsenic is said to have a powerful controlling effect over the disease, and general tonic measures and drugs are to be recommended.

To prevent the occurrence of the disease in pellagrous districts, the maize ought to be garnered in warm, dry and well-ventilated granaries.

J. J. PRINGLE.

PEMPHIGUS (*Pompholyx*; **Bladder Tetter**)—A disease of indefinite duration, characterized by the development of successive crops of blebs or bullæ on the skin, and more rarely on the mucous membranes.

It is so closely allied to the group of morbid conditions described as hydroa, and through it to the vesicating forms of multiform erythema, that no absolute line of demarcation, either clinical or pathological, can be drawn between them, the same case being frequently relegated by several equally competent observers to different categories. Nevertheless, the majority present the comparatively definite characters now to be described.

Acute Pemphigus is so rare a disease in adults, as to merit but short notice here. Its onset is preceded and accompanied by high fever and symptoms of severe nervous prostration; bullæ develop rapidly and indiscriminately over any part of the body, dry up, or burst, forming scales or crusts, and spontaneous recovery ensues in a few days, or rapid death with involvement of the mucous surfaces.

In cases of so-called **Pemphigus Solitarius**, the blebs are single or few in number, localized in distribution, and accompanied by little constitutional disturbance. Some doubt has been cast upon the existence of the disease as an "entity," and probably the majority of cases described are really examples of impetigo, or the "ecthyma" of older authors. The writer has, however, seen one case in an old man suffering from universal leucoderma with severe pruritus, in which the eruption of two large blebs on the feet—undoubtedly spontaneous—was accompanied by high fever, "typhoid" symptoms, and diarrhoea, resulting in death in four days. There was no autopsy.

Acute pemphigus occurring in children newly born (*P. Neonatorum*) is much less rare; it occurs epidemically or sporadically, is always generated in unsani-

tary dwellings, being of undoubted septic origin; it is infectious, and may extend to adults occasionally. Children affected may be otherwise healthy; an acute eruption of blebs resembling those of pemphigus vulgaris, accompanied by severe febrile disturbance, occurs on any part of the body except the soles and palms. A certain proportion of cases recover with careful treatment and nursing, but the large majority succumb at the end of two or three weeks. The disease must not be confounded with bullous syphiloderma, which occur at the same age, but invariably attack the palms and soles, and are associated with other evidences of congenital syphilis.

Chronic Pemphigus (*P. vulgaris*) is also a comparatively rare disease, but one of extreme interest. It more frequently attacks children than adults, but authorities differ as to its relative frequency in the sexes; probably both suffer about equally often. It is sometimes hereditary, and may affect several members of the same family.

The eruption may occur on any part of the body except the palms and soles, its seats of election being the abdomen, chest and thighs, the face, ears and neck, the genitals and the backs of the hands and feet. The lesions are always bilateral, sometimes grouped, sometimes roughly symmetrical, but usually remarkably indiscriminate in distribution. Occasionally an antecedent polymorphous erythema of varying duration may be present, but in typical cases the erythema is either absent or of extremely short duration, and an eruption of large bullæ testifies to the onset of the disease. These bullæ are hemispherical, tense, and rapidly increase peripherically, or coalesce to form blisters the size of a marble or walnut, or even larger. They may have a surrounding arcola of congestion, but its presence is atypical. Their contents are at first clear, but soon become turbid, flaky, and purulent; hæmorrhage often occurs into them in the severer forms; soon they dry up, forming crusts, or burst and discharge, forming thick scabs, the separation of which—after a variable time—leaves deep purplish stains, which become brownish and ultimately slowly disappear without leaving scars. The appearance of successive crops of fresh lesions—it may be daily (*P. diutinus*)—is very characteristic, and explains the coetaneous existence of lesions of different ages—e.g., erythema, blebs, ulcerations, scabs, pigmentation. After recovery, universal desquamation

generally takes place, even from areas unaffected by the disease—*e.g.*, palms, soles. The duration of the disease is indefinite; it may last weeks or months, or may run on for years with periodic aggravations. Even after apparently complete recovery, the tendency to relapse after varying intervals is very marked, and eminently dispiriting.

The *constitutional symptoms* are often surprisingly trivial, but in some cases, especially in old persons and children, each outbreak is preceded by rigors and fevers, sometimes with delirium. The amount of itching, burning and tension is very variable, but occasionally these subjective symptoms are intense (*P. pruriginosus*), and in great part account for the sleeplessness, which is often one of the most troublesome complaints, and undoubtedly plays an important rôle in the production of the extreme exhaustion, which results in death.

The most rapidly fatal cases, however, are those in which the mucous membranes are attacked; in them, as in allied diseases of mucous membranes, bleb-formation is not distinct, or is of very ephemeral existence, owing to rapid maceration and removal of the wall of the bleb; early ulceration thus occurs, and results in the production of diphtheritic-looking lesions. The mouth is generally first affected, the tongue swells, the breath is fetid, salivation is copious, and dysphagia ensues from involvement of the œsophagus. The vagina is often affected in like manner. Diarrhœa results from a similar condition in the large intestine, and the occurrence of pneumonia and nephritis, which may supervene, is probably due to an analogous process. In such cases a lethal termination is almost invariable, and generally after a short duration of the disease.

Pemphigus affecting the conjunctiva presents some special features; occasionally it occurs either long previously to, or independently of, skin lesions, the conjunctivæ undergoing a process of so-called "essential shrinking," which results in thickening and opacity of the cornea, and finally in atrophic destruction of the eyeball.

In the extremely rare form of the disease termed *P. Vegetans*, the bullæ on the mucous membranes precede those on the skin by days, and even weeks. They arise most frequently in the axillæ, or groins, and on the backs of the hands and feet. After rupture, they leave ex-

tensive excoriations, which have little or no tendency to heal, but ulcerate deeply and fungate, discharging offensive, viscid fluid. Recovery may occasionally take place, but multiple epitheliomatous growths are very apt to arise from the lesions, the patient dying from profound cachexia.

Pemphigus Foliaceus is another rare form of the disease, very dissimilar at first sight to *P. vulgaris*, but it has been observed to result from repeated attacks of the latter. The bullæ are small, never quite filled with fluid, and, therefore, flaccid and flat; they come in rapid crops, and so soon burst at the periphery that careful observation is often necessary to verify their existence as blebs. The resulting ulcers have little tendency to heal, and piled-up-scales, crusts and scabs—aptly compared to flaky pie-crust—are formed, which exhale a peculiarly offensive odour. There is more diffuse erythema than in *P. vulgaris*, and the whole body-surface is ultimately involved; the hair and nails fall out, the eyelids become everted, the nasal and buccal orifices dilated. Finally, the mucous membranes are involved, the constitutional disturbance is great, and the patient dies in an exhausted "typhoid" condition.

Pathology.—This is very obscure, but recent researches have thrown some light upon it. Probably the primary change is in the vaso-motor centres in the spinal chord, bleb formation being common in many of its diseases, especially myelitis, spinal meningitis, tabes dorsalis and progressive muscular atrophy. Local irritants—*e.g.*, pressure—may determine the localization of blebs, and, generally speaking, irritant lesions are more apt to produce the disease (or conditions similar to it) than paralytic ones. Evidences of inflammation and degeneration have been repeatedly demonstrated in the peripheral nerves, but the question whether these are primary or secondary is still a moot one.

The bullæ result from rapid serous effusion among the loose cells of the rete Malpighii, which soon filters through them to raise the granular and horny layers of the cuticle to form the roof of the bleb. Diapedesis of leucocytes, hæmorrhage, &c., ensue, according to the intensity of the process. In cases fatal from diarrhœa, extensive and deep ulceration of the large intestine has been observed.

Diagnosis.—After the preceding description, the differential diagnosis from

other vesicating diseases may be briefly dismissed. Scabies in children, impetigo, bullous dermato-syphilis, herpes, vesicating urticaria, and self-inflicted injuries with blistering agents, may present some superficial resemblance to *P. vulgaris*, acute or chronic. The relationship to erythema multiforme has been already referred to. Dermatitis exfoliativa (pityriasis rubra) and universal lichen planus may simulate *P. foliaceus* very closely.

Treatment must be constitutional as well as local, and prime importance must be attached to careful nursing. Complete rest in bed is, of course, necessary. The diet must be nutritious, and alcoholic stimulants—preferably wine—are often indispensable. A certain number of cases yield to arsenic freely administered, and with the usual precautions, but, unfortunately, the drug is by no means invariably the “magic wand” some enthusiastic partisans have described it as being. In a large number of cases, especially where the mucous membranes are involved, opium is of signal service; to ensure its full benefit, the remedy must be pushed and insomnia relieved. Iron and quinine may also be of service.

Local treatment varies with the phase of disease present. Mild forms may be simply dusted with oxide of zinc powder, salicylated starch, or lycopodium, and the parts wrapped in cotton wool. In severer cases the blebs should be pricked before these remedies are applied. Great relief is often experienced by swathing the parts in cloths soaked in carron oil, calamine liniment (calamine $\mathfrak{D}\text{ij}$, zinc oxide $\mathfrak{z}\text{ss}$, lime water and olive oil, of each, $\mathfrak{z}\text{ij}$), or weak carbolic oil. When the condition is subsiding the glycerole of lead subacetate (1 to 6 of water), or milk lotion (liq. plumbi subacetatis $\mathfrak{z}\text{ij}$ to $\mathfrak{z}\text{ij}$) are clean and convenient lotions. In the later stages, when the lesions are drying, oleates of zinc or bismuth, borax, &c., in the form of ointments, have their uses.

In the severest forms no treatment is equal to that of the continuous tepid bath, which affords the greatest relief to the sufferings of the patient, and may apparently be employed for an indefinite period of time. The fœtor of *P. foliaceus* and *P. vegetans* is best masked by dusting with iodol; while chlorinated soda gargles ($\mathfrak{z}\text{j}$ of the liquor to water $\mathfrak{z}\text{vj}$) are specially useful for the affections of the mouth.

J. J. PRINGLE.

PERCUSSION.—A method of physical examination in which some part of the body is struck with a view either to elicit sound or to estimate density of substance.

In the methodical examination of the chest and abdomen the act of percussion follows that of palpation.

A slight difference in resonance brought out by an experienced examiner can be easily appreciated by others, but it requires long practice before the student is able to elicit the true note for himself, percussion being by far the most difficult of the arts of physical diagnosis. As an indication of the condition of the subjacent structures the degree of “resistance” experienced on percussion is only second in importance to the alteration in sound.

Method of Percussing.—The use of any instrument, either in the form of a hammer as *plessor* or a flat piece of ivory as *pleximeter*, is, in this country at least, now almost a thing of the past.

The best pleximeter is the finger, the middle finger of the left hand being generally used. It must be applied firmly to the part, and should be struck with one, two, or three fingers of the right hand, the fingers being flexed, the blow delivered from the wrist, and not from the elbow, and vertically to the pleximeter.

Light percussion is best when it is desired to elicit sound from the parts immediately subjacent or to map the outline of the thoracic or abdominal viscera, also whenever there is tenderness of the chest wall and, speaking generally, when examining the front of the chest. Over the supra-spinous fossæ and inter-scapular regions, however, it is often necessary to give a firm blow in order to bring out slight differences in resonance. This is sometimes termed “deep” percussion.

The clavicles are percussed by tapping them directly with the finger. It is often possible to make out slight differences in resonance by percussion of the clavicles when no variation from the normal can be detected elsewhere; this step should therefore never be omitted in the examination of doubtful cases of apical phthisis.

The sounds elicited from different chests and from different parts of the chest vary considerably; it is therefore essential in all cases to compare the note obtained over any spot with that from the corresponding part on the opposite side; interspace must be compared with

interspace, clavicle with clavicle, and rib with rib, the pleximeter finger being similarly applied and struck with equal force in each case.

In percussing the back of the chest the patient must be directed to lean forwards, to fold the arms and to "let the shoulders drop," so as to completely relax the scapular muscles.

Theory of Percussion Sounds.—As already stated, percussion is an art only to be acquired by long practice, and its acquisition and application are but little assisted by a knowledge of the various conflicting theories which have been from time to time put forward to account for the normal and abnormal sounds so elicited.

It is now accepted by most writers that the sound which is obtained when the healthy chest is percussed is mainly due to "the vibration of the thoracic walls alone" (Bristowe), and that any condition which interferes with the vibration of the chest walls alters the percussion note. According to another view, however, the middle-sized and largest bronchia are the seat of the vibrations which produce the normal percussion tone.

The nomenclature of percussion sounds is almost as confusing as that of auscultation, but for the reason stated under that heading the terms mentioned in the Provisional Report of the Committee of the International Medical Congress have been here adopted.

Before proceeding to describe them, it is necessary to refer to some of the synonyms in ordinary use and also to describe the normal percussion signs. The term "dulness" is held to imply absence of "tone" (Gee). "Tone" being the result of the regular succession of impulses which are present in a musical sound, but lacking in a mere noise.

Not only may the normal tone be lost, but "adventitious" tones may be acquired which vary much in "pitch." Of these, the highest pitched tone is that produced by percussion over a bone (osteal); next in descending scale comes a tone resembling that produced by percussion of the trachea when the glottis is open (tubular or tracheal); the lowest pitched tone, being that produced by percussion over a hollow cavity, containing air, *e.g.*, the stomach (tympanitic). The tone over healthy lung (normal percussion tone) comes in point of pitch after the tracheal tone.

Normal Percussion Sounds.—By long practice a physician is able to form for

himself a normal standard of resonance for different regions of the chest, regard being had for the condition of the parietes and other considerations. This is of service when the percussion note of healthy lung cannot be obtained owing to the presence of disease in corresponding areas on both sides of the chest.

Taking the front of the chest from above downwards, the normal condition of the percussion sounds is as follows:—

Resonance commences about $1\frac{1}{2}$ in. above the clavicle; it is equal on the two sides until the sound is modified owing to the presence of the liver on the right side, and on the left of the uncovered portion of the heart.

The *liver dulness* commences at the sixth rib in the nipple line; it may be said to be bounded above by a horizontal line extending outwards on a level with the base of the ensiform cartilage, and below by the costal margin in the mammary line, in the median line it extends about $1\frac{1}{2}$ in. below the base of the ensiform cartilage. On the left side the outline of the *præcordial dulness* is normally roughly triangular, being bounded externally by a line drawn from the centre of the sternum opposite the junction of the fourth costal cartilages to the apex beat in the fifth interspace an inch within the mammary line, below by a horizontal line drawn from the latter point inwards, internally by the mid-sternal line uniting the two.

The *splenic dulness* extends from the ninth to the eleventh rib on the left side, in the posterior axillary line; it is oval in area.

Behind, the percussion note in the supra-spinous fossæ, owing to the thickness of the muscles, is less resonant; in the inter-scapular region it is somewhat more resonant, and in the infra-scapular region the note is almost equal to that beneath the clavicles.

The lower margin of resonance on the right side is at the tenth rib, and on the left at the eleventh rib or thereabout.

The following varieties of morbid percussion sounds are generally recognized:—

Increased Resonance; Hyper-resonance.—This sound has the quality of the exaggerated normal percussion note, combined with a trace of the tympanitic note; it is of more marked intensity than the normal note and of lower pitch. It is elicited by percussion over emphysematous lung.

Tympanitic Resonance.—A somewhat musical sound of varying pitch, heard on percussion over distended stomach or

bowels, or over a pleural cavity containing air, or over a very large pulmonary cavity.

Skodaic Resonance.—A clear high-pitched sound of tympanitic quality, produced on percussion over the upper part of the chest (infra-clavicular region especially) when the pleural cavity contains fluid. It is believed to be due to the relaxation of the upper part of the lung which, however, still remains in contact with the chest wall.

Diminished Resonance.—Dulness varying in degree. A sound shorter, sharper, and higher in pitch, and lacking the tone of the normal note. It may be of a quality similar to that produced by percussion over a piece of wood (wooden), or a bone (osteal). The sound usually signifies either incomplete consolidation or displacement of the lung, or the presence of some morbid condition of the pleura. With diminished resonance there is almost always increased resistance on percussion.

Absence of Resonance; Absolute Dulness.—A high-pitched note from which all tone is absent. The sound is elicited by percussion over a pleural cavity containing fluid, or over completely consolidated lung or a solid growth within the chest, in contact with the pleura.

Amphoric Resonance; Tubular Percussion Note.—A sound similar to that obtained by percussing the trachea with the glottis open, usually produced over a large superficial cavity, with free bronchial communication, and often accompanied by the "cracked-pot sound."

Cracked-pot Sound; Bruit-de-pôt-fêlé.—A sound having an amphoric and slightly metallic quality produced on percussion over a superficial cavity, with slightly yielding walls and free bronchial communication, the glottis being at the time open.

J. K. FOWLER.

PERICARDIUM, DISEASES OF.

—Under this heading the following affections of the pericardium are described:—

1. Pericarditis.
2. Pericardial Adhesion.
3. External Pericarditis.
4. Hydropericardium.
5. Hæmopericardium.
6. Pneumopericardium.

1. *Pericarditis.*—Inflammation of the pericardium accompanied by an effusion of fluid within the pericardial sac, may be the result of some morbid condition of the blood, as in acute rheumatism, scarlatina, measles, small-pox, septicæmia, nephritis, &c.; or it may be due

to extension of disease from neighbouring organs, such as the heart, pleura, lungs, bronchial glands, mediastinum, œsophagus, vertebræ, ribs, sternum, mammary gland, or peritoneum. In the great majority of cases the pericardial inflammation is dependent on acute rheumatism, chronic nephritis being the next most common cause.

Tuberculosis is not unfrequently concerned in the production of pericarditis. In one form the pericardium is involved in common with the pleura or peritoneum without similar disease elsewhere. At other times caseous mediastinal glands, or pleural tuberculosis, occurring in the course of pulmonary phthisis, may lead to pericarditis by extension, and occasionally the pericardial affection is part of a general tuberculosis. Pericarditis may supervene in the course of acute pneumonia, either as the result of extension or of toxæmic causes. In rare cases the affection can be traced to direct injury, and at times it appears to develop without any definite cause (idiopathic pericarditis).

SYMPTOMS AND COURSE.—In cases where the effusion is not very extensive, there may be no definite symptoms, though in individual instances pericarditis occasions severe pain in the præcordial region and epigastrium. Large collections of fluid are invariably associated with a sense of oppression, or even with severe dyspnoea, and palpitation is frequently complained of. Dyspnoea is to be attributed to the small amount of blood entering the heart and passing through the lungs, diminished pulmonary circulation leading to imperfect oxidation of the blood, with dyspnoea as its necessary consequence. Anæmia of the arterial system is very apt to give rise to cerebral symptoms, drowsiness, delirium, headache. Acute pericarditis is attended by a varying degree of pyrexia, and occasionally is ushered in by a distinct rigor. In other cases the onset of the affection is very insidious, and especially in the subjects of nephritis, pericarditis may escape detection altogether, as it commonly develops during the later stages of the disease. The existence of pericarditis can seldom be inferred from symptoms, and for its recognition we must depend on physical examination. In cases of long-continued effusion, a degree of venous stasis may be induced, resembling that which occurs in affections of the mitral valve. At the same time, however, it must be stated that this condition is often the result of more

than one cause, the effects of mechanical pressure being supplemented by the superposition of myocardial debility, which may depend on combined valvular disease and pericarditis.

Effusion into the pericardium occurring in the course of acute rheumatism is rarely fatal, though occasionally the amount of fluid may be so extensive as to endanger life from the effects of pressure upon the heart and large vessels. Absorption is usually a slow process, except when the effusion is a small one, and some degree of adhesion of the visceral and parietal surface usually results. In cases of pneumonia and renal disease, pericarditis is an ominous symptom, and generally augurs a fatal termination. Tubercular pericarditis is seldom accompanied by much effusion, and, as a rule, does not occasion marked symptoms. Purulent effusions are commonly fatal. The complications that are liable to arise are to be regarded as the effects of pressure. Thus dysphagia, aphonia and hiccup have been attributed to compression of the œsophagus, recurrent laryngeal, and phrenic nerves respectively. Large effusions exercise pressure on the left lung, and so increase the existing dyspnoea. Thrombosis of the left innominate vein has been known to result from pericardial effusion.

Patients suffering from this disease generally have a pale, ashy complexion, and some distension of the veins of the neck is often visible. The face betrays anxiety, and the respiratory movements are increased in frequency. Orthopnoea is frequently observed; but in some cases of extensive effusion the decubitus is dorsal, the object being to diminish the anæmia of the brain as far as possible.

PHYSICAL EXAMINATION OF THE CHEST.—*Inspection* reveals bulging of the præcordia, and effacement of the intercostal spaces. At times the chest walls are slightly œdematous. The impulse of the heart is indistinct, and may be invisible.

Palpation.—The apex beat is feeble, and the impulse is often diffused. Sometimes the apex beat appears to be situated in the fourth intercostal space, but in such cases the impulse is probably communicated from the right ventricle, the apex being separated from the chest wall by the effused fluid. A friction fremitus may occasionally be detected when the hand is placed over the præcordia.

Percussion.—The area of cardiac dul-

ness is increased. In the early stage, when the patient is in the recumbent position, the presence of pericardial effusion is first detected at the base of the heart, the dulness reaching up to the second or third rib on the left side. As the effusion increases, the præcordial dulness assumes a pyriform or roughly triangular shape, the apex pointing upwards, the base downwards.

These changes in the form of the cardiac dulness are thus explained.

Owing to the fact that the pericardial sac is more loosely disposed around the great vessels at the base of the heart than elsewhere, the fluid accumulates here in the first instance, but when the pericardium becomes further distended the effusion separates the two surfaces of the serous membrane in all directions, and the fluid gravitates towards the most dependent part. The area of dulness is greater when the patient sits up than when he lies down, inasmuch as in the latter case the fluid has a tendency to sink behind the heart. Changes in position are not uncommonly attended by a shifting of the line of dulness to the right or left.

In some instances the præcordial dulness extends further to the left than the position of the apex beat, owing to the distension of the pericardial sac.

Auscultation.—When the amount of effusion is not sufficient to separate the pericardial surfaces completely, a friction sound or rub is heard, corresponding more or less accurately in rhythm with the movements of the heart, but in some cases, and these often of a very acute character, no friction sound can be detected at any period of the disease. Pericardial friction is generally most marked towards the base of the heart, though it may be audible over the whole cardiac region. The rubbing sound is commonly systolic, but it may be both systolic and diastolic. The distinction of pericardial friction from an endocardial murmur is generally, though not invariably, an easy matter. Pericardial friction is often less accurately coincident with the heart sounds, it is rougher, more grating or creaking in character, and seems to be closer to the ear. The localization of the sound does not always agree with the point of maximum intensity of the different endocardial murmurs, moreover, it does not show the same tendency to propagation in definite directions, and is often heard over a very limited area. The loudness of the friction sound is usually increased by pres-

sure with the stethoscope, causing the two roughened surfaces of the pericardium to come closer together. Variations of intensity are often produced by a change of posture, friction being most distinctly audible in the upright position. As the effusion increases and separates the pericardial surfaces, the rub is no longer heard, and the heart sounds become weak and distant.

The degree of effusion cannot be determined solely by the extent of præcordial dulness, a point which should always be borne in mind. Cardiac dilatation, especially if it be combined with retraction of the margins of the lungs, may simulate an extensive effusion when the amount of pericardial fluid is comparatively small. Large effusions, on the other hand, sometimes give rise to very little increase of præcordial dulness when they gravitate to the posterior aspect of the serous sac. Emphysema also masks the existence of pericardial effusion to a considerable extent. Depression of the diaphragm, liver and spleen may be caused by large pericardial exudations. When the left lung is compressed, dulness to percussion and weak breath sounds are discovered at the posterior base. In cases of large effusion the pulse is generally weak, small and irregular, and its frequency is increased. It should, however, be remembered that the condition of the pulse is determined not merely by the amount of effusion, but also by the nutrition of the myocardium. In some cases a "pulsus paradoxus" is observed (*vide* External Pericarditis).

DIAGNOSIS.—Pericardial friction is the only pathognomonic sign of pericarditis, but this adventitious sound is sometimes wanting, when the conditions necessary for its production are present, viz., roughened surfaces without much effusion. Absence of the characteristic rub in these cases is believed to depend on weakness of the cardiac contractions. A pleuro-pericardial friction sound depending on roughening of the pleural surface in the vicinity of the heart, and commonly audible at the margins of the cardiac area, may sometimes be distinguished from true pericardial friction by observing that the sound is modified when the patient holds his breath, but at times an accurate decision is impossible.

When copious exudation has occurred and friction is no longer audible, the diagnosis of pericarditis can usually be made by attention to the following points:—The peculiar shape of the præcordial dulness, enfeeblement of the

impulse and sounds of the heart, and the occasional but characteristic relation of the apex beat to the left margin of the cardiac dulness. When pericarditis is complicated by effusion into the pleura, diagnosis may be impossible in the absence of a pericardial friction sound.

PROGNOSIS.—The prognosis depends to a great extent on the nature of the primary disease. When pericarditis appears in the course of rheumatic fever, the prognosis is favourable, whereas in chronic cases and in those which are complicated by valvular disease, the chances of recovery are not so good. Pericarditis, when secondary to pneumonia or renal disease, is generally fatal.

MORBID ANATOMY.—The changes met with in pericarditis are very similar to those that accompany inflammation of other serous membranes. The surface of the pericardium first becomes dull, slightly injected and roughened, and subsequently a fibrinous exudation occurs. The process may stop at this point, but very commonly an effusion of fluid ensues. The effusion is almost always sero-fibrinous in acute rheumatism and renal disease. Purulent exudation is generally a consequence of suppuration in adjacent organs (*e.g.*, empyema, spinal, costal, or sternal abscesses), perforation of the pericardium by new growths of the œsophagus, or pyæmia.

A hæmorrhagic character is occasionally imparted to the effusion, when the morbid process depends on tuberculosis, or malignant disease, and in the rare instances in which pericarditis develops in the course of scurvy or purpura. Putrefactive changes may be set up in certain cases of purulent effusion, and it has been asserted that this event is at times associated with the formation of gas in the serous cavity.

Sero-fibrinous effusions may become absorbed without leaving behind them any trace of their existence beyond a localized or diffused thickening of the serous membrane. More frequently, acute pericarditis is succeeded by a chronic stage in which the fibrinous exudation undergoes organization, and adhesion of the visceral and parietal pericardium is produced. When the adhesion is partial, effusion is apt to recur from time to time, and ultimately the two surfaces of the pericardium may become universally adherent. General or localized adhesions are not unfrequently the results of an essentially

chronic pericarditis. Calcification is occasionally associated with fibrous thickening and adhesions. The milk spots or white patches, so often met with on the visceral pericardium, especially over the anterior surface of the right ventricle, may be sequelæ of acute inflammation, but more often they represent a process that has been chronic from the first.

The inflammation of the serous membrane at times involves the outer fibrous laminae of the pericardium (external pericarditis), and may thence extend to the pleuræ. In other cases, external pericarditis is secondary to pleurisy or inflammatory affections of the mediastinum, the serous surface of the pericardium being frequently unaffected.

As the result of these changes, fibrous adhesions are apt to form between the pericardium, sternum, and large vessels at the base of the heart (mediastino-pericarditis, mediastinitis fibrosa).

Inflammation of the pericardium is always to some extent propagated to the muscular walls of the heart, though the degree of myocarditis produced varies considerably. The peripheral layers of the myocardium become more or less softened, and acquire a dull yellowish appearance. At times when the pericardial thickening is very extensive, the heart seems to be enveloped in a fibrous or calcareous capsule, and in such cases the cardiac walls are thin and atrophied. Dilatation of the heart is very commonly induced, as the result of concomitant myocarditis and fatty degeneration. Hypertrophy is never a direct result of pericardial adhesion, but is due either to co-existing valvular disease or to other recognized causes of cardiac hypertrophy.

When the amount of pericardial effusion is large, the diastolic expansion of the heart is interfered with, the quantity of blood entering from the veins is curtailed, and a condition of venous stasis and arterial anæmia is produced. Extensive effusions exercise more or less pressure on the left lung, œsophagus, trachea, recurrent laryngeal nerves and other neighbouring structures.

TREATMENT.—In most instances no direct treatment is called for beyond the application of a pad of cotton wool or a poultice to the præcordial region. The Germans prefer an ice-bag. Blisters sometimes seem to be of service. Iodide of potassium has been recommended to promote absorption, but its influence is doubtful.

Complete rest in bed and the avoidance of any sudden movement are of great importance. A light nutritious diet should be ordered.

When the heart's action is feeble and rapid, digitalis is indicated and alcoholic stimulants may be administered.

In cases of very great effusion, where pressure effects appear, the question of paracentesis should be considered. When this operation is contemplated, an exploratory puncture should always be made as a preliminary measure, the fourth or fifth intercostal space an inch to the left of the sternum being the point usually selected. Aspiration has proved successful in several cases, and when carefully performed, the operation is attended with very little danger.

Free incision has been practised in a few instances of purulent pericarditis with excellent results. (See a successful case by S. West, *Med. Chir. Trans.* vol. lxi.)

2. Pericardial Adhesion.—The two surfaces of the pericardium may be universally adherent without any ill effects being produced. In certain cases, however, this condition is accompanied by a marked degree of cardiac dilatation. These differences probably depend on the varying extent to which pericarditis involves the subjacent myocardium. The presence of pericardial adhesions may at times be recognized, but more often the diagnosis can only be conjectural. A general systolic retraction of the intercostal spaces over the præcordia is the most trustworthy sign of an adherent pericardium. If the two surfaces of the serous membrane be united and at the same time the pericardium be fixed to the sternum, this phenomenon is more likely to occur. In such cases rebound of the chest wall and sudden collapse of the jugular veins may occasionally be observed during diastole. Systolic recession confined to the region of the apex beat is less uncommon and is frequently unconnected with pericardial adhesion.

The fact that the margins of the cardiac dulness are unaffected by deep inspiration and the absence of any shifting of the apex beat with changes in the patient's position have also been regarded as symptoms of adherent pericardium, but neither of these signs can be relied upon.

3. External Pericarditis.—This condition may give rise to a pleuro-pericardial friction sound. When fibrous adhesions have formed between the

sternum, external pericardium and great vessels at the base of the heart, a peculiar modification of the pulse is sometimes observed (Griesinger and Kussmaul). This consists in distinct intermissions of the pulse corresponding with each inspiration (*pulsus paradoxus*). This alteration of the pulse has been attributed to tightening of the adhesions around the aorta by the descent of the diaphragm and by the outward movement of the ribs and sternum which occurs during inspiration (*see PULSE*).

The fact that the "*pulsus paradoxus*" has also been observed in pericardial effusion and in other conditions, *e.g.*, in a case of extensive effusion into the left pleura, proves that the explanation just mentioned does not suffice for all cases. Rosenbach found by experiment that when the intra-pericardial portion of the vena cava inferior was compressed to a certain extent, a typical "*pulsus paradoxus*" was produced. Each deep inspiration gave rise to complete constriction of the vein as it passed through the diaphragm, a fall of blood pressure and weakening of the heart sounds occurring simultaneously. These facts prove, as Rosenbach points out, that the "*pulsus paradoxus*" may be due to insufficient entry of blood into the heart.

4. **Hydropericardium.**—Dropsy of the pericardium is generally the result of renal disease, valvular lesions, or chronic affections of the lungs. Pericardial friction does not develop, but with this exception the physical signs are the same as in pericarditis with effusion, and the differential diagnosis of the two affections is not always easy.

Treatment must be directed to the primary disease, and when the amount of fluid is very great, paracentesis may be resorted to.

5. **Hæmopericardium.**—An effusion of blood into the pericardial cavity commonly depends on bursting of an aortic aneurysm, but this accident may also be caused by rupture of the heart or of aneurysms of the coronary arteries. Rupture of the heart may be the result of myocarditis, infarction, fatty degeneration or cardiac aneurysm, or it may be due to direct injury.

Death is speedily produced from the effects of pressure upon the heart.

6. **Pneumopericardium.**—The presence of gas in the pericardial sac is either the result of traumatic causes, or of communication between the pericardium and air-containing organs like the œsophagus, stomach, or lung, or the

pleura. In the latter case, perforation depending upon ulcerative or suppurative processes, almost always leads to purulent pericarditis, which terminates fatally. The physical signs of this rare condition are, tympanitic resonance over the præcordial region, metallic gurgling or splashing sounds, synchronous with the heart's movements, and amphoric echo of the heart sounds, endocardial murmurs, or pericardial friction. Slight dulness in the situation of the heart may sometimes be detected when the patient sits up.

PERCY KIDD.

PERIHEPATITIS.—Inflammation of the serous covering of the liver.

This affection may occur as part of a general peritonitis, but more frequently it is secondary to some disease of the liver or is an extension of inflammation from neighbouring parts. Acute perihepatitis, in addition to its relation to acute general peritonitis, arises from extension of inflammation in empyema of the same side, from ulceration of the stomach, and where an abscess of the liver reaches the surface. Chronic perihepatitis occurs in all forms of cirrhosis and in new formations, especially syphilis and tubercle, also as a result of pressure—*e.g.*, from tight-lacing and from the pressure of a greatly hypertrophied heart, and from other causes.

Symptoms.—The chief symptom of acute perihepatitis is acute cutting pain; there may be some degree of fever with slight jaundice, and a friction sound may be heard over the seat of the pain. In chronic perihepatitis the organ is often altered in size and shape; friction may be audible, but very often adhesions prevent the descent during deep inspiration. All these signs may, however, be absent, and frequently the condition can only be inferred during life, or is discovered after death.

Diagnosis.—As already stated, it is not always possible to detect chronic perihepatitis—acute perihepatitis is liable to be mistaken for pleurisy.

Prognosis.—The prognosis depends upon the cause.

Morbid Anatomy.—In acute perihepatitis, not being part of an acute general peritonitis, a circumscribed area of the surface of the liver presents a milky appearance, and is covered with lymph. In chronic perihepatitis the capsule is much thickened, in places forming fibrous bands and wedge-shaped layers of considerable thickness, especially where there has been loss of liver substance, as in

gummatous cirrhosis and tubercle of the liver. In cardiac cirrhosis the capsule is often universally thickened, and the organ assumes a globular form from flattening of its anterior margin. Adhesions to neighbouring organs often result.

In many cases of atrophic cirrhosis accompanied by ascites a fenestrated membrane can be detached from the liver, the fenestræ corresponding to the "nodules" on the surface of the organ. A similar membrane, but of more uniform texture, is generally in such cases present over the whole surface of the peritoneum, although its presence may easily be overlooked. The perihepatitis is in such cases part of a slowly progressive chronic peritonitis. A similar membrane is often present on the pleura in cases of hydrothorax secondary to valvular disease of the heart.

Treatment.—Acute perihepatitis may be relieved by rest and turpentine stupes, or hypodermic injections of morphia. This treatment should be combined with a dose of calomel or euonymin, followed by a saline purgative. In chronic perihepatitis no treatment can be of any real service. ROBERT SAUNDY.

PERIMETRITIS (Pelvic Peritonitis).—Inflammation of the peritoneum about the uterus, having its origin in disease of the uterus or its appendages. It is also called *pelvic peritonitis*. This latter term is less convenient, because the local peritonitis resulting from disease of the uterus or its appendages is not always limited to the pelvis, and because the pelvic peritoneum may become inflamed from disease of parts other than the uterus or its appendages.

Perimetritis is always a secondary affection, produced by inflammation of the uterus, or of the tubes, or of the ovaries, or by noxious discharges through or from the tubes or ovaries, or by mechanical injuries. More particularly may be mentioned injury in labour, intra-uterine pessaries, tents, operations upon the uterus, gonorrhœa, puerperal or other endometritis, uterine cancer, uterine fibroids, ovaritis, salpingitis and tubercular disease of the tubes. It may also arise by extension from parametritis, with which it often co-exists. It is often attributed to cold.

There are three chief varieties of perimetritis: *adhesive, serous, and suppurative*. The first of these is the most common, and is often attended with symptoms so slight as scarcely to be noticed by the patient. Serous perimetritis is the least

common. Suppurative peritonitis is the most serious.

Symptoms.—Perimetritis commences with febrile disturbance and pain in the lower abdomen. There may be shivering, but there is not usually a well marked rigor. There is rise of temperature, acceleration of pulse and respiration (which is less abdominal than normal), loss of appetite and thirst. The patient lies on her back, with the knees drawn up. The pain is referred principally to the lower abdomen, and often described as worse over one ovarian region. There is tenderness on pressure, and the abdominal walls are held rigid. There is often irritability of the bladder, and there may be slight scalding pain on micturition. Defæcation is often painful, the pain more especially preceding the act. These symptoms may prove to be the beginning of general peritonitis. But if the inflammation remain merely a perimetritis, in the course of a few days they will diminish in severity, the temperature falling, and the pain becoming less. The rapidity with which improvement begins to be apparent will depend very much upon the treatment. When the intensity of the onset has subsided, pain, tenderness, slight fever and debility linger on for, it may be, weeks, gradually becoming less. When all symptoms have completely disappeared, a slight relapse is common, and may be followed by another, so that the date of ultimate complete freedom from all symptoms cannot be definitely stated. These symptoms are met with in all varieties of perimetritis, and, indeed, all kinds of pelvic inflammation. The diagnosis of perimetritis can only be made by physical examination.

Signs.—In the early stage of the disease, when the process has not advanced beyond injection of the peritoneum, and the exudation of a little inflammatory lymph, the only physical signs are pain on moving the uterus and fulness, that is, increased resistance to pressure, around the uterus. At a later stage of the disease, the exudation of lymph becomes more abundant, and is gradually organized into fibrous tissue, which, in course of time, becomes increasingly hard and dense. After the first few days, there is felt as it were a hard roof to the pelvis, joining the uterus on each side, at or a little above the internal os, dipping down behind as low as the os externum or even lower; at the sides retreating out of reach of the finger, in front not felt by the finger. The uterus is fixed,

and after a few weeks' duration it becomes no exaggeration to say that the exudation feels "as hard as a board."

In *adhesive* perimetritis, although on vaginal examination the induration closely simulates a tumour, yet on bimanual examination, which is difficult to make satisfactorily without anaesthesia, owing to the rigidity of the abdominal walls, it will be found that there is no tumour, but that the hardness is merely thickening of the peritoneum covering the pelvic viscera. All the parts in contact with this sheet of peritoneum—uterus, tubes, and adjoining bowel—are matted together by adhesions. In the interspaces of these adhesions there is often a little serous fluid, but not enough to form a distinctly outlined swelling.

In some comparatively rare cases there is a large effusion of serous fluid, which becomes enclosed in a space limited by inflammatory adhesions. This is *serous* perimetritis. Such swellings are usually behind the uterus, and displace it forwards. They may obstruct defaecation or micturition. Being bounded by matted intestine, they are often resonant on percussion, whilst from the thickness of the parts which separate them from the exploring hands, it is seldom that fluctuation can be distinctly felt.

In *suppurative* perimetritis there is a collection of pus bounded by adhesions among the bowels. Inflammation so acute as to lead to the formation of pus, is apt to spread, and an abscess may form near the uterus; or the inflammation may be merely adhesive in the neighbourhood of the uterus, and suppurative at a part of the peritoneum remote from it; or there may be several abscesses at different parts. Hence perimetric abscesses are not at all regular in their position and outline, and the largest are not globular, but sinuous, irregular and present pouches in all directions.

Diagnosis.—It is not difficult to ascertain the existence of perimetritis. The pain, the fever, the fixity of the uterus, and the induration around it, plainly indicate the disease. If the case be not seen until after the acute symptoms of the onset have subsided, we may feel in doubt whether the swelling present behind and around the uterus is the result of inflammation, or a hæmatocele. An opinion can only be formed by the history of the mode of onset; it is not possible from the character of the swelling, to tell whether Douglas's pouch is occupied by blood, pus, or serum. In

perimetritis, the difficulty is to ascertain what morbid conditions underlie and co-exist with it. To do so may be impossible in the acute stage of the disease, but as the perimetritic symptoms subside, the symptoms and signs of any disease which remains, such as diseased tubes, ovarian cysts, or uterine fibroids, will become clearer. Serous perimetritis may form a swelling very difficult indeed to distinguish from an ovarian cyst; if a tumour, apparently a cyst, be discovered for the first time as an attack of perimetritis is subsiding, it is well to wait a few weeks and watch its course before deciding on an operation.

Prognosis.—In perimetritis, if the cause which produced it be not still in operation, the tendency is to recovery. In the course of time effused serum is absorbed, adhesions stretch and become looser, and the viscera are less firmly fixed, the adhesive bands may at length become elongated, so as to in no way interfere with the functions of the organs they bind together. But if the cause persist, repeated attacks are likely to occur. When the patient has had many attacks, as is often the case when the tubes are diseased, there may be great fibrous thickening of the peritoneum, and extensive and dense adhesions. These generally give rise to persistent pain. If the uterus be flexed, perimetritis may lead to its being fixed in the bent position, and when so held secretions may accumulate in its cavity, and hæmato-, hydro- or pyo-metra be the result. On the whole, therefore, the prognosis, although favourable as to risk to life, should be guarded as to the patient's future good health. In suppurative perimetritis the prognosis is more unfavourable than in the other forms.

Treatment.—The patient should be kept in bed as long as either fever or much pain is present. The pain of perimetritis is seldom severe enough to require opium, and if there be severe pain it seldom lasts longer than a few days. The drug, when needed, is better given locally, in the form of morphine suppositories, or a liniment of oleate of morphine (2 to 4 per cent.) may be painted on the abdomen, or laudanum may be sprinkled on poultices. Opium should be omitted as soon as possible, as it disturbs digestion, and by confining the bowels, favours the formation of scybala, the passage of which past the inflamed pelvic peritoneum, and the straining called for to expel them, may cause the patient a great deal of suffer-

ing. To relieve this, laxatives should be given, so as to keep the stools soft. Another reason for caution in the use of opium is that slight pain may persist long, and if the patient be accustomed to look to opium for relief, she may need increasingly large doses, and in time become unable to do without it. The best means of at once lessening inflammation and relieving pain is the use of counter-irritation, such as poultices of linseed and mustard (mustard 1, linseed 4: mix the mustard with the water before the linseed); turpentine stupes; small blisters, one every three or four days; or lin. iodi every other day, or less often. Aconite or belladonna may be used locally. Pessaries of aconitia (gr. $\frac{1}{2}$, gelatin mass $\mathfrak{D}\text{ij}$) are useful. Alcohol is better withheld, unless the pulse be so feeble as to clearly indicate its use, or it be found that small doses aid digestion. Regulation of the diet is not so important in this form of local peritonitis as in that which depends upon disease of the alimentary canal. Under treatment conducted on these lines, most cases progress slowly towards recovery although there may occasionally be a slight relapse.

It may be found within the first few days that the case, though carefully treated, is not tending towards recovery; the symptoms pointing rather to the spread of the inflammation. The pain becomes worse, the tenderness more diffused, the fever higher, and the prostration greater. Acute symptoms such as these may quickly develop in a case which seemed to be going on favourably. Under such circumstances it is clearly not advisable to wait for the peritonitis to become general, or for the patient to become hopelessly exhausted. The abdomen should be opened without delay, the site of the inflammation, which will probably be the tubes or ovaries, sought for, the products of inflammation removed if possible, and the abdomen washed out and drained.

In serous, or in suppurative perimetritis pressing on the bowel or the bladder, or associated with persistence of severe febrile symptoms, Douglas's pouch may be bulged downwards by the inflammatory effusion. In such a case, it will be proper to tap the swelling with an aspirator needle, and having thus ascertained beyond doubt that it is a fluid effusion, to make a free incision, and let the serum or pus out. But if, although the character of the symptoms calls for

interference, there are no clear indications that the effusion is so situated that it can be let out by vaginal incision, abdominal section is to be preferred.

G. E. HERMAN.

PERINEPHRITIS. — Inflammation of the fibrous and fatty tissue surrounding the kidney.

Perinephritis may be primary, that is, independent of disease in any other parts, or secondary. A further division of secondary perinephritis may be made according as the primary disease is situated in the kidney itself, or in some other part, not necessarily near the kidney.

The primary form is most frequently due to traumatism, in the shape of blows upon the lumbar region, bruises, or actual wounds penetrating to the perirenal tissue. It may also in some cases be the result of strain of the psoas and lumbar muscles, or of sudden chill of the heated body, and it arises occasionally in the course of pyæmia and the specific fevers.

Secondary perinephritis is more frequent. Its most usual cause is some previous disease of the kidney itself. This may be an inflammation of the kidney or of its pelvis, which, however induced, affects the perirenal tissue by direct extension, or which, being itself suppurative in character, causes extravasation of pus into the surrounding parts.

Tumours, hydatid and other cysts, and tubercle of the kidney may so irritate the surrounding tissue as to produce inflammation. Calculus of the kidney is a most frequent cause of perinephritis. It acts either by inducing an inflammation of the kidney tissue, which, by direct extension, or by rupture of an abscess, affects the perinephric tissue, or by causing ulceration of the pelvis of the kidney and extravasation of urine. The stone itself may come to lie actually outside the kidney. It is to be noted also that such a renal fistula may be caused by other conditions, such as tubercle, tumour, or hydatids of the kidney. Further, disease of other parts even far distant from the kidney may cause perinephritis. Thus, typhlitis and perityphlitis, parametritis (pelvic cellulitis), the result of operations upon, or of inflammation of the pelvic organs, ulceration and perforation of the colon, and of the gall-bladder, abscess of the lung or empyema, and abscesses in connection with caries of the vertebrae, may by extension along the planes of con-

nective tissue, affect the perirenal tissue, whilst leaving the kidney intact.

When not the result of rupture of a renal abscess, or of extravasation of urine, perinephritis is frequently non-suppurative. It then shows itself as a thickening of the perirenal tissue causing firm adhesion of the capsule of the kidney to the surrounding parts. In such a condition, the kidney is found embedded in a hardened mass, and when the organ is removed, its capsule is commonly left behind. The majority of the causes mentioned above do, however, usually produce suppuration. The abscess may be of almost any size. The pus most frequently lies behind the kidney, with the organ intervening between the abscess and the peritoneum, but it may completely surround the kidney, and may in rare cases lie entirely between the kidney and the peritoneum. The pus is often fetid even if there be no communication with the bowels. The surroundings parts are congested and often show small hæmorrhages; they may in some cases contain masses of sloughy tissue.

Symptoms.—At the commencement the symptoms are variable; they may be acute or latent, obvious or not well pronounced. They may again be masked by the symptoms of the primary disorder which causes the perinephritis. The earliest symptom is pain in the lumbar region of one side, uncertain in character, but usually dull, aching and deep seated, often shooting down to the inner side of the thigh, and sometimes accompanied by retraction of the testicle. The pain may, however, be paroxysmal, may disappear for a time and afterwards recur, and may be reflected even to the knee of the same side, as occurs in disease of the hip-joint. At the same time there is tenderness on deep pressure in the renal region, and a sense of resistance is experienced by the examining hand. The patient, too, feels a heaviness in the same locality. The position of the patient is often characteristic. He assumes a fixedly bent position, inclining also somewhat towards the affected side, and on lying down the thigh on that side is maintained in the flexed position. In sitting, the weight of the body is thrown on to the opposite tuber ischii, and in walking lameness is observed from a similar tendency to throw the weight on to the opposite leg. These constrained attitudes are due to attempts to avoid the pressure or strain upon the inflamed parts in the loin which would result from the contrac-

tion of the psoas muscle. There are at the same time the constitutional symptoms of the sub-febrile condition; a temperature slightly and irregularly raised, slight rigors, and coated tongue. The urine is febrile, and may contain a little albumen; it may also, of course, present the changes characteristic of the affection causing the perinephritis; the bowels are constipated.

Such are the symptoms of perinephritis without suppuration. When pus forms the pain and also the constitutional symptoms are increased in severity. Rigors and sweating are now pronounced features, and a more or less definite tumour appears in the loins, obscurely fluctuating and sometimes attaining a great size. The skin over the part may be œdematous, and may also be reddened. Nieten and Morris have each related a case where œdema of the lower extremity was an early sign of pus formation.

In the early stages, before pus has formed, the inflammation may undergo resolution and spontaneous cure.

When pus has once formed, unless it be liberated early, it will burrow in various directions. Most frequently it makes its way upwards, bursting into the pleura, causing empyema, or discharging itself directly into the bronchi, or else proceeds downwards in the sheath of the psoas muscle, showing itself at the groin. It may also, though more rarely, reach the cellular tissue of the iliac fossa, or of the pelvis, and may make its exit at Poupart's ligament, or at one or other of the foramina of the pelvis, or may burst into the vagina or bladder. Again, the pus sometimes finds an entrance into the large bowel, or bursts into the peritoneum; it may make its way through the kidney to the renal pelvis and the ureter, and, finally, it may open externally in the loins. By taking the latter course, the abscess finds a communication between the interior of the kidney and the external surface, by which portions of a calculus may be discharged. The fistula so produced may remain patent for years.

Diagnosis.—The symptoms may, especially in the early stages, be mistaken for those of disease of the hip-joint. The unilateral pain sometimes shooting to the knee, the flexure of the thigh and the bend of the body are similar in the two disorders, but in perinephritis the pain and tenderness are situated higher up. There is no pain on pressure over the trochanter or head of the femur,

passive movements of the hip-joint are painless when the limb is flexed so as to relax the psoas muscle, and there is no alteration in the length of the limb. Disease of the vertebræ, too, may be closely simulated, especially if the pus formed in a case of perinephritis have burrowed in the psoas muscle. But in perinephritis the body is inclined to one side, more or less, and is not held so stiffly as in caries of the vertebræ. Also there is distinct lameness, not merely tenderness of gait, there is no prominence of the vertebral spines, no bilaterally radiating pains, and no tenderness over the vertebræ. Moreover, the pain of vertebral caries is greatly relieved by suspension.

The symptoms and even the signs of typhlitis and perityphlitis closely resemble those of perinephritis of the right side. The diagnosis may be made by remembering that pain and swelling of perinephritis are higher in situation than are those of typhlitis, although in the further course of the two disorders the distinction may disappear. Vomiting is more common, and peritonitis occurs earlier in typhlitis than in perinephritis. Tumours of the kidney, lumbago, and fecal accumulations may possibly be mistaken for perinephritis; but their diagnosis will be clear from the account of the symptoms of perinephritis already given.

Prognosis.—If no pus have formed, the prognosis is favourable; but cases are rare which go on for any length of time without suppuration. Primary perinephritis, if recognized early, and the pus liberated by free incision, admits of a favourable prognosis. In all other cases the prognosis is grave. Death takes place from exhaustive suppuration, from pressure, or from severe peritonitis, pleurisy or pneumonia. Much depends, however, on early diagnosis and prompt liberation of pus. Even then, as a rule, the disease pursues a long and wearisome course.

Treatment.—In the early stages the measures recommended for abscess of the kidney (*q.v.*) should be adopted. Rest in bed and light diet, warm fomentations and poultices, and cupping or leeches to the loins. The bowels should be kept open after a preliminary purgation. As soon as pus is detected it must be at once liberated by lumbar incision, and search should be made for it by the aspirator if there be even a suspicion of its presence. The further treatment should be based upon the ordinary rules of surgery.

ROBERT MAGUIRE.

PERITONEUM, MALIGNANT DISEASE OF.—Malignant disease of the peritoneum may occur as a primary affection, but it is more commonly secondary to cancer of the abdominal viscera. The primary growth is situated with greatest frequency in the stomach and ovaries, and next in the uterus and pancreas, but it may be found in the rectum, large or small intestine, the testicle or the liver.

Symptoms.—The general symptoms are indefinite; abdominal uneasiness, nausea, diarrhoea, or alternating constipation and diarrhoea may first attract the patient's attention. If peritonitis occur there may be some fever. Ascites is one of the most constant symptoms, the effused fluid being generally of a brown or red colour, and at times containing so much blood that coagula form. Nodules, or tracts of induration of the omentum may be made out, or the primary tumour may be discovered. In a considerable number of cases a hard nodule may be found in the skin and subcutaneous tissues immediately about the umbilicus, produced probably by extension of the growth along the obliterated umbilical vessels. In colloid cancer the dense gelatinous masses which fill up the peritoneal cavity, and which are particularly apt to develop in the pelvis and the hypogastric and iliac regions, produce very great distension of the abdomen and absolute dulness. In these cases, especially towards their termination, the temperature is often remarkably depressed, and the patient is liable to shivering attacks with great coldness of the extremities, presenting a general resemblance to rigors, but without any elevation of temperature.

The *diagnosis* is often extremely difficult; when a malignant tumour of the stomach, ovary, or other organ is known to exist, the occurrence of ascites must excite the suspicion that the peritoneum has become secondarily affected, a surmise which will be strengthened, but not conclusively established, if the ascitic fluid be found to be blood-stained. The resemblance to tubercle of the peritoneum will be noticed. The age of the patient, and the absence of pyrexia, together with the nature of the primary lesion, if that can be discovered, will assist the diagnosis.

The *prognosis* is necessarily fatal, but the duration of the affection varies in different cases in relation with the rate of growth of the malignant tissue.

Pathology.—Peritoneal cancer may consist of a single tumour, or it may be limited to the pelvis. In typical cases of generalized peritoneal cancer, a large number of roundish or flattened granules or small tumours are stretched over the peritoneum, and present some resemblance in distribution to tuberculosis. The smallest of the tumours are, as a rule, not less than peas in size, and the majority are larger. As they increase in size the centre undergoes degeneration, and gives to the finger a sensation of softness, so that each growth is at a late stage umbilicated. At the periphery each nodule throws out processes, as it were, which tend to contract so that the serous membrane is dragged in towards the nodule; in this way the omentum is puckered up until it forms a solid mass lying transversely below the stomach; and the mesentery is thickened, indurated, and retracted; in this way also the calibre of the intestine may be greatly diminished and obstruction produced.

This description applies to hard carcinoma; soft carcinoma also occurs, but more rarely; multiple tumours commonly exist, but in the early stage are more globular, or even pedunculated, and tend later on to form large tumours.

Colloid Cancer of the Peritoneum is a distinct clinical variety produced by colloid degeneration of a true carcinoma. In its early stage it forms gelatinous nodules irregularly distributed; these quickly involve the submucous tissue and grow with great rapidity, coalescing with other nodules until the whole, or a large part, of the peritoneal cavity is filled up, and distended by soft gelatinous growth.

Sarcoma is, in most cases, secondary to gastric sarcoma. Lymphadenoma may spread from the retro-peritoneal glands along the mesentery, causing great thickening of the peritoneum and sub-peritoneal tissue; when the growth has completely surrounded the intestine, it does not produce contraction but converts the gut into a thick-walled rigid cylinder; the stomach may be similarly affected. The peritoneum is also liable to become the seat of papillomatous growths, secondary to rupture of papillomatous cysts originating in the parovarium or hilum of the ovary; these growths "are very liable to infect the whole peritoneal cavity, exhibiting the most malignant tendencies" (Doran), but in other cases they are not distinctly malignant.

Malignant disease of the peritoneum spreads in several ways: the multiple nodules probably originate by lymphatic infection, and subsequently extend by continuity of tissue. Cancer may also extend from the one to the other of two opposing surfaces of the peritoneum without the previous production of adhesions. Finally, it seems probable that portions of growth may become detached and find their way into the pelvis or other dependent parts and there set up the cancerous process.

Cancer of the peritoneum may be accompanied by peritonitis leading to adhesions between opposing surfaces, or to effusion of fluid which may be puriform. The ascites, however, must not always be attributed to this cause; it may be due to interference with the portal circulation by pressure of the new growths.

Etiology.—The disease is seldom or never observed below 30 years of age, is most common between 50 and 60, and is not uncommon at a later age. It is more often met with in women than in men.

The *treatment* can only be palliative; opium is the drug which may be given with greatest advantage, and no hesitation need be felt in administering doses sufficiently large and frequent to relieve discomfort and pain. Localized pain should be treated by fomentations, or leeches; diarrhoea by ordinary astringent remedies, and constipation by a mild laxative—preferably castor oil.

DAWSON WILLIAMS.

PERITONITIS.—Inflammation of the peritoneum may be acute or chronic, general or local.

Acute Peritonitis presents a complex of symptoms liable, especially in the early stage, to considerable variation, in accordance with the cause.

Symptoms.—In a case in which the early symptoms are not masked by some concurrent malady, such as enteric fever, the first to be observed is often a sudden rigor, or there may be vomiting, or purging, or both. Abdominal pain quickly becomes the most prominent symptom; it is generally referred at first to the hypogastric region, and the patient in sitting or standing remains rigidly bent forward. Being soon compelled to take to bed, he there assumes a characteristic attitude: he lies on his back with his shoulders raised, and knees and hips flexed; this position is assumed to relieve the abdominal pain, which is aggra-

vated by the erect or extended posture and by any movement or pressure of the abdominal muscles. For the same reason diaphragmatic respiration is abolished, breathing being mainly upper thoracic. The pain is sharp, cutting or darting, and has a burning character; there is also great tenderness, so that even the pressure of the bed-clothes is dreaded. The face is flushed, the features pinched, the eyes sunken and the expression anxious. The pulse is sharp, small, hard, wiry, and increased in frequency (100 to 150). The temperature is raised, commonly to 100° or 101° F., but it may reach 104° or 105° F. The skin is hot and dry, the tongue often furred and dry, thirst is distressing, and appetite is abolished. Vomiting is not uncommon, and it is, indeed, the rule for all food to be thus rejected. Owing to the abdominal movements, vomiting may cause great distress. Constipation is the rule, but there may be diarrhoea.

On examination of the abdomen it will be found to be exquisitely tender to the lightest touch, while deep pressure is insupportable. The abdominal muscles are rigidly contracted, so that in the very earliest stage the abdomen may appear a little retracted; later, however, more or less distension occurs, due either to gas in the intestines or fluid in the peritoneal cavity, or to both causes; when extreme, it seriously increases the existing embarrassment of respiration. Occasionally peritoneal friction may, in the early stage, be detected, either by palpation or auscultation. When fluid has collected, dulness may be detectable in dependent situations, but fluid may be masked by the flatulent distension of the intestines; for the same reason the areas of hepatic and splenic dulness are diminished. Ineffectual intestinal peristalsis may be perceptible to the eye or hand. The urine is scanty, high coloured, and deposits abundance of urates. Where the peritonitis is mainly pelvic, frequent and painful micturition may be a troublesome symptom, and is often succeeded by retention due to paralysis of the bladder.

Peritonitis from *perforation* or rupture is one of the commonest, as it is one of the most fatal, forms of the disease. The patient may be, apparently, in good health up to the moment when he is seized with sudden intense pain in the region of the lacerated organ—most often the stomach. The pain is accompanied by extreme collapse, evidenced by coldness of the surface, cold sweats,

and a small or almost imperceptible pulse. The symptoms, however, are not always so well marked, and may be entirely masked. This is especially the case in perforation of the intestine in the third or fourth week of enteric fever. In such cases it may only be possible to surmise the occurrence of perforation from the rapid fall of temperature and increased prostration, weaker pulse, cold extremities, the onset or increase of tympanites, and the presence of general abdominal tenderness. When air is present in the peritoneal cavity it tends to collect between the liver and diaphragm and abdominal wall, the result being a displacement of the liver backwards, and *obliteration of the hepatic dulness*, which thus becomes an important physical sign of perforation of the stomach or intestine. It must, however, be remembered that gas is occasionally, although probably very rarely, formed within the peritoneal cavity independent of perforation of the bowel.

Course.—Acute peritonitis terminates in death, recovery, or chronic peritonitis. In favourable cases the temperature and pulse fall, the pain and tenderness diminish, the respirations become natural, and the patient slowly recovers. In unfavourable cases the distension of the abdomen increases, whilst persistent vomiting and hiccough contribute to exhaust the patient's strength. The tongue becomes small, irritable, red at the tip and edges or all over, and tends to become dry. Sordes form on the lips, the face gets somewhat cyanosed, the eyes sunken and haggard, and pulse and respiration still more hurried. The whole aspect of the patient as he lies doubled up in bed, with anxious face, distended abdomen, dreading every movement, is now exceedingly characteristic. Death may ensue during this stage while the temperature is high; more commonly it is preceded by a fall of temperature, often to below the normal, and a sudden cessation of pain. The last-named phenomenon is of very bad omen; it appears to be a part of the general condition of collapse into which the patient has sunk. The pulse is so feeble, rapid and irregular as to be, perhaps, uncountable; the extremities are cold, the face pinched and blue, the respirations shallow and hurried, the voice a whisper. As a rule, the mind remains clear, but death may be preceded by coma, or by low muttering delirium.

Acute peritonitis has hitherto been considered as a general inflammation of

the peritoneum, but it may be limited to any part. *Local* or *circumscribed* peritonitis is always secondary to injury or visceral disease, and the symptoms of peritonitis are often masked by those of the primary malady. Circumscribed peritonitis is most commonly met with in the pelvis in association with inflammatory diseases of the uterus, Fallopian tubes (*q.v.*), ovaries or rectum: in the right iliac fossa in association with ulceration of the appendix and cæcum (*see* PERITYPHLITIS): in the right hypochondrium in association with abscess of the liver or gastric ulcer: and in the left hypochondrium in association with disease of the spleen or with gastric ulcer. The symptoms are the same in kind as those of acute general peritonitis, but vary in severity; cases of every degree may be met with, from the fully developed attack to instances in which the occurrence of circumscribed peritoneal suppuration is only discovered after death. The physical signs are limited to the affected region; pain and tenderness are localized, and probably a firm swelling with ill-defined edges will after a short time be discoverable. When suppuration has occurred fluctuation may be obtained.

In some cases the fluid effused into the peritoneum becomes blood-stained; this may be due to a very acute form of inflammation at the onset, or, at a later stage, to rupture of newly formed vessels in the false membranes.

The symptoms of **Chronic Peritonitis** are not well defined. Tenderness with uncomfortable dragging sensations, or pain aggravated by movement, may be referred to some part of the abdomen. Attacks of colic are common, and are especially liable to follow the taking of food. Appetite is impaired; constipation is commonly present, but may alternate with diarrhoea. When not due to tuberculosis, there may be no pyrexia, and all the symptoms may easily be attributed to dyspepsia. Physical examination may reveal the presence of fluid in the abdomen, but, as this may be confined by adhesions, the dullness may not shift with position. Irregular thickenings and a peculiar doughy feeling may be discovered on palpation.

The *diagnosis* of peritonitis sometimes presents great difficulties; this is especially the case for the first few hours in perforative peritonitis, during which period, moreover, death may occur. The difficulty of diagnosing peritonitis due to perforation of a typhoid ulcer has

already been mentioned. In simple colic and in lead colic the pain is intermittent or at least varies in intensity, and is relieved by pressure; the belly is generally hard and retracted, and the patient is restless. In colic complicated by hysteria the simulation of peritonitis may be closer, but the tenderness is mainly superficial, is not aggravated by deep pressure, and is not constant. Colic is said sometimes to cause a slight rise in temperature, but it would be imprudent to rely on so rare an occurrence as a guide to treatment.

The *prognosis* of acute peritonitis depends largely upon the nature of the exciting cause. Peritonitis produced by perforation of the stomach or duodenum may be fatal within two days and perforation of the intestine occurring during typhoid fever always, or almost always, causes death. Acute peritonitis is ill borne by young children, and is so serious a disease at all ages that the prognosis is always grave unless the inflammation be distinctly limited. During the progress of a case unfavourable symptoms are, change in the character of the pulse, which becomes soft, feeble, and faster; great abdominal distension; restlessness; sudden or rapid subsidence of pain without corresponding improvement in other symptoms; hiccough and the onset of collapse.

The *pathology* of the vast majority of cases of peritonitis is simple, the inflammation being due to the direct action of some irritant. In acute general peritonitis the primary lesion is more often situated in a hollow, than in a solid viscus, for perforation of the stomach, intestine or gall-bladder leads to extravasation of material which is not only irritant, but capable of producing sepsis. The same remark applies to the peritonitis which occurs as a consequence of parturition, the inflammation of the peritoneum being due to extension of suppuration from the septic cavity of the uterus. Salpingitis is another cause of purulent peritonitis, which may be in some cases septic, but is in others gonorrhœal. Septic peritonitis may also be originated by decomposition occurring in a hernial sac. Peritonitis due to intestinal obstruction is at first circumscribed, but may become general. Inflammation of solid viscera is less liable to produce general peritonitis, but circumscribed peritonitis is a common complication of hepatitis and ovaritis. General suppurative peritonitis may be due to rupture of an hepatic abscess or

of a splenic abscess (due to suppurating infarct), to rupture of a psoas abscess or of an hydatid cyst, or to suppurative nephritis. Pyæmic peritonitis probably always arises by secondary extension from local mischief. Peritonitis, generally suppurative, is a not very infrequent complication of chronic Bright's disease, occurring with the variety of kidney known as the "large white." Instances in which acute peritonitis was apparently due to sewer gas have been reported, and many believe that the disease may be produced by exposure to cold; to such cases the term idiopathic peritonitis is applied. The peritoneum may also become inflamed by extension from the pleura and pericardium; this is especially liable to occur in children, and the inflammation is commonly suppurative. Children also appear to be specially liable to sub-acute general peritonitis accompanied by more or less effusion. Some of these cases are undoubtedly tubercular, but the pathology of others is obscure, the patients recovering without surgical interference. Severe blows, even if no organ be ruptured, may determine peritonitis. The collapse and cardiac disturbance are reflex, being produced by the irritation of the peritoneum, and the hurried respiration may be in part due to the same cause.

Chronic peritonitis appears to be most commonly the result of one or more attacks of acute peritonitis, or of extension from localized acute peritonitis which has subsided; it may be limited to, and associated with, chronic disease of the liver, spleen or other viscera. It is a frequent accompaniment of tubercle and less often of cancer. In some cases it appears to arise spontaneously, the first symptom to attract attention to the belly being its increased dimensions, which are found to be due to ascites. Limited chronic plastic peritonitis appears generally to follow tapping for ascites due to cirrhosis of the liver.

The *morbid anatomy* of all cases of peritonitis is fundamentally the same, but the appearances vary greatly with the intensity and character of the inflammation. The earliest changes are dilatation of the small vessels, infiltration of the sub-serous tissue, and epithelial proliferation. Inflammatory redness is apt to be limited to two narrow longitudinal bands, parallel with, and about equidistant from, the mesenteric attachment. Exudation now takes place at the surface. This exudation may be (a) plastic, leading to the formation of a greyish lamina con-

sisting of fibrinous material enclosing cells; or (b) fluid, containing more or less numerous pus cells. Peritonitis produced by blows, and circumscribed and chronic peritonitis tend to plastic exudation, and in this way a small collection of pus may be shut off from the general cavity of the peritoneum. Even in cases where perforation of a typhoid ulcer has occurred it is not unusual to find only a small area of suppurative peritonitis, limited in all directions by plastic adhesions between the intestinal coils. In general peritonitis of the plastic type the false membranes may become enormously thickened. If the acute process subside early, organization of the false membrane occurs, and adjoining organs become firmly adherent; in this way a large part or the whole of the peritoneal cavity may be obliterated. If the exudation be fluid, the peritoneal surface, instead of becoming dull and lustreless, owing to the layer of lymph, remains glossy and becomes greasy to the touch; the fluid may be of any degree of corpuscular richness.

Every gradation between well-marked plastic and well-marked suppurative peritonitis may be met with, but, as a general rule, when the fluid is distinctly purulent, the plastic effusion is limited. In circumscribed peritonitis a collection of pus may be contained within a cavity lined and formed by organizing lymph.

Adhesions the result of acute peritonitis, if limited in extent, may become gradually lengthened, forming bands under which gut may pass and become strangulated; or a coil of intestine may be so fixed that a kink is produced, which may eventually determine an attack of obstruction. Chronic peritonitis when not due to tubercle is generally plastic, with but little effusion, and that serous. When the intestines are involved, their coils may be almost universally adherent to each other, and retracted into a single mass against the spine; or the peritonitis may chiefly affect the mesentery, diminishing its area in every direction, so that the intestine is much shortened and moored down to the vertebral column, although the coils may not be adherent to each other.

Treatment of Acute Peritonitis.—The first indication is usually held to be to procure general and local rest. The patient should be put to bed and propped in the attitude which is found most comfortable. The only drug of any proved value is opium; it should be given at once in full doses. Two grains of opium,

or its equivalent in laudanum, should be given every two or three hours, and the patient carefully watched, relief of pain being taken as an indication to diminish, but not to stop, the opium; its administration should be continued even after danger has apparently passed. The existence of constipation or of intestinal obstruction is not a contra-indication; on the contrary, its effect in acute obstruction has led to the paradoxical statement that "opium is a purgative." Morphine may be administered hypodermically. Purgatives should not be given under any circumstances. No solid food must be allowed, and, if vomiting be troublesome, nothing beyond a little ice should be taken by the mouth. Nutrient enemata or suppositories may be used if thought necessary. Local depletion by leeches (ten to thirty) is strongly recommended by some in the early stage of acute peritonitis in robust individuals. Warm local applications are most generally used, but flannels dipped in ice-water are said to allay pain and anxiety and to limit inflammation. Depression is to be combated by diffusible stimulants, of which the best are good brandy, champagne, ether, or ammonia and quinine. Stimulants should not be given as a part of routine treatment. Flatulent distension is not easily relieved; turpentine stupes may be tried, or small turpentine clysters, or the cautious introduction of the long rectal tube. If the distension be seriously interfering with respiration, and other means of relief fail, puncture of the intestines with a fine trocar may give relief. Hiccough, if not checked by opium, may be relieved by ether, by the combination of camphor with opium, by sinapisms to the epigastrium, by a small blister in the same situation, the resulting sore being dressed with morphine. Strong coffee, combined with a large dose of bromide of ammonium, may succeed, but the symptom is sometimes so intractable and causes so much pain and distress that it is necessary to resort to the inhalation of chloroform.

If the peritonitis be due to perforation of a gastric ulcer, the injunction to allow nothing, whether food or drug, by the mouth need hardly be given. In such cases, and in suppurative peritonitis due to disease of the pelvic organs, or to the rupture of a hydatid cyst or abscess, the question of performing abdominal section may be raised. At present the cases in which primary laparotomy has been performed with the object of treating per-

forative peritonitis are too few to allow of a definite opinion being here expressed.

Treatment of Acute Circumscribed Peritonitis.—This does not differ from that above detailed; the main anxiety is to prevent the inflammation from becoming general.

In *chronic peritonitis* a flannel roller carefully applied favours absorption and preserves from cold. Careful manipulation of the abdomen (massage) is believed to favour absorption of fluid and to relieve constipation. Ascites is better treated by the Turkish bath, or even by tapping, than by purgation; repeated tapping may end by greatly improving the patient's condition owing to obliteration of the cavity in which the fluid accumulated. Where local tenderness can be made out, counter-irritants, such as iodine, should be used.

DAWSON WILLIAMS.

PERITONITIS, TUBERCULAR.—There are several distinct clinical forms of this affection. (1) The peritoneum may share in a general acute-miliary tuberculosis affecting the meninges, the lungs and the abdominal viscera, and, to quote the words of Dr. Hilton Fagge, "it is often almost an accident whether a case should be regarded during life as one of tubercular meningitis, or tubercular peritonitis, or of miliary tuberculosis of the lungs." (2) The peritoneum is sometimes affected by tuberculosis which is limited to the serous membranes of the pleura, pericardium and peritoneum. (3) The peritoneum may be secondarily infected by direct continuity from tubercular ulcers of the intestine (*q.v.*), over areas which are, at first at least, limited. (4) The tubercular process may apparently originate in the peritoneum, and being accompanied by inflammation, gives rise to the condition known as tubercular peritonitis.

Tubercular peritonitis is a term commonly reserved for cases in which the affection of the peritoneum is well marked. Such cases present features which entitle them to be placed in a special clinical class. The aetiology of the condition is obscure; as observed in the dead-house it is often accompanied by intestinal tubercle, but whether as cause or effect is not clear. The lungs are affected in seven cases out of nine (Fagge), probably secondarily. The Fallopian tubes are frequently affected, sometimes perhaps primarily. It is more frequently observed in children

than adults,* though not rare in the latter.

Symptoms.—The onset is insidious; abdominal fulness, pain and tenderness, with slight evening pyrexia, wasting and general impairment of health and activity are early symptoms. Pain and tenderness may be absent, and there is not often evidence of ascites, the fulness being due to gaseous distension of the intestines. Later the pain becomes greater, and occurs in paroxysms; constipation and diarrhoea alternate; fluid may be detectable in the abdomen, and the thickened omentum, or the cords of lymph which fix the intestines together and lie in the grooves between them, may be felt. Tension of the parietes is, however, often considerable and interferes with palpation. Emaciation progresses rapidly in the later stages, the child becomes confined to bed, the face is pinched and anxious, abdominal pain is severe; tenderness is extreme and the legs are drawn up; the pyrexial excursions become higher (104° F.), the pulse rapid, the tongue dry, red and tremulous, and the lips covered with sordes. Death may be due to exhaustion, hastened often by intercurrent pulmonary disease. In children meningitis is very common.

Not infrequently the disease appears to become arrested and this arrest may be permanent even after symptoms have existed for many months or even years; more frequently relapse occurs: arrest, partial recovery and relapse may recur several times and the patient finally recover. Not infrequently inflammation extends along the track of the obliterated umbilical vessels leading to an erysipelatous redness about the umbilicus which may end in an abscess which discharges externally; occasionally a fistulous communication is established with the peritoneal cavity, which is thus emptied. It is stated that where the distension is very great the umbilicus may give way without previous inflammation.

Course.—Though usually a chronic malady, it occasionally runs an acute course lasting only four weeks.

Diagnosis in the early stage is extremely difficult; abdominal pain and

distension, with diarrhoea and wasting, may be due to imperfect digestion, but if to these symptoms be added distinct abdominal tenderness evidenced especially by the care which the patient takes to avoid a blow, or even a slight jar, the case will be looked on with suspicion and systematic observation may reveal slight nocturnal rise of temperature. Later this dread of any sudden movement or jar gives the patient a rather characteristic aspect.

Acute cases, and to a lesser degree chronic cases during periods of exacerbation, are liable to be confounded with enteric fever. The absence of rash and of enlargement of the spleen, and the more irregular character of the pyrexia will be of use in distinguishing the acute cases from enteric fever. In more chronic cases the history of the case, especially the duration of the illness, will assist the diagnosis. The discovery of fluid in the pleura will also be confirmatory as it points to tubercular pleurisy. In women amenorrhœa is a suspicious symptom as it may be due to tubercular salpingitis; the same may be said of chronic epididymitis and orchitis in men.

Erysipelatous redness about the umbilicus, sometimes ending in abscess, is a characteristic occurrence due to extension of inflammation along the obliterated umbilical vessels. The discovery of the thickened omentum, which must not be confounded with the edge of the liver, or of bands or nodules of lymph, will leave little room for doubt in the later stages.

Morbid Anatomy.—The extent of surface affected varies greatly; sometimes the under surface of the diaphragm and the flanks are most affected, but in the most typical cases the intestinal serous membrane is thickly set with tubercles, and the several coils of intestine are glued together by lymph. Fluid may be contained only in small pockets or there may be a large quantity of fluid in the peritoneal cavity, the intestines being matted together and packed back against the posterior wall of the abdomen. The fluid may be serous or purulent, and is sometimes blood-stained. The omentum is generally affected, forming a thick, and often very large, flattened mass; thick layers of lymph may overlay the intestines and other abdominal organs, or the solid effusion may be chiefly collected in the grooves formed by the adjacent coils of adherent intestine.

Treatment.—Rest in bed, regulated

* Dr. Fagge's statistics ("Principles and Practice of Medicine," 1886, vol. ii. p. 428) probably contain some fallacies. In 28 consecutive fatal cases 2 were under 10 years, 6 from 10 to 20, 8 from 20 to 30, 5 from 30 to 40, 3 from 40 to 50, and 4 over 50; he also states that the disease is more than twice as common in men as in women.

diet, opium to control pain. combined with bismuth if diarrhoea be present, are amongst the most important measures. Counter-irritation is recommended by many writers. Henech advises the daily use of tincture of iodine to one quarter of the abdominal surface; the application may be continued for weeks: Alonzo Clark recommends a solution of iodine in olive oil (gr. viij or x or even xxx to 3j) rubbed in twice a day and covered with oil silk. Mercurial applications are reported to cure "the great majority of cases" admitted into Guy's Hospital; Dr. Fagge recommended linimentum hydrargyri spread freely over the surface of a flannel belt stitched tightly round the abdomen; Dr. Goodhart prefers to have the abdomen painted with oleate of mercury, or the following:—R Ung. hydrarg. 3j, ext. bellad. 3j, glycerin. 3j, ol. olivæ ad 3ij. The application of belladonna and glycerin (equal parts) is useful in relieving pain. In the early stage or during remissions, a residence at the seaside, and the administration of cod-liver oil are important measures in treatment. The syrup of the iodide of iron is supposed to be specially useful, and may be given when cod-liver oil cannot be digested.

Laparotomy and washing out of the peritoneal cavity have been followed by recovery, which was apparently complete and permanent; in future therefore the desirability of resorting to this heroic treatment must be considered in every case. It is said that cases in which spontaneous evacuation at the umbilicus occurs yield a large percentage of recoveries.

DAWSON WILLIAMS.

PERITYPHLITIS AND TYPHLITIS (Inflammation of the Appendix Cæci).—By the former is to be understood inflammation around or outside of the cæcum; by the latter, inflammation of the cæcum itself. As the two conditions generally co-exist and cannot be separated from each other clinically, it will be convenient to describe them together.

Symptoms and Diagnosis.—The disease is generally ushered in by an attack of constipation, alternating, it may be, with diarrhoea; and this is followed by pain in the right iliac fossa, and often by vomiting. Not a few cases occur in which the symptoms are practically those of intestinal obstruction. On examining the seat of pain there is found an elongated swelling, commencing in the right iliac region and extending for

some distance up the colon. This swelling gives a dull note on percussion, and is very tender to the touch. There is also a class of cases, and those the worst, in which no tumour may be felt, and the symptoms are those of acute peritonitis. The right thigh is flexed as the patient lies in bed, so as to diminish the tension of the abdominal wall; and in cases which have commenced acutely the temperature is raised to the extent of two or three degrees, or perhaps more. There is loss of appetite also, and the tongue is coated, of a brownish tint down the centre, and dry. As might be expected, thirst is often complained of, and the urine is small in quantity, high coloured, and often contains indican.

In typical cases the diagnosis presents no difficulty. Although there are other diseased conditions which show points of resemblance with typhlitis, there are also points of difference sufficient to guide the observer to a correct conclusion. Cancer of the cæcum may be mentioned as one of these. Here the chronicity of the complaint, the age of the patient, the history of the symptoms, and the emaciation will help to establish the differential diagnosis. Enteric fever, also, by the pain and tenderness in the right iliac fossa, the appearance of the tongue, and tumidity of the abdomen may suggest typhlitis; but a careful inquiry into the history, the range of temperature, and the absence of swelling will serve to make the distinction. Intussusception will be negatived by the less urgent nature of the symptoms and by the absence of the passage of mucus and blood characteristic of that affection. Simple impaction of fæces, which occurs mostly in old people, may present the sausage-shaped swelling of typhlitis, but the general condition and the absence of pain and tenderness exclude the latter disease.

The graver class of cases above referred to, in which the symptoms are those of a general peritonitis, presents more difficulty, and here the diagnosis is established more by excluding other causes of peritonitis than by any positive physical signs. Whenever a sudden peritonitis becomes developed in a young person, and we can exclude injury and tubercle, mischief in the vermiform appendix may be fairly suspected.

Prognosis.—In cases in which the iliac tumour is marked and the development of the disease is gradual, the prognosis is very favourable. In the more severe cases, characterized by rapid onset and

peritonitis, it is necessarily very grave. If the peritonitis be only local, good hope may be entertained of a favourable result with prompt surgical treatment; but where the original mischief is not hemmed in by adhesions, and rapidly spreading peritonitis occurs, the case is likely to end in death at no long interval. And even where recovery occurs relapses are very common.

Ætiology.—Perityphlitis and typhlitis occur most frequently in the young, and in the male sex more often than in the female. It is now generally acknowledged that, in the great majority of cases, if not, indeed, in all, the starting-point of the disease is to be found in the vermiform appendix. The anatomical condition of the appendix renders it especially prone to become a focus of disease. The feebleness of its muscular coat invites accumulation of faecal matter, and disables it from expelling such accumulation. This gradually becomes inspissated and acts as a foreign body, setting up an ulcerative process which may in time end in perforation. Short of this, however, inflammation may spread from the mucous to the serous coat of the appendix and to the cæcum itself, and this is probably the history of the frequently relapsing form of the disease. The appendix is also sometimes found bent at an acute angle and greatly distended with mucus, and in this condition it presents a source of irritation which may at any time light up an attack of typhlitis. It should be noted, also, that the appendix is sometimes the seat of tubercular, and sometimes of typhoid, ulceration. Foreign bodies, too, have been found in it, although by no means so frequently as used to be thought, the inspissated concretions of faecal matter before referred to being, no doubt, often mistaken for date- or cherry-stones. It is doubtful whether simple faecal accumulation in the cæcum ever leads to typhlitis; it is more probable that the accumulation is a result of the inflammatory process, which at first beginning in the appendix, affects by extension the walls of the cæcum, inducing paralysis of the muscular coat.

Pathology and Morbid Anatomy.—Even before perforation of the appendix has taken place, and all the more after that event, peritonitis is set up. This may be local in the first place, and may continue so, or it may rapidly become general. In the former case adhesions take place by which the pus which is formed is hemmed in where it may re-

main for an indefinite time. In the latter, besides the ulcerated appendix, intense inflammation will be found in the cæcal region, with formation of pus and a general involvement of the whole peritoneal membrane. Or an abscess, at first localized, may be found to have burst into the general peritoneal cavity, or into the bladder, colon, rectum, or elsewhere in the abdomen. It may also burst through the abdominal parietes. A faecal concretion is, in the great majority of cases, found in the appendix or in the pus around it. In the last dozen cases of death from perforation of the vermiform appendix occurring in the Middlesex Hospital, the post-mortem records show that such concretions were found in nine. Death is usually due to peritonitis, but in exceptional cases to long-continued suppuration, inducing, it may be, albuminoid disease, or to septicæmia, as in a case reported by the writer in the "Clinical Society's Transactions" (vol. xviii. p. 16. 1885).

Treatment.—In the class of cases in which a well-marked tender swelling is found in the cæcal region, the vermiform appendix is probably but little affected, and the indications for treatment are simple enough. Strict rest in bed must be enjoined, with liquid diet and hot poultices or fomentations to the right iliac region. Under the hot applications, equal parts of extract of belladonna and glycerine on lint may be applied with advantage; or, if the pain be very severe, two or three leeches before poulticing. As regards drugs, opium is the sheet-anchor, on account of its power of alleviating pain and checking the peristaltic action of the bowels. It may be given in the form of pill ($\frac{1}{4}$ to 1 grain of the extract) every four or six hours, according to the age of the patient and the amount of pain; or the tincture may be substituted if preferred. If vomiting forbid medication by the mouth, the subcutaneous injection of morphine may be practised instead.

Above all, purgative medicines must on no account be employed. Many a patient has been done to death by purgatives, in whom an opposite plan of treatment would have been instrumental in saving life.

When the temperature has become normal and the pain and tenderness have passed off, the bowels should be moved by simple enemata. As regards diet, only slops should be allowed, and great caution is necessary during convalescence and for a long time after, as relapses are

apt to occur after the slightest indiscretion. The patient should be restricted to soups, milk, panadas and the like, for as long a period as possible. Treated thus, the disease almost uniformly ends favourably in resolution. If, however, in spite of treatment, the symptoms become aggravated and point to suppuration, an incision must be made and the pus evacuated, the parts being irrigated with a warm antiseptic solution and drained.

Where the presence of pus is suspected, it is advocated in America to explore with a needle. But this proceeding is attended with considerable risk, and it is safer and better to make an exploratory incision at once. The needle may get into adhesions and fail to reveal pus when it is really present.

In the more alarming class of cases where a sudden onset of severe pain with collapse and peritonitis indicates that perforation of the appendix has taken place, opium must be freely given, but prompt surgical intervention also is necessary to give the patient a chance for his life. DAVID W. FINLAY.

PHANTOM TUMOUR.—A localized swelling in the abdomen, peculiar to women. The swelling is tympanitic and tumid and unconnected with disease of any of the abdominal viscera. It is usually situated in the middle line below the umbilicus, and may vary much in size. It disappears completely under chloroform, to return even before the effect of the anæsthetic has entirely passed off. The cause of it is obscure, but it must be regarded as a manifestation of hysteria and treated accordingly.

PHARYNGITIS, ACUTE (Acute Pharyngeal Catarrh).—An acute inflammatory affection of the pharynx and adjacent parts.

Symptoms.—The patient usually complains of a frequent desire to swallow, but, has at first discomfort in so doing, soon passing on to pain. If the uvula be markedly enlarged there will be the sensation of a foreign body in the throat and probably a hacking cough, especially on lying down, from the uvula coming into contact with the back of the tongue or epiglottis. Extension of the inflammation downwards into the larynx will cause hoarseness; its extension upwards and forwards will lead to interference with nasal respiration and will consequently give a nasal twang to the voice.

The Eustachian tubes may be occluded, giving rise to a feeling of fullness in the ears and temporary deafness. There is usually some amount of stiffness and discomfort about the neck. As regards general symptoms, the attack is ushered in with a feeling of malaise, and chilliness sometimes amounting to rigors, and after a short time a rise in temperature occurs. The tongue is furred, there is loss of appetite, constipation and febrile urine. On inspection, the soft palate, uvula, tonsils and pharynx will be seen to be swollen and the surface covered with viscid mucus. The uvula at times attains the size of the thumb and may be cedematous — to this condition the term *uvulitis* has been applied (*see* UVULA).

Diagnosis.—A careful examination of the back of the throat should suffice to settle the nature of the malady.

Prognosis.—Simple catarrhal pharyngitis is usually an affair of a few days to a week, it is only when the inflammation is of an erysipelatous type that danger need be apprehended.

Pathology.—There is at first hyperæmia and swelling of the mucous membrane, with arrest of secretion, and then a viscid, muco-purulent fluid is poured out.

Ætiology.—A chill, especially in persons of the rheumatic diathesis, errors in diet, a sedentary life and a strumous inheritance predispose to pharyngitis, as they do to inflammatory affections of other mucous surfaces.

Treatment.—At the commencement 3 grains of calomel, followed by a saline aperient, are useful. If the temperature range high, minim doses of tincture of aconite every half-hour for two or three doses, and then at less frequent intervals, will have a good effect. Guaiacum has long been a favourite remedy in pharyngeal inflammation; it may be given in 5-grain doses mixed with jam every two or three hours, or the trochisci guaiaci of the Throat Hospital Pharmacopœia may be ordered. If the patient be at all below par, carbonate of ammonium in 10-grain doses with 15 grains of bicarbonate of sodium, given with 17 grains of citric acid while effervescing, will act as a stimulant. In cases of rheumatic origin, 10 or 15 grains of salicylate of sodium may be added to the mixture. Later on quinine is well borne. Locally, ice, both externally and internally, is to be preferred to warmth. Spraying the throat with a 10 per cent. solution of cocaine will facilitate deglutition if this be very painful.

F. DE HAVILLAND HALL

PHARYNGITIS, CHRONIC
(Chronic Pharyngeal Catarrh).—Chronic inflammation of the pharynx and adjacent parts.

The *symptoms* are those enumerated under the head of ACUTE PHARYNGITIS, but they are less severe. One of the most troublesome is the hawking and clearing of the throat necessitated by the presence of viscid mucus at the back of the pharynx; this may give rise to vomiting.

Diagnosis.—The relaxed condition of the mucous membrane, the presence of dilated venules and sticky mucus at the back of the throat are the characteristics of the disease.

Prognosis.—The affection is very troublesome and obstinate, but free from danger to life.

Pathology.—Briefly the changes present are chronic hyperæmia of the mucous membrane of the pharynx, with cell proliferation and dilatation of the small vessels of the part.

Etiology.—It may be the sequel of an acute attack, but the disease more commonly comes on gradually in persons leading sedentary lives in an unhealthy atmosphere, especially if there be excess in smoking and drinking. The strumous rheumatic and gouty diatheses predispose to the disease. Of late, attention has been directed to the dependence of chronic pharyngeal affections on obstructed or disordered nasal respiration. Atrophic rhinitis, for example, is almost invariably attended with a dry, glistening condition of the pharynx, to which the term *pharyngitis sicca* has been applied.

Treatment.—The essential points in the treatment of chronic pharyngeal catarrh are to combat, as far as possible, the constitutional causes which underlie it and to treat any nasal trouble which may exist. A tepid or cold sponge bath, with vigorous friction of the skin, wearing flannel next the skin, exercise in the open air, great moderation in the use of stimulants, leaving off smoking, avoidance of pepper, mustard, curry and other pungent articles of diet, will be of service. A gorged state of the pharynx is often found associated with piles; in these cases saline aperients will be found to act beneficially on both conditions. If there be any affection of the nose this must be treated as is directed under the head of RHINITIS. As regards local treatment, painting the throat with glycerin of tannin, or with an application composed of equal parts of tincture of iodine, tincture of catechu and

glycerin, may be tried. The medicated throat pastiles will be found a convenient mode of applying local remedies. Among the most valuable may be mentioned those of chlorate of potash and borax, rhatany and chloride of ammonium. If there be much irritation, the compound rhatany pastiles, which contain $\frac{1}{10}$ grain of hydrochlorate of cocaine, may be ordered. Gargles are of little use, sprays being more efficacious; any of the sprays mentioned for use in the treatment of chronic laryngitis may be employed with advantage in chronic pharyngitis. If the pharyngeal irritation be kept up by the presence of an elongated uvula, this must be removed.

F. DE HAVILLAND HALL.

PHARYNGITIS, GRANULAR
(Clergyman's Sore Throat).—A chronic form of pharyngitis characterized by the presence of granular bodies on the mucous membrane of the pharynx.

Symptoms.—The amount of discomfort the patient suffers is out of all proportion to the objective condition. A feeling of irritation is complained of, as though a foreign body were in the throat, there is also cough, but usually without expectoration. The voice is not at first affected, but sooner or later the individual finds that he must clear the throat before beginning to speak, and in course of time he finds that he cannot talk for long without clearing the throat, and eventually the voice becomes much impaired in consequence of the strain thrown on the larynx by the constant hawking. The mental effect must also be borne in mind, as patients are apt to imagine that they have some grave disorder of the throat, such as cancer or consumption, and are consequently subject to great depression.

The objective symptoms consist in the presence of roundish or oval prominences on the mucous membrane of the pharynx. They are of red colour and usually rather darker than the neighbouring mucous membrane; they vary in size from a pin's head to a pea, but by coalescence larger masses may be formed. The vessels of the pharynx are enlarged and a stellate arrangement is not uncommon.

Diagnosis.—The irregular granular condition of the pharynx and the chronicity of the symptoms are diagnostic of the disease.

Prognosis.—No danger is to be apprehended to life, but the disease is apt to be very chronic, and, until recently, treatment was not very successful.

Pathology.—The granules are due to a circumscribed proliferation of lymphatic tissue around the efferent ducts of the mucous glands; the pavement epithelium of the mucous membrane extends over the granule, though it is thinned, and may be absent over the top of it. In some instances the inflammatory process is limited to the lateral walls of the pharynx. To this condition the term *pharyngitis lateralis hypertrophica* has been applied. In such cases a round or flat swelling may be seen immediately behind the posterior pillar of the fauces. The swelling consists of a conglomeration of granulations, with more or less hypertrophy of the salpingo-pharyngeal fold.

Ætiology.—The causes which have been mentioned as producing chronic pharyngitis are also concerned in the production of granular pharyngitis, but the most powerful of all causes is undoubtedly over-use of the voice, especially under unfavourable circumstances, as, for instance, when the individual is suffering from catarrh, or in an impure atmosphere, or in the open air.

Treatment.—Though relief may be obtained by carrying out the measures suggested under CHRONIC PHARYNGITIS, the only hope of curing the patient consists in the destruction of these granules. For this purpose the galvano-cautery is by far the best form of caustic. Each granule must be touched with the galvano-caustic point or blade at a dull red heat; four or five applications can be made at a sitting. Any prominent vessels may be divided by applying the blade at right angles to them. If the throat be unusually irritable, it may be sprayed with a 10 per cent. solution of cocaine, but, as a rule, so little pain is experienced that this is unnecessary. The feeling of sore throat which follows is best relieved by effervescing lozenges containing chlorate of potash and cocaine, or by the compound rhatany pastiles already mentioned. Only in very exceptional cases does the amount of inflammatory reaction require the use of ice pills. The sittings should be at intervals of a week to ten days, and usually four or five suffice for the cauterization of all the granules. If this be thoroughly carried out, the result is most satisfactory, and there is but little tendency to a relapse. As regards general treatment, if the reflex irritability be excessive, bromide of potassium with a bitter infusion is indicated, but, as a rule, most improvement results from the administration of iron and arsenic. F. DE HAVILLAND HALL.

PHARYNX, ULCERATION OF.

—Ulceration may be met with as a result of syphilis, tuberculosis, lupus and malignant disease.

(a) **Syphilitic Ulceration.**—This is so much the most common that the possibility of the disease being due to syphilis should be excluded before any other diagnosis is arrived at. Syphilitic ulceration is generally due to the breaking down of a gumma, so that the ulcer is usually round or oval in shape, and is most often situated in the centre of the posterior wall of the pharynx, but in severe cases it may spread in all directions. After the ulcers heal, white cicatrices are left which give rise to contraction of the neighbouring parts. There is very little pain attending syphilitic ulceration.

Treatment.—This is as for syphilis generally. Locally, after the surface has been cleaned by a detergent spray, iodoform may be insufflated, or a solution of sulphate of copper (20 grains to the ounce) applied.

(b) **Tubercular Ulceration.**—Tubercular ulcers of the pharynx are lenticular in shape, with no apparent excavation; the base is pale yellow, the edges are irregular and ill-defined, and the surface covered with thin unhealthy pus. The presence of the tubercle bacillus will establish the diagnosis. Pain, which is almost absent in syphilitic ulceration, is a prominent symptom in the tubercular affection, and radiates to one or other ear; there is also great pain on deglutition. The remaining symptoms are those usually met with in tubercular disease of the larynx and lungs, with which the pharyngeal affection is almost invariably accompanied.

Treatment as for laryngeal tuberculosis.

(c) **Lupus of the Pharynx** is usually met with as an extension from lupus of the nose and of the pharynx.

For diagnosis and treatment, see LARYNX, LUPUS OF.

(d) **Cancer of the Pharynx** is generally of the scirrhus variety. It begins as a hard irregular mass, which subsequently softens and ulcerates. The marked induration of the edges and the fungous-looking surface will usually suffice to distinguish it from tertiary syphilitic ulceration. If there be any doubt, iodide of potassium in full doses will soon set it at rest.

F. DE HAVILLAND HALL.

PHLEGMASIA DOLENS.—A disease occurring chiefly in the puerperal

state. Its main characters are denoted by its name, "phlegmasia alba dolens" = "painful white œdema." It is due to obstruction of the veins and lymphatics of the part affected.

Clinical History.—The affection usually comes on towards the end of the second week after delivery, but the date of onset varies much. It begins with pain and fever, the pain being generally in the groin and upper part of the thigh of the affected side. Then comes swelling, which extends down over the whole limb and the corresponding labium. This rapidly increases, so that in a day or two the limb may be twice the size of the other. The pain may extend over the back and lower abdomen, and the whole of the affected limb. The pain and swelling in some cases begin in the foot and thence extend upwards. For the first two to four days the limb is tender, and the swelling pits. Then the swelling acquires the solid character that has been mentioned, and does not pit on pressure, nor when pricked does serum ooze out. The œdema is not altered by position; and there is more loss of power over the limb than is usual in ordinary œdema. This condition lasts from three to eight days. Then the swelling begins to get less hard, and to again pit on pressure, and about this time the pain, tenderness and febrile symptoms diminish. The swelling takes, as a rule, from three to five weeks to subside, but some amount of enlargement of the limb persists long after this date, and, if not treated, may be permanent. During the height of the pain and swelling there is some degree of numbness in the limb. The pain is often so severe as to prevent the patient from sleeping. There are seldom any signs of inflammation about the limb. The plugged veins may sometimes be felt as hard cords.

As a rule, phlegmasia dolens ends in recovery. The chief danger lies in the possible detachment of a clot, and its being carried into the heart, and thence into the pulmonary artery, thus causing pulmonary embolism (see PULMONARY ARTERY, EMBOLISM AND THROMBOSIS OF). This does not occur until a sufficient time after the formation of the clot to admit of its having softened and become friable, which is seldom until at least three weeks after delivery.

In rare cases the thrombosis extends up to the vena cava and thence to the heart, and in that way kills the patient.

Pathology.—Ordinary phlegmasia dolens, such as has been described, is

pathologically different from phlegmonous erysipelas of the cellular tissue, and from suppurate phlebitis and periphlebitis, although either of these conditions may exist along with it.

The statement that the veins are obstructed rests upon the fact that in every case in which the parts have been dissected the veins have been found plugged. That there is also obstruction to the return of lymph from the limb is inferred from the fact that the œdema, during the few days in which the disease is at its height, is of a peculiar solid, non-pitting character, such as is never seen from simple venous obstruction, but is seen in inflammation of the lymphatics, and in elephantiasis, a disease known to depend upon plugging of lymphatic vessels. In elephantiasis the change is more marked because the obstruction is permanent, while in phlegmasia dolens it is temporary. We do not know what is the cause of the venous thrombosis and lymphatic obstruction in phlegmasia dolens. There are very seldom signs of inflammation in the limb.

Ætiology.—The disease has been ascribed to a blood poison; but nothing is known about the poison, if there be one. It is most common in the puerperal state. It is seen occasionally in the terminal stages of phthisis and cancer, and still more rarely in other conditions of anæmia and debility. As a puerperal disease it is most apt to occur after labours that have been accompanied with hæmorrhage. Its frequency in the lying-in period is attributed to the combination at this time of slowness of the circulation with a varicose condition of the veins and an excess of fibrin in the blood. It is generally in one leg, and that more often the left, probably because the veins of the left side are more often varicose than those of the right. It may affect both legs, or even the arms.

Treatment consists in absolute recumbency so long as the pitting œdema is present. During the febrile symptoms diet must be regulated according to the patient's digestive powers. For the relief of pain local applications are best, but these should not be of an irritating character, and should not involve friction. Lint smeared with ext. bellad. and glycerin, p. æq., laid on the limb is useful. If pain be severe, a 4 per cent. solution of oleate of morphine in olive oil may be painted on the limb. The limb should be slightly raised to favour the return of blood from it, the pressure of

the bed-clothes taken off by a cradle, and, unless the weather be warm, the limb wrapped in cotton-wool. After the sixth week, if oedema be slow in subsiding, the limb may be bandaged from the toes upwards with a Martin's perforated india-rubber bandage, put on before the patient rises from bed. The patient and her friends should be most strictly cautioned against friction or kneading of the limb—measures which they are very likely to think useful.

G. E. HERMAN.

PHOSPHATURIA.—A condition in which an excess of phosphates is passed in the urine.

This must not be confused with a mere deposition of phosphates from the urine. Such a phenomenon is merely a sign of alkalescence of the urine, and may take place when a normal, or even a less than normal, quantity of phosphates is present. Nevertheless, it was this latter condition which was believed by Prout to constitute a distinct disease, and which he termed the "phosphatic diathesis." True phosphaturia can only be diagnosed after a quantitative analysis of the urine for phosphates by the uranium method (see URINE, EXAMINATION OF).

The clinical relations of an excessive discharge of phosphates are not yet clearly understood. In great activity of the brain, as when delirium is present, Dr. Bence Jones showed that phosphates were passed in excess. During later years Teissier of Lyons, and Dr. Ralfe, have observed an excessive phosphatic discharge in association with emaciation, thirst, polyuria and other symptoms of diabetes mellitus, and have termed the disease "phosphatic diabetes." With these exceptions, the clinical interest of the phosphates of the urine attaches entirely to their deposition in the urinary passages as a result of loss of acidity of the urine.

ROBERT MAGUIRE.

PHOSPHORUS, Poisoning by.—Phosphorus is met with either in the common yellow soluble form or in the allotropic form; of these the former only is poisonous, the latter being quite inert. Cases of phosphorus poisoning most commonly arise from children sucking the heads of lucifer matches or from the taking of "phosphorus paste" or "rat paste." The symptoms may appear in either an *acute* or *chronic* form; the subjects of the latter affection are usually workers in lucifer-match factories.

Symptoms.—**Acute Poisoning by**

Phosphorus.—The symptoms commence with the taste and smell of garlic. There is also intense pain in the mouth extending down to the stomach, with nausea and vomiting; the vomit may be blood-stained and luminous in the dark. Purging is also present. In severe cases delirium and fatal coma may come on in a few hours; otherwise, about the third day, jaundice and retention of urine, albuminuria, numbness and cramps in the limbs, fainting, somnolence, and convulsions become the most prominent symptoms. In cases less speedily fatal there may be subcutaneous, intestinal and other hæmorrhages, leading to the patient's death from exhaustion; recovery may, however, follow such symptoms. Acute yellow atrophy of the liver presents some features in common with phosphorus poisoning, but jaundice makes its appearance earlier in that disease, and nervous symptoms are present almost from the first. The speedy diminution of liver dulness would be a valuable sign of the disease as against poisoning. Acute yellow atrophy runs an even more rapid course than the poisoning, and is almost inevitably fatal.

Post-mortem Appearances.—The skin may be jaundiced, and, as well as the viscera, may show ecchymoses; the contents of the stomach and intestines smell of garlic, and may be luminous in the dark; the liver is enlarged, yellow, pale and mottled. Microscopically, the mucous membrane of the stomach is swollen, owing to the blocking of the tubular glands with degenerated and fatty epithelium, and the hepatic cells are found to have lost their outline and to be filled with oil globules. Fatty degeneration is present in the renal epithelium and throughout the muscular system generally.

Treatment.—Emetics should be given, and subsequently mucilaginous drinks; oil of turpentine (in 10-minim doses administered at short intervals) is the chemical antidote. The rest of the treatment would be symptomatic.

Chronic Poisoning by Phosphorus commences with pain in a tooth. After extraction of the painful tooth the wound in the gum does not heal; gradually the alveolus becomes exposed, the gums grow spongy, and the teeth fall out. The disease of the jaw progresses, and large pieces of bone are removed. The patient may then recover, or he sinks slowly from exhaustion consequent upon the long-continued drain upon his system. Now that

matches are made with allotropic phosphorus, cases of chronic poisoning by phosphorus are becoming very rare.

PHRENIC NERVE, PARALYSIS OF.—This is rarely due to disease or injury of the nerve trunk, but commonly to disease of the anterior grey matter of the spinal cord at the level of the third and fourth cervical nerves. It occurs in acute or chronic spinal myo-atrophy, and is not rare after diphtheria. Paralysis of the diaphragm has also been observed in lead palsy. In a few cases the loss of function has been attributed to rheumatic neuritis of the nerve trunk, and cases are recorded in which it was due to compression in the neck.

Symptoms.—The evidence of paralysis of the phrenic is inaction of the diaphragm. After experimental section of the phrenics, the two most constant phenomena observed are increased scope of the thoracic excursions and a distinct reversal of the abdominal movements in respiration. Clinically these symptoms are present in most cases, but in very varying degree. In ordinary quiet breathing they may be almost imperceptible, but become more clearly marked on the quickening of respiration which attends any exertion on the part of the patient. The extent and character of the abnormal movements also vary according as one or both nerves are paralysed.

In bilateral paralysis, such as is not rarely met with after diphtheria, there is nearly always excessive action of the lower ribs, and the abdominal movements are reversed, the wall receding instead of coming forward during inspiration and bulging out during expiration. The precise nature of the modifications of the normal movements will depend to some extent on the integrity or otherwise of the abdominal and intercostal muscles and on the degree of affection of the phrenics. When the paralysis is gradual in onset, the altered movements become established imperceptibly. But if, as has happened in the writer's experience, paralysis be suddenly developed, there is always more or less dyspnoea and lividity, of temporary duration. Accidents of this nature have probably sometimes been erroneously attributed to sudden heart failure. All spasmodic respiratory actions—sneezing, coughing—are performed with less energy. In post-diphtheritic cases the non-explosive character of the cough is very striking and constant. Paralysis of the diaphragm *per se* gives rise to but few symptoms,

but the supervention of bronchitis places the patient in a position of great danger.

Diagnosis.—This is not always easy. The symptoms should be looked for during quiet breathing, for in voluntary deep breathing the extra action takes place chiefly in the upper part of the chest. It must also be remembered that in women breathing is less diaphragmatic than in men, and in them also conscious attention to the act of breathing is apt to arrest the action of the diaphragm.

Further, immobility of the diaphragm may result from causes other than paralysis. Such are diaphragmatic pleurisy, injury, ruptured fibres, &c., and the diminished movements observed in cases of extreme emphysema of the lungs.

Then, again, in cases where the diaphragm is really paralysed there may be some doubt as to whether it moves or not. In patients with collapsed abdomen the expansion of the lower ribs is apt to lift forward the lax parietes so as to simulate a descent of the diaphragm. In other cases a sudden contraction (expiratory) of the abdominal muscles, more especially the recti, occurring almost before the end of inspiration, and tending to fill up the epigastrium, may be mistaken for a late inspiratory effort. In post-diphtheritic cases the lungs sometimes furnish confirmatory evidence. The writer has met with weak breathing and, more rarely, relative dulness, and moist râles at the bases, in several cases, and is inclined to attribute these physical signs to the presence of collapse and œdema of the pulmonary bases, occurring as a direct effect of the diaphragmatic paralysis on the lungs.

Prognosis.—This is favourable in the rare instances due to cold; rather less so in lead poisoning. It is unfavourable when the paralysis is part of a progressive spinal myo-atrophy. When due to acute cornual myelitis, it will depend on the evidence afforded by other symptoms of the extent of the damage to the region of the cord from which the nerves arise.

After diphtheria, the occurrence of diaphragmatic paralysis materially increases the gravity of the general prognosis. Out of fifteen cases in children under the writer's observation, only eight recovered. The gravity of the prognosis varies directly with the degree of paralysis, not only of the diaphragm but of the limbs and trunk, for in these cases the former is always part of a more general multiple paralysis.

If the view put forward above prove correct, the presence of signs of con-

solidation (collapse) at the bases, with evidence of oedema, will possess a grave significance not only as probably indicating a marked enfeeblement of the diaphragm, but also a condition of lung which must materially increase the work thrown on the right side of the heart, which in many instances is already showing signs of weakness. The development of broncho-pneumonia, with rise of temperature, is of the gravest import, and frequently ushers in a fatal result.

Treatment.—In all cases causal indications must be met. Counter-irritation over tender spots, if they exist, is called for in cases due to cold, while systematic faradization may be of value if the irritability of the nerve be not altogether lost. One rheophore should be applied in the neck just above the scaleni and the other over the diaphragm. A strong current is necessary.

In post-diphtheritic cases the treatment is largely that of the general disease, but, owing to the tendency towards recovery which characterizes this form of paralysis, no effort should be spared to help the patient to tide over the critical period. In the hope of being able to counteract to some extent the occurrence of pulmonary collapse and oedema, the writer has practised artificial respiration at regular intervals (three or four times a day) for ten or fifteen minutes at a time. This method of treatment has appeared to be decidedly beneficial in some cases, more particularly where the onset of the paralysis has been accompanied by distress of breathing and lividity. The results obtained, although far from uniformly satisfactory, have been sufficiently encouraging to warrant a more extended trial of this mode of treatment.

W. PASTEUR.

PHTHISIS.—A tubercular disease of the lungs, characterized by the occurrence of lesions, partly specific and in part inflammatory, which tend either to cascade and soften or to become fibrous.

This definition emphasizes the view, now held by most pathologists, that pulmonary phthisis is a single disease, and that it is invariably attended by the appearance in the lungs of the pathological product known as tubercle.

The conflicting views as to the nature of the tubercular process, the great variety in the lesions met with in the lungs, and the undoubted fact that in the production of many of them inflammation (though probably of a specific nature) plays an important part, have

been hitherto the chief obstacles to the general acceptance of the theory of the "unity of phthisis" and of its dependence upon a specific virus.

It is unnecessary to review at any length the various theories as to the nature of tubercle and its relation to phthisis which have at different times been more or less generally held.

Laennec believed that tubercle was a particular matter which was liable to be deposited in the lungs or elsewhere, either in the form of miliary nodules or as infiltrations of considerable portions of the lung (infiltrated tubercle). In either form the deposit was at the outset grey and transparent, but with a tendency to change into yellow or crude tubercle.

Buhl discovered that the pre-existence of a caseous focus was a frequent antecedent to the outbreak of tuberculosis—a fact which tended to confirm Laennec's view of the specific nature of the product.

Virchow subsequently urged that the process in phthisis is largely of an inflammatory nature, with a special tendency for the products of inflammation to undergo caseation, that the existence of caseous material is no proof of tuberculosis, and that the tubercle when present is, in many cases, grafted on to lesions which are of non-specific origin. Niemeyer's dictum, that "the greatest danger for the majority of consumptives is that they are apt to become tuberculous," is the terse expression of this view.

The researches of Villemin proved that tuberculosis could be produced by the introduction of caseous matter into a healthy animal; other observers, who have since admitted the error of their conclusions, maintained that they had disproved the specific nature of tubercle by producing acute tuberculosis by the inoculation of non-tuberculous material.

The doctrine of the unity of the disease and its dependence on a specific virus received important support from the publication by Koch in 1882 of his discovery of a bacillus in tubercular diseases of man and animals. This he had proved to possess pathogenic properties by the fact that, after repeated cultivations, acute tuberculosis was produced by the inoculation of healthy animals with the pure virus.

The numerous observations and experiments which have been made during the period which has since elapsed have, with few unimportant exceptions, tended to

confirm the truth of Koch's views, and at the present time the discovery of tubercle bacilli in the sputa of a patient suffering from some affection of the lungs is held to be conclusive evidence of the tubercular nature of the disease.

As yet no serious attempt has been made to prove that these organisms are constantly absent from the sputa of any considerable number of cases of phthisis, and it may be stated with confidence that the view of the essentially tubercular nature of the disease is now generally accepted.

The want of uniformity in the clinical features and morbid appearances of the disease is probably due to the varying degree of resisting power of the tissues of different individuals to the action of the virus, leading in the one case to death in the course of a few weeks or months, and in another allowing life to be prolonged for many years.

MODE OF ONSET.—This varies much in different cases. The following clinical types may be recognized:—

(1) *Insidious Onset.*—This is certainly the most common form in which the disease appears. The patient either is unable to fix definitely the time when his health became affected, or perhaps dates the attack from a cold of no unusual severity. There is a history of gradual failure of strength, with cough, some expectoration and emaciation. Sweating may have been present at night, and, on exertion, the breath is probably noticed to be short. Loss of appetite and dyspeptic troubles often form a prominent feature in the history of such a case. The patient is usually anæmic and emaciated. The tongue may be furred, with prominent red papillæ. If the temperature be taken in the afternoon or evening, it will probably be found to be from one to two degrees above the normal.

(2) *Bronchitic Onset.*—The cases presenting this mode of onset are scarcely less numerous than the last. There is usually a history of repeated attacks of bronchial catarrh or of acute bronchitis; cough may have been present in the winter for some years, and there may have been attacks of dyspnoea, with wheezing. Expectoration has possibly been profuse, and perhaps occasionally tinged with blood. The onset of the tubercular disease may be ill-defined or marked by emaciation, loss of strength, an alteration in the character of the cough, and often by the occurrence of night-sweats.

(3) *Pleuritic Onset.*—In these cases the appearance of the disease has been preceded by one or more attacks of acute basic pleurisy, either dry or with effusion; if the latter, the fluid may have been completely absorbed. In some cases there is a history of pleurisy, with effusion, affecting first one side of the chest and then the other, and in both complete absorption of the fluid may have taken place, the pleural surfaces probably becoming adherent.

The immediate onset of the pulmonary lesion is generally marked by cough, emaciation, pyrexia and night-sweats. In such cases, as in the types previously described, there is often a history of tubercular disease in the parents or in other members of the family.

(4) *Hæmoptoic Onset.*—In a certain proportion of cases of phthisis the health is apparently but little affected prior to the occurrence of an attack of hæmoptysis. This attack may be immediately followed by the ordinary symptoms and signs of phthisis, or, as not uncommonly happens, the attack is quickly recovered from, and, on examination of the chest shortly afterwards, few, if any, definite signs of disease may be detected. In such a case there may be a considerable interval before another attack of hæmorrhage occurs, but, after a time, the ordinary symptoms and signs of the disease appear. It is almost certain that in many cases of this kind there is an old tubercular lesion in the lung, and that the attack of hæmoptysis apparently marking the onset of pulmonary tuberculosis has really been preceded by symptoms and signs which have escaped either notice or memory. Such cases are not uncommon in men beyond middle age in whose family there is no history of tubercular disease.

(5) *Acute or Pneumonic Onset.*—This is probably the rarest mode of onset of the disease. Two forms may be recognized.

(a) *The Lobar Pneumonic Type*, in which the attack somewhat simulates one of acute lobar pneumonia of the apex, being marked by rigors, high temperature, quickened pulse and respiration, and expectoration, which may be more than simply "rusty," slight hæmoptysis being sometimes present. The case is very likely to be regarded as one of ordinary croupous pneumonia, until the unusual degree of emaciation or the absence of a crisis suggests an examination of the sputa, when the discovery of tubercle bacilli shows its real nature.

(b) *The Broncho-pneumonic Type.*—This is the most serious and rapidly fatal

form of phthisis, and has been termed "galloping consumption" and "florid phthisis." The lesions are not localized to the apex or a single lobe, but spread rapidly through both lungs; caseation quickly follows consolidation, and is in its turn soon succeeded by softening. The patient is usually of a markedly "tubercular type," the face is flushed, the eyes are bright, there is high fever, with rapid emaciation and severe cough, hectic sweatings, and purulent or blood-stained sputa.

(6) *Acute Miliary Tuberculosis*.—It is usual to describe this form of pulmonary tuberculosis as a separate disease, and doubtless its widely different clinical and pathological characteristics to some extent warrant the distinction, but according to the view above stated both are manifestations of the tubercular process, and the fact only serves to illustrate how various may be the appearances assumed by tubercular lesions of the lungs, and also how widely different may be the symptoms which accompany the condition. It is not suggested that a case of acute miliary tuberculosis of the lungs should be described as one of phthisis, but there is a possibility that when the view of the essentially tubercular nature of that disease is completely accepted the term pulmonary tuberculosis may displace phthisis in its nomenclature (see TUBERCULOSIS, ACUTE MILIARY).

It is important also to recognize that one of the greatest dangers to which phthisical subjects are liable, and one of the modes in which the disease often proves fatal, is an outbreak of acute tuberculosis, in which miliary granulations are rapidly formed throughout portions of the lungs hitherto free from infiltration.

On the other hand, it is to be remembered that in a certain proportion of cases of acute miliary tuberculosis the lungs are not the primary source of the general infection.

SYMPTOMS.—In the account of the various modes of onset of the disease, incidental reference has been made to the symptoms; these will now be described in detail.

Cough is perhaps the most prominent, and is certainly the symptom which most attracts the patient's attention. It is usually present in the earliest stage of the disease, and is rarely absent for any lengthened period throughout its course. At first "hacking," it becomes in the advanced stages loud and hollow; it is especially common on lying down at

night and on rising in the morning, when, if severe, it may cause retching or vomiting, and leave the patient much exhausted. It is often especially troublesome after taking food or after exertion.

Expectoration.—This in the early stages is frothy and viscid, small in quantity, and may occasionally be blood-streaked. When softening is in progress, it is profuse, purulent and "nummulated;" the latter appearance is, however, not characteristic of excavation, as it may be observed in the sputa of chronic bronchitis. The methods of examining the sputa for bacilli and elastic tissue are fully described in the article on EXPECTORATION (q.v.).

Fever.—The course of the temperature in phthisis is subject to much variation. It is generally considerably raised during those periods of the disease when active changes are in progress in the lungs, but cases are recorded in which, although extensive lesions occurred, the temperature did not rise above 99° F. The rise, as a rule, begins in the early part of the afternoon and attains its maximum between 8 and 10 P.M., the temperature then falls, so that during the after-part of the night and in the early morning it may be sub-normal. When softening and cavity formation are in active progress, the temperature often assumes a hectic type, rising to 103° or 104° F. in the evening, and falling to the normal, or below that point, during the night.

It is noteworthy that the pyrexia of phthisis is not generally accompanied, as in other diseases, by thirst, loss of appetite and other evidence of constitutional disturbance, so that patients not uncommonly continue at their work although in a state of high fever. When pyrexia gives place to a normal temperature at all periods, a favourable change has almost certainly occurred at the site of disease in the lung. The significance of the rise of temperature, which often occurs after an attack of hæmoptysis, is discussed in the article on that subject (q.v.).

Emaciation is one of the most prominent symptoms of the disease, and its degree is usually a trustworthy indication of the severity of the case. In such as present the "acute" or "pneumonic" mode of onset, the loss of weight is often extremely rapid.

Hæmoptysis.—As the subject is fully treated in the article under this heading (q.v.) but little need be added here. The idea that phthisis may originate from an attack of hæmoptysis (phthisis

ab hæmoptoe) is no longer entertained; that the hæmoptysis is the consequence, and not the cause, of the pulmonary changes is now made evident by the fact that, in cases of so-called primary hæmoptysis, an examination of the blood ejected may demonstrate the presence of tubercle bacilli, sometimes in considerable numbers. It is, however, true that in many cases, after a profuse hæmorrhage, there are no distinct signs discoverable on examination of the chest; but, unfortunately, it is not generally recognized that the "absence of physical signs" and the "absence of disease" are not one and the same thing. The presence, in the great majority of cases of profuse hæmoptysis, of an aneurysm of some branch of the pulmonary artery is insisted on in the article to which reference has already been made.

Dyspnœa.—Although the patients generally admit to some shortness of breath on exertion, there is rarely any obvious dyspnœa until the lungs have become extensively involved in the disease. The anæmia which is almost invariably present reduces the requirements of the system, and so enables the diminished pulmonary area to supply the blood with sufficient oxygen.

Pain is often present even in the early stages; it is generally referred to the pectoral regions, and may be associated with tenderness. It is probably due to the condition of the underlying pleura, where possibly adhesions may be either forming or present, or it may be evidence that intra-pulmonary changes are approaching the surface.

Night-sweating is often present from the onset of the disease, and constitutes one of its most distressing symptoms; if the patient fall asleep during the day, sweating may also occur. The perspiration is at times so profuse as to necessitate a change of linen more than once during the night. Patients usually complain of feeling much exhausted after the sweating.

Pulse.—There is, as a rule, some increase in the pulse rate, associated with a low state of the arterial tension.

Digestive Disorders are of frequent occurrence, loss of appetite, especially for fatty food, nausea and vomiting being amongst the most common symptoms. Vomiting is occasionally present in the early stages; later, it often follows the violent attack of coughing which so many patients experience in the early morning.

Diarrhœa is usually a phenomenon of the advanced stages of the disease, and

is then, as a rule, due to the presence of tubercular ulceration of the bowel combined with catarrh of the mucous membrane of intervening areas. Albuminoid disease is another not infrequent cause of diarrhœa.

THE SO-CALLED STAGES OF PHTHISIS.

—It has been customary to describe three stages of the disease—the first, or stage of consolidation; the second, of softening; and the third, or cavity stage. These stages mark the advance of a pathological process, but have no relation whatever to the disease as a whole, or any clinical value as guides to prognosis, a patient with a well-marked cavity being often in a far more satisfactory condition than one in whom the disease has not advanced beyond the stage of consolidation. It is also in great part owing to the general use of these terms that the tendency of tubercle to undergo fibrous transformation has received comparatively little attention.

PHYSICAL SIGNS.—It is convenient to describe the physical signs of the disease as they are elicited in the course of the examination of the chest.

Inspection.—Although it is true that phthisis may affect persons of any physiognomy and any build, most writers agree in regarding two types of chest as specially liable to be attacked—the one, a long narrow chest with wide intercostal spaces, a small antero-posterior diameter and projecting scapulæ; the other, a broader chest, which is very flat in front, the sternum sometimes being actually curved backwards instead of forwards.

The chief points to which attention should be directed on inspection are the supra- and infra-clavicular regions, where signs of flattening may be observed. The movement of the point of the shoulder should be watched during inspiration for any slight differences in the degree of expansion of the upper part of the chest. A considerable defect of the whole of one side is readily observed when the chest is viewed from the front, the patient being seated in a good light, but slight changes are more obvious when the observer stands behind the patient and looks over his shoulders.

Palpation.—When the hands are placed upon the chest defective expansion at one apex often becomes more evident than it was on inspection. Changes in the vocal fremitus are of great importance in determining the presence of early disease of the upper lobes. The reader is referred to the article FREMITUS for a full account of their significance. It

may, however, be stated here that when in consequence of the retraction of a cavity at one apex the overlying pleura has undergone considerable thickening the vocal fremitus may (as is usually the case with thickened pleura) be less distinctly conducted there than beneath the other clavicle.

Percussion.—In the early stages a slight difference in the percussion note may sometimes be elicited on tapping the clavicles, when elsewhere the difference is unappreciable. It may also be found that the resonance does not extend so high above the clavicle on one side as on the other, and, again, a slight difference on the two sides may be noted when the breath is held after a deep inspiration, owing to less air entering the affected lung. Firm percussion in the supra-spinous fossæ will often elicit a dull note when the evidence obtained from the front of the chest is doubtful. The note may also obtain a slightly tympanitic quality, and at a later stage varying degrees of dulness up to wooden percussion note may be elicited. When a large cavity is present at the apex, a cracked-pot sound (*bruit de pôt fêlé*) may be present (*see PERCUSSION*).

Auscultation.—The earliest sign in cases with insidious onset is usually weak inspiration with prolongation of the expiratory sound. The inspiratory sound at a later period becomes harsh, and is often "wavy." At a still later period it is bronchial in quality. In cases of the "pneumonic" type there may be well-marked tubular breathing below the clavicle and in the supra-spinous fossa, but the tubular (whiffing bronchial) quality of breath sound is not commonly present in phthisis unless some area of lung be completely consolidated as the result of an accompanying pneumonia.

When a cavity has formed, the signs of that condition will be observed beneath the clavicle or in the supra-spinous fossa (*see AUSCULTATION*).

It is important to note that the breathing over the unaffected apex is usually exaggerated (harsh), with a prolonged expiratory sound, a compensatory change; and that, when one apex is certainly diseased, the absence of this change at the other may be an indication of early disease there also.

The only adventitious sounds in the early stage of a case with insidious onset are, as a rule, a few fine crackling râles on inspiration or after cough. At a later period, when softening is in progress, moist crackling râles and clicking sounds

appear, and are replaced by gurgling râles when a cavity has formed, if it contain secretion.

In a case of the pneumonic type, tubular breathing and crepitation may be present over a considerable area.

It not infrequently happens that the physical signs are more marked in the supra-spinous fossa than above or beneath the clavicle, probably owing to the fact that the lesion is often situated nearest to the posterior surface of the lung (*see PHTHISIS, LOCALIZATION OF LESIONS*).

The changes in the vocal resonance are fully described in the article on *AUSCULTATION OF THE VOICE (q.v.)*.

DIAGNOSIS.—The diagnosis of phthisis has become a much simpler matter since the discovery of the bacillus tuberculosis. In all cases in which there are definite physical signs of disease of the lungs it is now customary to examine the sputa; if bacilli be present, the case is regarded as one of pulmonary tuberculosis, whilst their absence after repeated examination tells very strongly indeed against such a diagnosis. In cases with a pneumonic onset it may be necessary to wait until the period at which a crisis should occur is past before pronouncing an opinion.

In cases of anæmia, in which the presence of phthisis is often suspected, the discovery of the various hæmic murmurs is generally sufficient to exclude the presence of phthisis, as the two conditions are rarely, if ever, associated. A caution must, however, be given against mistaking the sound which can nearly always be produced by the pressure of the stethoscope on the jugular vein for the true *bruit de diable*, with which a thrill is nearly always associated. The stethoscope should be placed upon the sternal end of the clavicle where it cannot compress the vein. It is also important not to mistake the false murmur in the second left interspace, which is so commonly present with disease of the left upper lobe, for a pulmonary hæmic murmur (*see AUSCULTATION OF THE HEART*, p. 78, section 4). The occurrence of slightly blood-stained expectoration in the early morning often leads to a suspicion of phthisis, but in such cases the blood generally comes from the gums, and disease of the lungs is rarely present.

Emphysema may mask the presence of a tubercular lesion; hence it is always desirable to examine the sputa in cases of emphysema and bronchitis occurring in spare individuals.

COURSE; DURATION; PROGNOSIS.—Whilst the discovery of lesions indi-

cating arrest of pulmonary tuberculosis is one of the most common occurrences of the post-mortem room, the complete arrest of cases of phthisis clinically recognized is unfortunately an event much less frequently met with. It may occur during the stage of consolidation, a caseous mass remaining, which shrivels and becomes encapsuled, the surrounding lung becoming emphysematous, or after a cavity has formed. In the latter case the cavity contracts, and the overlying pleural surfaces are separated, the intervening space being filled by the effusion of fluid from the vessels of the neighbouring adhesions; this fluid subsequently assumes a gelatinous consistence, and afterwards undergoes changes ending in fibrillation, the resulting tissue being in time of almost cartilaginous density.

As already stated, the most rapidly fatal cases of phthisis are marked by an acute onset of the "broncho-pneumonic type," death may occur in such cases in a few weeks or months, but, as a rule, no matter how acute the symptoms at the onset, some amelioration in the patient's condition takes place after a time. In the cases of the lobar pneumonic type, a tendency to arrest is often noted after the expulsion of the softened caseous material and the formation of a cavity. The cases with an insidious onset are generally slowly progressive, with occasional periods of quiescence. The average duration of such cases has been variously given as two years and a half (Pollock) to eight years or more (Williams), but such statements are really of but little value, owing to the great variety of circumstances which have to be taken into consideration in forming an estimate as to the probable course and duration of any given case. The greatest dangers which beset the subject of chronic phthisis are the formation and rupture of a pulmonary aneurysm, and the occurrence of acute pulmonary tuberculosis from the sudden infection of the blood or lymph vessels with the virus of the disease. A caseous nodule may remain quiescent and encapsuled in the apex of a lung for many years, giving, perhaps, little or no sign of its presence, when from some cause its capsule gives way, a communication with a bronchus or vessel is established, and acute tuberculosis is set up.

The duration of cases of the hæmorrhagic type is often prolonged, and in those characterized by the bronchitic mode of onset the course is generally

chronic. The prognosis in cases of the pleuritic type is, as a rule, unfavourable, there being a distinct liability to the occurrence of acute tuberculosis.

It may be stated, in conclusion, that complete arrest of the disease is occasionally observed under the most unfavourable circumstances, such cases falsifying every rule of prognosis.

Complications.—The complications of phthisis are for the most part the effects of the transference of the specific virus from the lungs and its arrest in other parts of the body, the result being the formation of tubercles, which generally either undergo softening or set up inflammation; on the other hand the tubercle bacillus may have been present in the body before it attacked the lungs. As the greater number of such affections are described under their appropriate headings the mere enumeration of them will be here sufficient.

The complications connected with the serous membranes are described in the articles on PERITONITIS, TUBERCULAR; PLEURISY, TUBERCULAR; PNEUMOTHORAX, and MENINGITIS, TUBERCULAR.

Those of the mucous membranes in the articles on INTESTINES, TUBERCULAR DISEASES OF; LARYNX, TUBERCULOSIS OF; PHARYNX and TONGUE, TUBERCULAR ULCERATION OF.

Those of the lymphatic glands in the articles on LYMPHATIC GLANDS, DISEASES OF, and TUBERCULOSIS (including Scrofula).

The tubercular affections of the large viscera, all of which may occur as complications of pulmonary tuberculosis, are treated of in the articles on ADDISON'S DISEASE (tubercular disease of the suprarenal capsules); BRAIN, TUMOURS OF (tubercular); KIDNEY, TUBERCLE OF; LIVER, CIRRHOSIS OF (tubercular).

Albuminoid disease is a frequent complication of chronic phthisis, it will be found described under its appropriate heading.

The affections of bone and joints are mentioned in the article on TUBERCULOSIS.

Disease of the middle ear occasionally occurs as a complication of phthisis.

Enlargement of the male breasts has been noted as a comparatively rare event in the course of the disease.

Fistula in Ano.—This affection is probably not quite so common amongst phthisical patients as used to be thought. It has been observed in about 2 per cent. of the in-patient cases at the Brompton

Hospital. It is believed to be due to the occurrence of a tubercular ulcer of the bowel, which perforates the wall of the intestine and subsequently forms an external opening by the side of the anus, but the invariable existence of the ulcer has not been clearly demonstrated.

Treatment.—The condition rarely gives rise to any very troublesome symptoms and may safely be left alone, the old idea, and one that is still entertained by many writers, being that it is dangerous to resort to operative measures in such cases as the existence of the discharge has a beneficial effect upon the lung. Whether this be so or no it is difficult to say, but it is certain that the presence of another morbid process in the body has a distinct influence upon the tubercular process, witness the extreme frequency with which evidence of arrested tubercular disease is found in the bodies of those dying from cancer.

If an operation be performed the diseased tissues must be completely removed.

PATHOLOGY.—According to the view here adopted, phthisis is a local tuberculosis of the lungs accompanied by inflammatory changes, the resulting morbid products tending either to caseation and softening or to fibrosis.

Initial Lesion.—The first effect of the presence of the bacillus in the air passages is to set up changes in the finer bronchi, which extend either into the alveoli or into the surrounding connective tissue; in the one case the initial lesion is intra-alveolar, in the other inter-alveolar.

Tubercles are continuously formed throughout the progress of the disease, and according as the alveoli or connective tissues are affected, rather tend to undergo, on the one hand caseation and softening, on the other fibrosis; softening, however, may occur in either extra or intra-alveolar lesions.

In the *Caseous Form of the Initial Lesion* it appears to the naked eye as a small rounded nodule of consolidation, having a somewhat lobular appearance. In the centre the colour is either whitish or yellow, and opaque; towards the periphery it is of a greyish tint. A large area of consolidation is formed by the coalescence of a number of such small nodules.

The initial lesion in the intra-alveolar form is seen microscopically to centre around a minute bronchus, which is plugged with an inflammatory exudation composed of round cells and desquamated epithelium; the neighbouring alveoli are also stuffed with large catar-

hal cells, derived from the alveolar epithelium; the epithelial cells are often enlarged, and may be desquamating. The wall of the bronchiole is generally considerably infiltrated with round cells.

These constitute the appearances in that part of the lungs where the process has most recently commenced. Where it has been in operation for some time, large caseous areas may be found; in parts where the process is of still older date, cavities of various size and irregular shape and outline will have formed. The larger cavities, like the large areas of consolidation, are formed by the coalescence of smaller ones (*see VOMICA*). Caseation often begins within the bronchus and extends to the alveolus; softening commences in the central parts of the caseous masses, often in the neighbourhood of a bronchiole.

The process of caseation consists essentially in the death of the cell elements, followed by their fatty degeneration. The evidence of the specific nature of the changes here described is furnished by the discovery of the bacillus chiefly within and around the giant cells of the tubercles.

In the *Fibroid Form of the Initial Lesion* hard pigmented tubercles of varying size are found, with well-defined outline, presenting the typical appearances of the miliary tubercle. The microscopical appearances differ, in that the changes are chiefly inter-alveolar, being mainly in the wall of the bronchiole and in the surrounding connective tissue; the intra-alveolar changes are much less marked, and the evidence of inflammation there is but slight.

In this form there is far less tendency to caseation and softening than in the other; if cavities form they tend to contract, and progress is slow, the general course of the disease being chronic. Pleural thickening may be extreme.

These cases constitute one of the forms of so-called *Fibroid Phthisis*, which, as the late Dr. Moxon said, is only "phthisis of which the history has been forgotten," owing to its very chronic course. In such cases the upper lobe of the lung often presents the most typical picture of "fibroid" phthisis, whilst in the lower lobe the changes characteristic of ordinary chronic phthisis are seen in progress.

In some cases large areas are found infiltrated with tubercle of a dense fibroid consistence, often forming deeply pigmented, rounded masses having a racemose arrangement. These are seen to be

spreading slowly at their margins, and undergoing fibrous changes in the central portion, but they show but little tendency to break down.

ÆTIOLOGY.—The condition of the lungs which affords a favourable soil for the multiplication of the bacillus tuberculosis may be either inherited or acquired. There is apparently a deficient resisting power in the tissues of the subjects of inherited phthisis, so that they are unable to resist the attack of the bacillus. In them the onset of the disease usually occurs at an earlier period of life than in those who have no such family history. Dr. Reginald Thompson, comparing 2000 cases of phthisis with an hereditary history with an equal number in which the disease was acquired, shows that the liability for the disease to manifest itself before the age of twenty-five is much greater in the former case (1131 to 871). When there is a history of phthisis in both parents, the disease is likely to appear at a still earlier age.

It may be stated generally that everything which tends to lower the state of the bodily health also tends to favour the development of phthisis; and, conversely, that everything which increases the resisting power of the body to disease diminishes the tendency to pulmonary tuberculosis.

The question of diathesis is a very difficult one. All those who have seen a very large number of cases of phthisis have probably formed some mental picture of the type of individual whom they consider specially liable to the disease, but in the opinion of some authorities such types are merely examples of individuals who are lacking in robustness and vigour, or are ill-grown or badly developed. The tendency at the present time is to regard what used to be called *scrofula* as the manifestation of a tendency to tuberculosis, if such a condition exist; *scrofulous* and *tuberculous* lesions being practically identical, and alike due to the action of the specific bacillus.

The breathing of impure air, the want of good and sufficient food, excess in alcohol, and residence on a damp clay soil are all important factors in lowering the resisting power of the individual to the specific virus of the disease.

Frequent pregnancies and prolonged lactation are also potent in producing the tendency, although whilst the mother is carrying the child the tuberculous process generally undergoes temporary arrest or amelioration. The rapid extension of the disease which often occurs

after delivery has been attributed to the wide inhalation of the specific virus during the deep inspirations which accompany parturition.

The subjects of diabetes are specially likely to develop consumption, and syphilis is also a factor in the ætiology of the disease. Workers in various trades in which dust is given off from the materials employed are frequently the subjects of the disease; such are particularly coal-miners, iron-workers, stone-masons, knife and fork grinders, needle-makers and potters. Exposure to cold and wet, by lowering the general health, and locally by diminishing the resisting power of the pulmonary tissues, predisposes to the disease. The entrance of a foreign body into the lung may be the starting-point of disease which terminates with pulmonary tuberculosis.

Phthisis may occur at any period of life; it is generally believed to attack young adults (aged from twenty to twenty-five years) in greatest numbers, but this is denied by some authorities.

Treatment.—As the children of phthisical parents are certainly more prone than others to acquire the disease, prophylaxis is naturally of very great importance. Every care should be taken to maintain the general health and nutrition of the child. This is to be effected by careful attention to diet, clothing and place of residence, a dry and bracing air being preferable. Special attention should be paid to all the ailments of childhood, and especially to those, such as measles and whooping-cough, which tend to be complicated by catarrh of the pulmonary mucous membrane. Cod-liver oil and syrup of the iodide or phosphate of iron are of especial value at this period. It is undesirable that a phthisical mother should suckle her own child.

The occurrence of glandular enlargements in the children of phthisical parents should be considered a serious indication of the presence of the inherited tendency.

In youth and early manhood precautions are still more necessary, and at that period removal from this country to New Zealand or Australia, coupled with the adoption of a healthy out-of-doors life may prevent the appearance of the disease.

If the onset be of the acute or pneumonic type, rest in bed is essential during the continuance of the pyrexia. Antipyrin, antifebrin or hydrobromate of quinine may be given with a view of lowering the temperature, but they have no specific effect upon the course of the

disease. An effervescing mixture with aconite is sometimes useful, and at a later period, when the most acute symptoms have passed off, small doses of iodide of potassium in a bitter infusion are of use. When there is a distinct remission of the acute symptoms, a mixture of hypophosphite of lime gr. v, syrup of the phosphate of iron and glycerin āā ʒj, in an ounce of water may be given two or three times daily.

The treatment of hæmorrhage from the lung is fully discussed in the article on HÆMOPTYSIS (*q.v.*). Cough is an important symptom, and the patient is always urgent for its relief. If sedatives be given it should only be to check an ineffective cough or one which prevents the patient from obtaining rest; such a linctus as the following—Liq. morphinæ acetatis ℥viij, sp. chloroformi ℥iiij, succi limonis ℥xv, mucilaginem acaciæ ad ʒj—is often efficacious under such circumstances. Or a linctus containing honey (℥xxv) and dilute sulphuric acid (℥v) ad ʒj may be tried. Lozenges, such as the tr. morph. et ipecac. of the British Pharmacopœia, or a lozenge containing liquorice, are often of service. An inhalation of oil of pepperment (℥xv) on the sponge of a perforated zinc inhaler is very efficacious in checking cough. Menthol may also be used for the same purpose. If the digestive powers be impaired, and there be loss of appetite and a furred tongue, an alkali with hydrocyanic acid and compound infusion of gentian is preferable. Counter-irritants, such as a blister the size of half a crown or equal parts of the tincture and liniment of iodine, applied to the affected apex are also of use. The iodine should always be applied in the morning, as, owing to the irritation produced being sometimes in excess of that desired, it is liable to keep the patient awake if applied at bedtime.

Cod-liver oil is generally best taken either after meals or at bedtime; at first one or two teaspoonfuls may be given twice daily, the quantity being gradually increased; if it cannot be borne, maltine or cream may be substituted.

Night-sweating is best treated by regular bedtime doses of sulphate of atropine, from $\frac{1}{16}$ to $\frac{1}{8}$ grain, in the form of pill. The majority of cases obtain relief by this means, but in some the atropia has no effect whatever, while in others it produces the dry throat and dilated pupil to such an extent as to prevent its regular use. Oxide of zinc, in 5-grain pills, should then be tried, or, failing

success by them, picrotoxin, in doses of $\frac{1}{16}$ grain. A trial may be given to strychnine if these fail. Sponging the chest with toilet vinegar at bedtime is often of service in checking the sweating. The exhausting effect of continual sweating is very great.

In ordinary cases the first attack subsides under this form of treatment, and the patient is left with a slight cough and more or less mental and bodily depression. Advantage must be taken of this pause in the progress of the disease to restore and build up the strength by nourishing food and tonic treatment on the one hand, and by guarding against exposure to risks of fresh cold, on the other. It must always be remembered that the disease shows a marked tendency to extend at irregular periods, and with each of these attacks a similar line of treatment requires to be followed out to that suggested for the initial stages. It must, however, be frequently modified according to the progress which the disease has made. Each successive attack will leave behind it some trace in the shape of a further area of lung tissue rendered unfit for service. In the more advanced stages and when the periods of febrile disturbance are longer, and the patient has become inured to them, it is less necessary to confine him to the house, but in cases whilst there is a definite tendency to recurrent attacks of bronchial catarrh, the best results are obtained when the patient is kept in a warm and equable temperature, and not allowed to expose himself to the frequent changes of temperature which are inseparable from an outdoor existence in England in the winter.

The treatment of cases during the periods of comparative quiescence of the disease must of necessity vary with the patient's social position. If he be independent of the necessity for work he should at once be placed in the best climatic surroundings suitable to his particular case (*vide infra, Climatic Treatment*). Warm and transpirable clothing to the limbs as well as to the trunk is essential for all patients, whether they be at home or abroad.

For those less fortunately situated, who must perforce remain at their own homes, close supervision is necessary to guard against the risks of catching cold. The prevention of draughts of cold air within the patient's own house is often a most important factor in the prophylactic treatment. Avoidance of chill and strict rules as to the changing of damp

wearing apparel, are of the utmost importance, and it is equally essential to insist upon the patient's remaining within doors after dusk. As regard remaining in the open air, it may be said that the longer the patient can remain out of doors the better, always provided that the temperature be above 55° F. and that he be not exposed to winds, damp air or actual wet. Quiet corners can often be arranged even in the smallest town gardens in which a phthisical patient can spend the greater part of the day, during the summer months, in fresh air, without risk of such exposure. He should endeavour to sit as much as possible in the sun. Nourishing food is an essential, but care is required in regulating the diet for individual cases, as there is very frequently a tendency to dyspepsia, even when the lung symptoms have become quiescent. Milk is the most important article of diet, and the richer and more creamy it is the better it suits the phthisical habit, provided that it can be borne at all, for, like cod-liver oil, it is sometimes repugnant to the stomach. Although it is always an advantage to maintain a large proportion of fatty matter in the diet, it is not advisable to give large quantities of milk or cream in association with cod-liver oil. Maltine after meals, or light bitter ale with the chief meat meal, will generally be of service, but moderation is necessary in the use of alcoholic liquors generally. Hot milk, with a little rum in it, is a favourite prescription for the early morning hunger which so commonly follows the attack of coughing with which the patient may wake. Strychnine, phosphoric acid and the hypophosphites of lime and soda are largely used in this stage, but not with uniform success.

The diarrhoea which sometimes complicates the later stages of tubercular phthisis, if it be due to ulceration, is best treated by a pill of sulphate of copper (gr. $\frac{1}{4}$) powdered opium (gr. $\frac{1}{2}$) ext. gent. (gr. ij) of which one or two may be given for a dose, or by frequent doses of aromatic sulphuric acid and tincture of opium, or opium enemata, with occasional saline purges given in the early morning. A close watch must be kept over the diet, which must be plain and non-stimulating. Diarrhoea, the result of amyloid degeneration of the intestinal wall, is most intractable and can rarely be checked altogether. Strong astringents are, on the whole, the most successful. Complete rest directly after taking food, and support to the abdomen by

means of a broad flannel binder, should be insisted upon.

Since the demonstration of the presence of the bacillus in tubercular tissues, a variety of efforts have been made to discover some method whereby the active vitality of the micro-organism may be checked and its reproduction prevented, after it has established itself within the pulmonary tissues. The inhalation of antiseptic vapours, the subcutaneous or intra-pulmonary injection of antiseptic fluids, and the injection of large volumes of sulphuretted hydrogen or carbonic oxide gas into the rectum, in the hope of the rapid absorption through the portal system and conveyance hence to the lungs, have each in turn been suggested and tried by competent observers. The results, however, are not such as to warrant the adoption of any one of them as regular modes of treatment. By thus deluging the whole body with the antiseptic fluids or gases some effect has undoubtedly been produced in the lowering of the body temperature for the time, and in some instances, an improvement of the general condition with respect to appetite and gain of weight has ensued, but on the other hand it has not been shown that any marked diminution in the number or reproductive activity of the bacilli has been effected, nor have the good results been maintained for long after the discontinuance of the treatment, whilst the treatment itself is in each case either unpleasant, painful or positively nauseating and repugnant, and hence by no means popular with patients. This line of treatment has been most successful in the later stages when cavities have formed, and when active suppuration is in progress, and the patient is suffering from the effects of septicæmia.

Attempts have often been made to check septic influence in the lungs by keeping the patient for many hours in a room in which the atmosphere is continually charged with antiseptic vapour. Favourable cases have been recorded, but against these must be set a long array of patients in whom headache, nausea, and complete loss of appetite have been the only results achieved.

Inhalation of air medicated with creosote, pinol, iodoform, eucalyptol or other antiseptic and sedative substances is at times comforting to individual patients, and may have a marked effect in allaying cough. The simple

oro-nasal inhaler is sufficient for this purpose. Where there is much laryngeal irritation, the steam draught inhaler medicated with carbolic acid or tincture of benzoin may be employed (*see* INHALATION). Spray inhalations are useless in the treatment of phthisis.

The all-important object being to maintain general nutrition, it is obvious that no line of treatment of phthisis which may be liable to interfere with appetite or digestion should be attempted, even though it may promise relief to some particular symptom; caution should therefore be exercised in prescribing for phthisical persons to put the requisite drugs into a palatable form. Phthisical patients as a rule suffer from the consumption of too much physic, as the hopefulness which is characteristic in some types of the disease leads the sufferers to try every new nostrum that may be offered to them by the professional remedy-mongers. It is never advisable to prescribe physic to a phthisical patient as a mere *placebo*; the temporary good that may be obtained by the faith that the physic may inspire is not commensurate with the disadvantages in the way of disturbed digestion or appetite that are at all times liable to be induced from very slight causes.

Climatic Treatment.—The climate of the British Isles during the cold months of the year is, with a few local exceptions, unsuitable to phthisical persons. During the summer months, on the other hand, the climate is, as a rule, to be preferred to that of any foreign health resort. In selecting a residence for phthisical patients during the winter season, one or two cardinal points require to be considered both by patient and physician.

First, it must be clearly understood that a partial climatic treatment is not worth attempting. Patients seeking to benefit by it must follow it out to its conclusion, and be content to forego all thoughts of business matters, and to give themselves up entirely to the mode of life prescribed for them. Secondly, hopes should not be held out that one or more winter's residence abroad will cure the disease. Climatic treatment is only curative in so far as it guards against recurrence of inflammatory attacks affecting the air passages, and enables the patient to live a healthy out-of-door life without fear of exposure to risks of "catching fresh cold." The natural tendency of the diseased tissues to return to a state of health is then allowed free play, and nature alone can complete the cure.

Thirdly, the patient's own habits and surroundings must be carefully taken into consideration. To some persons a sea life is intolerable, others are unable to speak foreign languages and have an aversion to foreign customs; some are only happy in a whirl of gaiety, others derive the most enjoyment from solitary life in the mountains, &c. Such considerations as these are of real importance in selecting a climate or health resort for each variety of temperament.

The most favourable climate for the arrest of phthisical inflammation is one which shall be free from all impurities, organic or inorganic; of high temperature, subject to regular variation in the evening and not liable to sudden changes; abundant in sunshine and free from cold winds. The relative moisture or dryness of the air cannot be so positively defined for all cases, as some require a more humid atmosphere than others.

Added to these, it is necessary that the hygienic conditions of the locality should be satisfactory, and the accommodation and the food supply sufficient. All these advantages can hardly be found combined in any one locality, but the greater number of them may be met with in many of the southern health resorts, and on long sea voyages. The treatment of phthisis by residence at high altitudes, requires separate consideration.

At the Swiss and American altitudes, besides the advantages of purity, equability and stillness of the climate, the rarefaction of the air places the respiratory organs under new and unaccustomed conditions. The muscular movements of respiration are increased and the chemical interchange of gases goes on more freely. The common result of this extra activity thrown upon the lung is the production of more or less emphysema, which is often most marked about the diseased area and may, by masking the abnormal physical signs, lead to the erroneous idea that local disease has disappeared. No cases of well-marked laryngeal tuberculosis should be sent to high altitudes, or such as are in a febrile state, nor should any be allowed to go who do not possess a sufficient area of healthy lung to enable them to breathe without discomfort in the rarefied atmosphere. Cases of dilated or enfeebled heart are specially unsuitable for mountain residence. With these provisos the following list will indicate approximately the appropriate climatic treatment for various stages of phthisis.

Patients with a family predisposition

and any threatening of actual phthisis should not spend the cold months in England if they are in a position to avoid it. A slow sea voyage in a sailing ship to Tasmania or Queensland, starting in October, a journey to the Cape and a few months' residence in the neighbourhood of Cape Town (not in Cape Town itself), with a visit to Madeira and the Canary Islands *en route*, should be advised. The journey to India, going out in October and returning in April, with a short stay in Egypt on the way home, can also be safely undertaken, but at other times of the year the transitions from heat to cold are too great. For those obliged to remain in England, the East coast watering-places of Scotland and England should be selected during August and September, but with the onset of cold weather and damp winds, the sheltered places on the south and west coasts should be sought. Hastings, Ventnor, Bournemouth, Sidmouth, Torquay and Tenby are all preferable to the northerly and easterly towns and counties.

In cases where disease, whether inherited or not, has definitely declared itself, and has begun with hæmorrhage, the patient should, if possible, be removed from the English climate as soon as the first part of the autumn is over, but not until the constitutional disturbance brought about by the hæmorrhage has quieted down. The selection of a suitable climate must depend upon the temperament of the individual. Excitable persons who are liable to febrile disturbances do best at sea, provided that they can afford all the luxuries obtainable on board ship, and that they are able to withstand the first effects of seasickness; for them the Australian voyage round the Cape should be chosen. The phlegmatic temperament on the other hand, is more likely to benefit by a residence at one of the Swiss health resorts at a high altitude. It is only permissible to send a patient for the first time to the altitudes, before the onset of winter, and if time allows, it is better that pauses should be made at a lower level station before finally settling down for the winter at the highest level. In the same way, the return in the late spring should be made gradually, and no patient should return to England before the third week in May. Of the high level health resorts, Davos Platz, St. Moritz, the Maloja, and Wiesen are all provided with every luxury that can be reasonably desired, and they are all approachable

by easy stages where halts can be made, both going and returning. Patients should be guided as to their mode of life at the altitudes, by local medical advice.

It has been claimed for the mountain health resorts, that the purity of their atmosphere has an antiseptic effect, but this idea is disproved by the well-ascertained fact that the number of bacilli in the sputa does not decrease in proportion to the improvement in the general health.

Cases which begin insidiously with catarrh, wasting and anæmia, and varying degrees of fever, are as a rule most benefited by the Mediterranean coast climate. The French or Italian Riviera presents a variety of climates suitable to various phases of this condition, but local advice should be sought before a definite selection is made. For the febrile cases, Hyères is especially adapted; and, for the more anæmic and feeble, either Cannes or San Remo may be chosen. A slow ascent to the altitudes may sometimes be advisable when all fever has subsided, but caution is required. Of the English coast resorts, Ventnor and the upper levels of Torquay are the best.

For the class of cases in which the disease has already produced well-marked structural changes in the lungs and in which there is a tendency to pneumonic consolidation, or where bronchitis is apt to occur with some rise of temperature, there are few climates better than those of Madeira and the Canary Islands. Such cases, however, do very well at Hyères, and, if there be not much fever, at most of the sheltered places on the Riviera, and at Algiers. For chronic cases with limited phthisical lesions, but a good deal of chronic bronchial irritation and dilated tubes, coupled with emphysema or much expectoration, a residence in Egypt and especially in Upper Egypt, is to be commended. The coast of California and the districts around Santa Barbara and Los Angeles are also suitable to these cases, provided that a good part of the time be spent on the higher grounds.

Cases of advanced chronic disease, where the respiratory surface has been much reduced, must never be sent to elevated health resorts, but will be most benefited by equable warm and fairly moist climates. Madeira and Algiers may therefore be selected provided that local advice be taken as to the choice of position for residence in either place. The results of climatic treatment may be roughly summed up thus:—That the

early cases if they be not attended with much pyrexia, do best at the altitudes; that cases of an excitable and irritable kind are more fitted either for sea voyages or for the warm and moist climates; that established disease is best treated by residence in equable climates where prolonged periods of sunshine can be enjoyed and where as few irritating elements as possible are present, such as dust, insects or cold winds (*vide CLIMATE*).

J. K. FOWLER.

PHTHISIS, LOCALIZATION OF LESIONS OF.—An examination of the literature of pulmonary phthisis will show how little attention has been paid by most writers to the exact site of the lesions in the lungs and their relation to the chest-wall. Whilst almost every one has his own explanation to offer for the apex-site of the primary lesion, and all recognize that in the early stages of phthisis the base is but rarely affected, scarcely any mention is made of the mode in which the disease progresses between these two points, or of the order in which the various parts of each lobe are affected.

The only reference to this part of the subject which is to be found in the writings of Laennec* is as follows:

"Tubercles are almost always developed primarily in the summits of the superior lobes, and especially in that of the right; and it is for this reason that, in these points, and particularly in the latter, vast tuberculous excavations are frequently met with. It is not very rare to find similar ones on the summit of one lung, the rest of these organs being quite healthy and presenting no tubercle; but in these cases, also, the patient has often betrayed no sign of pulmonary phthisis, or has displayed none but such as were very equivocal, and has died of another disease. It is more common to find an excavation, and some crude tubercles already far advanced in the summit of the lungs, and the rest of these organs which are still crepitant and healthy in other respects, infarcted with a countless number of very small semi-transparent miliary tubercles, of which scarcely any yet present the central yellow point.

"It is evident that these miliary tubercles are the product of a secondary crop, and one much more recent than that which had given rise to the excavations.

The results of dissection, compared with those drawn from observations on the living subject, have convinced me that these secondary crops take place at the period when the first-formed tubercles begin to soften.

"We frequently find within the same lung evident proofs of two or three successive secondary eruptions, and we may then almost always observe that the primary eruption occupying the summit of the lung has already reached the stage of excavation; that the second, situated around the first, and rather lower down, is formed by tubercles now yellow, at least for the most part, but as yet smaller in size; that the third, formed of crude miliary tubercles, with some yellow points in the centre, occupies a still lower zone; and finally, that the base of the lung, and its inferior border, present a last eruption of entirely transparent miliary tubercles, some of which are likewise found in the intervals left here and there by the preceding eruptions. . . .

"Exceptions to this order of development are uncommon. Primary excavations are very rarely met with in the centre or at the base of the lung: it is less frequent for the left lung to be more affected than the right."

Louis* on the same subject writes as follows:

"Tubercles were almost always more numerous, larger, and more advanced in development at the apex than at the base of the lungs; among the cases analyzed in this work—one hundred and twenty-three in number—two only furnish exceptions to this rule."

The statements in the writings of Bayle, Andral, Portal, and others do not vary materially from the foregoing, and add nothing to our knowledge of the exact site of the lesions.

Walshe,† in describing the anatomical characters of phthisis states:

"Yellow tubercle, whether preceded or not by the semi-transparent grey granulation, and whether accumulated in isolated or grouped masses, or infiltrating the pulmonary stroma, affects a special preference for the apex and upper lobe—either spreading thence downwards uniformly, or leaving islets of parenchyma of various sizes unoccupied in its transit towards the base. Exceptions to

† "Diseases of the Lungs," fourth ed., p. 415, par. 1228.

* "Traité de l'Auscultation Médiate," trans. Ed. Th. Herbert, 1846, p. 265.

this topographical mode of progress (on which the diagnosis of the disease so often turns) are infinitely rare in chronic tubercularization, the base of the lung proving the primary seat of the process, not oftener, it has been calculated, than once in sixty or eighty instances.

"The softening process, like that of original deposition, commences at the apex of the lung and spreads downwards."

To Dr. William Ewart* belongs the credit of having been the first to draw attention to the "remarkable proneness to disease" of the dorso-axillary region, and of its "greater proneness to excavation." In an examination of 304 lungs he found cavities in this area in 227 cases. He states:—"I doubt whether clinical observations have hitherto led to so high an estimate of the frequency of this lesion. A knowledge of this pathological fact cannot fail to stimulate a more searching clinical exploration of a region so liable to disease, and to strengthen the conclusions which our diagnosis may derive from physical methods of examination."

Dr. Ewart adopts the areas of the chest-wall as the basis for his classification of cavities according to their situation; in this article the lesions are described as they affect the different lobes of the lungs.

The following extract is from the work of a writer of a still more recent date, the late Dr. Hilton Fagge:†

"... I must insist on a point which has long been known both to physicians and pathologists, namely, that the upper parts of the lungs are almost invariably affected with phthisis, in whatever form, before the lower parts; and that in all but the most exceptional instances the disease spreads downwards from the apex to base often with almost perfect regularity.

"I must not omit to add that the rate of the proclivity of the apex is liable to some other exceptions. In certain cases the tubercles appear a little lower down, leaving one or two cubic inches at the extreme summit of the upper lobe free from them. But sometimes the middle of the organ is first affected, or even the lower lobe, the upper angle of which is indeed very often the seat of a vomica, in ordinary instances of phthisis.

"But I believe it never happens that the tubercular process spreads upward from the base of a lung into and through the upper lobe. And it is certain that what has sometimes been called 'basal phthisis' is a distinct affection, which has been described above under the name of chronic pneumonia."

It may fairly be said that, until quite recent times, our knowledge of the progress of pulmonary phthisis has been limited to the fact that "the softening process, like that of original deposition, commences at the apex and spreads downwards."*

The writer has not anywhere met with the statement that *the disease, in its onward progress through the lungs, in the majority of cases, follows a distinct route, from which it is only turned aside by the introduction of some disturbing element.* Now, this fact, if fact it be, is of great importance in that it tends to give increased definiteness and certainty to information which we may gain from an examination of the chest. If we are prepared to find lesions anywhere and (the apex excepted) attach no particular importance to their being situated in one place rather than another, our knowledge of the conditions present and our ability to forecast the future progress of the case may be very different from what it would have been had we begun the examination with a clear idea, not only that the disease as a rule followed a definite line of march, but also of the actual route likely to be taken. We should then first have searched the apex in various sites of election of primary lesions; finding evidence of disease there, we should have followed it along its usual course in the upper lobe and have estimated its extent by noting its furthest limits. Then, turning to the lower lobe, with a knowledge of the point most likely to be first attacked and of the lines along which the disease progresses in that part of the lung, we should have determined the presence and amount of infiltration; and our examination completed, the mental picture of the extent of lung involved might have been almost as clear as though the organs had been exposed to our view.

On the other hand, we might discover that the disease had not followed its ordinary course, and that, whilst the total area of lung involved was still very small, a part usually affected at a late period only, already showed signs of

* Gulstonian Lectures, 1882, on "Pulmonary Cavities: their Origin, Growth, and Repair."

† "Principles and Practice of Medicine," 1st ed. vol. i. p. 647.

* Walshe, *op. cit.*, p. 415.

infiltration. This would start us on a search for some disturbing factor, such as a previous attack of pleurisy, which, by diminishing the resisting power of a portion of the lung, had allowed such an inversion of the natural sequence of events to take place; or, more important still, it might inform us that the disease was not of that subacute or chronic type in which the progressive development of lesions about to be described is usually found. Or again, it might be a question whether or no the disease was of a tuberculous nature; now the probability of such being the case is much increased if the lesions are found in situations most affected by tubercle.

This is no fanciful statement of the exact knowledge to be obtained from physical examination of the chest in phthisis, if the assertion of the existence of a definite "line of march" of the disease should prove correct. Extensive lesions may of course be present of which there may be no evidence; but that fact tells for nothing, as we are only concerned with cases in which physical signs are to be found.

These conclusions are based on considerable experience in the post-mortem room; but, as the particular distribution of lesions here described is likely to be overlooked unless sought for in a certain way, it is necessary to describe first the mode of examining the lungs adopted. Following the recommendations of Virchow,* the sections should always be in the same lines, the first exposing the largest possible surface, and all others in the same lobe parallel with it; the organ after the examination presenting an appearance similar to the leaves of a book. The left lung is placed on the table with the root downwards and the *base* towards the examiner. If there be no interlobar adhesions, or only such as can be easily broken down, holding the blade parallel with the table, make a section through the upper lobe at the level of half the depth of the interlobar sulcus, commencing just below the apex and extending thence along the posterior border and the sulcus. The section must stop before the part is entirely severed. This "leaf" should then be turned over, and the whole of the upper lobe will be displayed.

The first section through the lower lobe is made along the prominence of the posterior border, through the base, and

then towards the sulcus again, stopping before the part is completely separated.

If the interlobar adhesions cannot be separated without injury to the lung, a single long section should be made from apex to base along the posterior border, and carried through the lung toward its anterior margin.

The right lung is placed on the table with the root downwards and the *apex* towards the examiner.

Any easily separable interlobar adhesions having been dealt with as already directed, the point of the blade is inserted at the lower and anterior extremity of the upper lobe, and an incision is made at the level previously mentioned, upwards and outwards towards its apex and anterior margin. The middle lobe is separately incised from below upwards. The incision in the lower lobe, starting from the anterior margin of the base, is continued through this part and along the prominent posterior border, stopping short of the sulcus, so that the section may not be complete.

If the interlobar adhesions cannot be easily broken down, a single section is made as in the left lung, but from base to apex instead of *vice versa*.

If it be made a rule to examine the lungs after this method, there is no difficulty in appreciating the arrangement of lesions about to be described; if, however, a number of irregular incisions be made, and no definite plan adopted in the examination of each lobe separately, all traces of the progressive march of the disease may easily be lost.

As it is rare to find any one who, without having had reason to study the subject specially, is acquainted with the exact relations of the different lobes of the lungs to the chest-wall, and as such knowledge is obviously necessary in order to follow the spread of the lesions from one point to another, it is necessary to introduce here a few brief anatomical details.

The apex of each lung rises about one inch and a half above the clavicle. On the left side almost the whole of the front of the chest is occupied by the upper lobe, only the anterior extremity of the lower lobe being visible. On the right side the front of the chest above the fourth interspace is occupied by the upper lobe, below that by the middle lobe, only the point of the lower lobe coming in, as on the opposite side. Behind, the fact which is chiefly to be noted is that the lower lobes reach as high as the third dorsal spine, and the

* "Handbook of Post-mortem Examinations."

right, being, however, usually rather lower than the left, thus occupy almost the whole of the posterior surface of the chest, except that part which roughly corresponds to the supra-spinous fossæ. The septum between the left upper and lower lobes, starting from the third dorsal spine posteriorly, extends obliquely downwards and forwards, crossing the fourth and fifth interspaces, passing behind the scapula and sixth rib in the axilla to the upper border of that rib in the mammary line.

On the right side the line of the septum terminates at the eighth rib just outside the nipple line; a second septum, starting behind the scapula, just external to the posterior fold of the axilla, runs transversely forwards along the fourth interspace to the middle line, thus forming the middle lobe. The above statements are approximately true in the majority of cases, but the exact relations of the various lobes and septa vary somewhat in different subjects. The limits of the bases of the lungs are not now of importance.

The erroneous views most commonly held with regard to the relation of the lobes to the chest-wall are, first, that a considerable portion of the front of the chest is in relation with the lower lobes; secondly, that the right middle lobe is situated much further back than is actually the case; and, thirdly, that the lower lobes occupy far less of the posterior surface than they really do.

In the diagrams, for the sake of greater clearness, the outlines of the lobes are completed, and in Fig. 1 the upper lobes are separated more widely beneath the sternum than is actually the case.

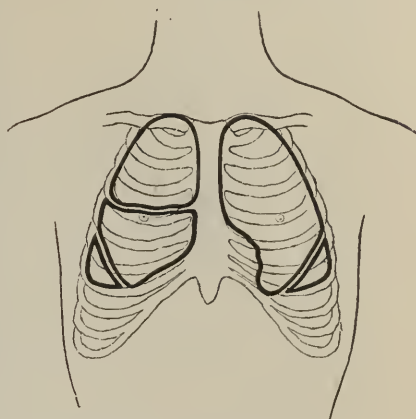

The exact situations occupied by the primary and secondary lesions in the different lobes of the lungs will now be described in detail.

Sites of Lesions in the Upper Lobes.—

The extreme apex of the lung is not often, in the experience of the writer, the site of the primary lesion; this usually occupies one of the two situations marked on the accompanying diagrams (Figs. 3 and 4). Of the two the former is by far the more common; it is situated from an inch to an inch and a half below the summit of the lung, and rather nearer to the posterior and external borders. Lesions in this situation tend to spread in the first instance backwards, possibly from inhalation of the virus whilst the patient is lying down. This line of extension explains the fact that an exam-

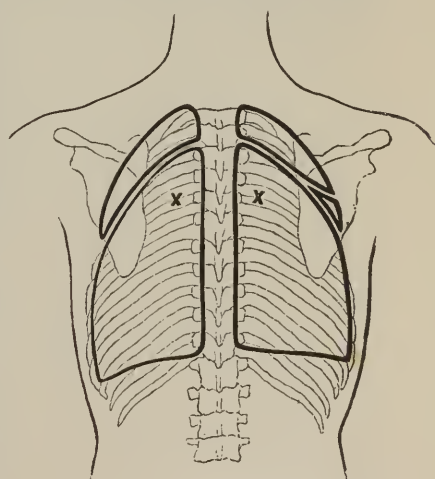

ination of the supra-spinous fossa will often give certain evidence of the presence of disease when the physical signs in front of the chest have left us in

FIG. 1.

Showing the relation of the lobes of the lungs to the front wall of the chest.

Showing the relations of the lobes to the wall of the chest posteriorly. The X marks the usual site of early infiltration of the lower lobes.

N.B.—The apex of the right lower lobe should have been slightly lower than the left.

doubt, proving that the changes, as is generally the case, are more advanced there than towards the front of the

chest. *The investigation, therefore, of this part of the lung is so important that it should never be omitted.*

From this primary focus, which in front corresponds either to the supra-

FIG. 3.

clavicular fossa or to a spot immediately below the centre of the clavicle, the lesions often first spread downwards along the anterior aspect of the upper lobe, about three-fourths of an inch

within its margin, frequently occurring in scattered nodules, separated perhaps by an inch or more of healthy tissue. If, therefore, the disease appear to be limited to the upper lobe, a careful examination should be made along a line running about an inch and a half from the inner ends of the first, second, and third interspaces. It is not unusual to find in these scattered nodules the only evidence of disease on the anterior aspect of the lung, when, posteriorly, excavation has advanced to such a degree that little more than the two layers of the pleura, united by adhesions, remain. This is an additional reason for making a careful examination of the supra-spinous fossa.

The second and less usual site of the primary affection of the apex is seen in Fig. 4. This corresponds on the chest-wall with the first and second interspaces below the outer third of the clavicle. The lines of extension are usually downwards, so that after a time an oval area of lung is involved, occupying the outer part of the upper lobe in the situations just mentioned. It has seemed to the writer that the spread of the disease is more rapid when the primary lesion occupies this site. The lesions in the advanced stages—cavities—are of course formed by the coalescence and extension of these primary foci. The scattered nodules of consolidation on the anterior surface of the lung often unite and break down, forming a long sinuous cavity, which may extend almost to the lower anterior margin of the upper lobe; posteriorly, where, as already stated, the signs of excavation are usually most distinct, the further progress of the disease is generally arrested at the pleural reflexion in the interlobar septum. This was found by Dr. Ewart to be destroyed, and the cavities in the upper and lower lobes united, in only five out of 152 consecutive cases of phthisis examined post mortem.

In rare cases the whole of a lung may undergo destruction, a large sac, bounded by the pleura, being formed.

Site of Lesions of the Middle Lobe.—The middle lobe of the right lung, which is believed by Aebv, from the arrangement of the bronchi, to be the analogue of the upper lobe of the left, is rarely the site of a primary tuberculous lesion. It is, almost invariably, affected after the upper lobe of the same side and usually at a rather late period of the disease,

whilst not uncommonly it escapes altogether. The lesion most commonly found there is a coarsely granular tuberculo-pneumonic nodule, often of large size, in process of caseation at its margin, with an area of softening in the centre.

Extension of the Lower Lobe.—The lower lobe of the lung primarily diseased is usually affected at a very early period of the disease, often long before any extensive infiltration or destruction of the upper lobe has taken place, and as a rule before the apex of the opposite lung.

The site of the secondary infiltration of the lower lobe is indicated in Figs. 2 and 3. It is situated about an inch to an inch and a half below the upper and posterior extremity of the apex of the lower lobe, and about the same distance from its posterior border, although in some cases it may be found nearer to and even at the apex of this lobe. This situation nearly corresponds on the chest-wall to a spot opposite the fifth dorsal spine (*vide* Fig. 2), midway between the border of the scapula and the spinous processes.

The infiltration of the lower lobe at this site in the early stage of phthisis is one of the most constant features in the pathological anatomy of the disease, and its recognition is a point of the greatest clinical importance, as the existence of a lesion in the lower lobe at this spot coincident with physical signs at the apex, even though the latter be in themselves of doubtful import, is strongly suggestive of the presence of pulmonary tuberculosis.

At what an early period this infiltration of the lower lobe takes place may be gathered from the fact that from a careful observation extending over several years, it may be stated that in the great majority of cases, when the physical signs of disease at the apex are sufficiently definite to allow of the diagnosis of phthisis being made, the lower lobe is already affected.

It would therefore appear that the upper and posterior part of the lower lobe is a spot in the lungs only second in point of vulnerability to the apex itself. The writer cannot confirm the statement of Fagge, already quoted, that "sometimes the middle of the organ, or even the lower lobe" (not at any rate this part of it) "is first affected," as he has never yet met with a case, either during life or on the post-mortem table, in which this area was affected whilst the apex on the same side was

free from disease (but *vide infra* as to "crossed lesions").

The absence of any sign of infiltration there is not, however, proof of the non-tuberculous nature of an apex lesion, as it is quite possible in some cases, from the physical signs alone, to arrive at a diagnosis of phthisis before the lower lobe is affected. The importance of the examination of the sputa has been already referred to.

On one point it is possible to speak positively, viz., that no report of the condition of the lungs in a case of apical disease is complete without a distinct statement as to the condition of the "posterior apex" (for so, for brevity's sake, it may be called) of the lower lobe. If careful attention be given to this point less will be heard of cases of "catarrh of the apex," which are often assumed to have been non-tubercular from the subsequent disappearance of the physical signs; such cases must often be examples of arrest of the disease in the first stage and help to explain the very frequent discovery of that condition post-mortem.

In the description of the result of climatic or medicinal treatment in the early stage of phthisis it is commonly stated that the disease was limited to the apex of one or both lungs. In a recent account of the climatic treatment of twenty cases of phthisis, in thirteen of these the disease is said to have been limited to one apex, whilst in four both apices were affected, and in no case is there any mention of the condition of the lower lobes except when the whole of a lung is stated to have been affected.

Cases in which the lesions are confined to both apices, no other portion of either lung being affected, are not common. In a case recently observed in which death occurred from tubercular meningitis, with recent pulmonary tuberculosis, the apices of both lungs were the seat of old disease, whilst the lower lobes had at that time entirely escaped infiltration. There were signs of arrest of the disease at each apex, showing clearly that in both lungs the process had been stayed before the lower lobe on either side had become affected. In the left lung the changes were of much older date than in the right, and the patient had clearly been the subject of two separate attacks of tuberculosis.* It is common enough

* In a very similar case in which death occurred from acute pulmonary tuberculosis,

to find arrest of pulmonary tuberculosis when one apex and its corresponding lower lobe have been affected, but it rarely happens that arrest occurs at both apices without infiltration of either lower lobe. The early stage of the disease at which the lower lobe is implicated is well illustrated in lungs presenting apex lesions which have undergone arrest. The area of disease may not be larger than a cherry or an olive, but if the process was tuberculosis a nodule will almost invariably be found in the lower lobe. This arrangement of lesions thus becomes an important rough post-mortem test of the presence of tubercle, and is strong evidence in favour of the existence of a "line of march" of the disease.

In a few of the cases observed, post-mortem lesions not presenting a trace

FIG. 5.

Showing the line of extension of a lesion of the lower lobe along the interlobar septum.

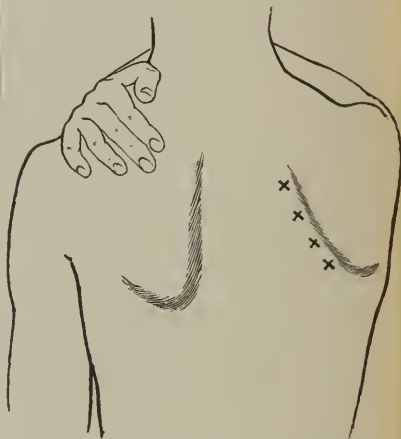

of tubercle were present at the apex—*e.g.*, collapse followed by bronchiectasis, or changes resulting from old pleurisy the lower lobes were quite free from disease.

This lesion once established tends to spread backward towards the posterior border of the lung, and at the same time laterally along the line of the interlobar septum (Fig. 5), forming a doubly

an old caseous lesion the size of an olive was present in each apex; one was completely encapsuled, the other had recently broken down and had been in part discharged through a bronchus, the walls of which were ulcerated; death occurred from acute pulmonary tuberculosis.

wedge-shaped area of infiltration gradually narrowing as it extends outwards. It follows from this that even in the early stages of the disease, in order to ascertain the extent of lung affected, we must examine the lower lobe, not only opposite the fifth dorsal spine, but also along the line of the interlobar septum. This line is roughly marked by the vertebral border of the scapula, when with the hand upon the spine of the opposite scapula the elbow is raised above the level of the shoulder (Fig. 6).

FIG. 6.

Showing the position of the arm when the vertebral border of the scapula indicates (roughly) the usual line of extension of lesions along the interlobar septum.

The mode of extension towards the base of the lung is not usually by an advancing line of consolidation but by scattered nodules of infiltration often arranged in a racemose manner (Fig. 7). Even at the termination of a chronic case some healthy, or at least uninfected, tissue will generally be found at the base, even of the lung primarily affected. This freedom of the bases from phthisical lesions is another very marked feature in the pathological anatomy of the disease. In estimating the probability of any basic lesion being tuberculous in origin, it is important to observe whether the physical signs of disease in the lower lobe are continuous from its apex posteriorly, downwards to its base; if so the lesion is probably tuberculous. If the base be affected, but the apex of the lower lobe be free from disease (*vide* Fig. 8), the basic

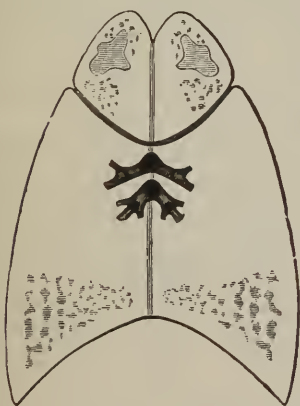

lesion is either non-tuberculous—*e.g.*, due to œdema and collapse, followed by bronchiectasis, catarrhal pneumonia, or

FIG. 7.

Showing the usual mode of extension of the disease towards the base of the lung.

FIG. 8.

pleurisy, &c.; or if tuberculous, the resisting power of the base has been diminished by some previous affection—for example, an attack of pleurisy followed by partial collapse; but the presumption is strongly in favour of a non-tuberculous lesion.

In enumerating the exceptions to the usual arrangement of the lesions, the varieties of chronic disease which may be

met with at the bases of the lungs have been tabulated.

Mode of Extension to the Opposite Upper Lobe.—Tuberculous infiltration in the upper lobe of the lung not primarily affected often occurs at an early period, but not usually until after the disease has attacked the lower lobe of the lung first affected.

The lesions may be found in either of the common situations indicated in Figs. 3 and 4, and are therefore symmetrical in site, but in different stages on the two sides.

There is, however, a third site for the secondary infection of the opposite upper lobe, which is figured in the accompanying diagram (Fig. 9). It is situated close to the interlobar septum, about midway

FIG. 9.

Showing an occasional site of lesion in the lung not primarily affected.

between its upper and lower extremities, and corresponds on the chest-wall to the upper part of the axilla. Small areas of consolidation form here and coalesce, but rarely break down into a cavity of any considerable size. Once established, this lesion tends to spread laterally, inwards and upwards, and is often found to occupy a considerable area of the lung when the apex is quite free from disease.

Infiltration of this area, when present, generally follows that of the lower lobe of the lung first affected.

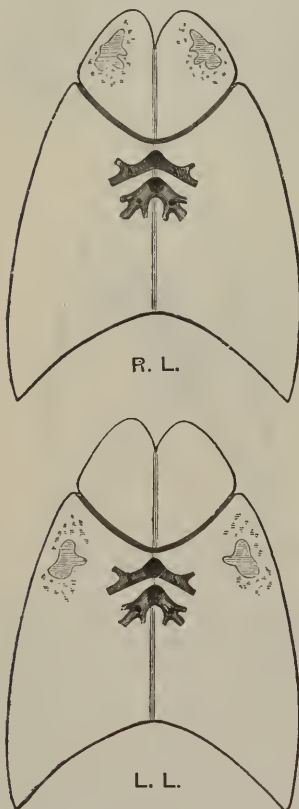

It follows from this fact that, in addition to the apex, the upper part of the axilla must be carefully examined before the other lung can be pronounced to be free from disease in a case of phthisis apparently limited to one apex.

Extension to the Lower Lobe.—The dis-

tribution of the lesions in the lower lobe of the lung secondarily diseased is usually similar to its fellow on the opposite side and presents no peculiarities. The first infiltration is situated below the posterior apex, and this extends along the interlobar septum and ultimately downwards towards the base, but it is rare for the lower margin to be reached before death takes place.

Crossed Lesion of the Lower Lobe.—The writer has met with a considerable number

FIGS. 10 AND 11.

Illustrating a "crossed lesion," i.e., from right apex to left lower lobe.

of examples post-mortem, and has been able to recognize a few clinically of what may be termed a crossed lesion of the lower lobe (Figs. 10 and 11). The usual mode of extension to the lower lobe is, as just stated, from (say) the left apex to

the left lower tube, but occasionally the lower lobe of the lung primarily affected escapes infiltration, and the disease crosses over to the right lower lobe. In such a case, the site of secondary infiltration is the usual one near the posterior apex. In all cases, therefore, of apex disease it is necessary to examine both lower lobes before deciding that the disease is limited to that spot.

Exceptional Arrangement of Lesions.—As already stated, the line of march here laid down, although covering the great majority of cases, is subject to certain exceptions. Speaking generally, this arrangement of lesions is seen in its most typical form when the progress of the disease is slow, and is less distinctive of cases marked by acute symptoms and rapid extension from lobe to lobe and from one lung to another. Time is necessary for the temporary localization of the disease which such a mode of progress as is here described requires, but there is rarely any inversion of the natural order. The disease spreads in each lobe from above downwards, hardly ever from below upwards, but in the lower lobe the onward march may be so rapid that one does not find that limitation of the affection for a time to the posterior apex and extension along the interlobar septum which are such marked features in the pathological anatomy of cases which run a subacute or chronic course.

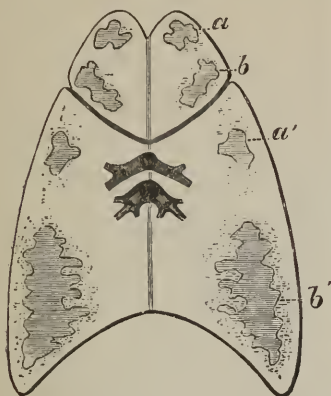

Upper Lobe.—In an example lately observed a lesion which had gone on to the stage of cavity appeared to be placed almost midway between the two sites of primary lesions indicated in Figs. 3 and 4. In this case the posterior part of the upper lobe and the apex of the lower lobe were apparently not affected, as there was a complete absence of physical signs in the supra-spinous fossa and also opposite the fifth dorsal spine. It is possible that further observations may show that the disease tends to run a different course when the primary lesion occupies this site.

When the usual sites of infiltration in the upper and lower lobes are already occupied by arrested lesions, and a second tubercular infection of the lung occurs at some later and perhaps distant date, the more recent lesion in the upper lobe usually occupies a position close to the interlobar septum, whilst that in the lower tube is situated along the posterior border, and extends almost to the base (Fig. 12).

This observation is of importance in so far as it helps to explain the occur-

rence in some cases of basic disease, and will be referred to again in the descrip-

FIG. 12.

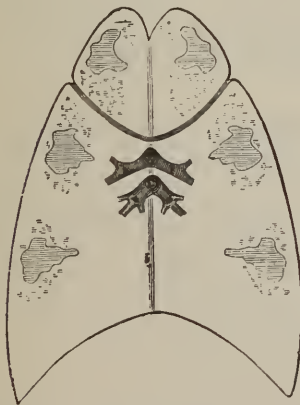

Illustrating the situation of lesions in secondary infection of a lung the seat of arrested phthisis; *a, a'*, arrested lesions; *b, b'*, recent lesions.

tion of lesions of the lower lobes occupying exceptional situations.

Lower Lobe.—The accompanying diagram (Fig. 13) illustrates an unusual

FIG. 13.

Illustrating an unusual arrangement of lesions in the lower lobe.

lesion, of which the writer has met with several examples.

A second cavity, almost equal in size to that at the posterior apex, is seen in the lower lobe about midway between that spot and the base, and close to the posterior border, the intervening area

being almost free from disease and the base quite unaffected. In no case observed has this cavity been present whilst the usual area of disease in the lower lobe remained uninfiltated.

Basic Lesions.—Reference has already been made to the comparative freedom of the bases of the lungs from tuberculous disease; whenever, therefore, a lesion is found in this situation a most careful survey should be made, both of the history of the case and of the physical signs present, before coming to the conclusion that the basic disease is tuberculous.

The most common varieties of chronic disease affecting the basis of the lungs may be classified thus:

(a) *Non-Tuberculous Basic Disease.*

1. Collapse of the lower lobe caused by pleural effusion; followed by absorption of the fluid and falling in of the lower part of the chest on the affected side.
2. Collapse from the same cause, followed by cirrhosis of the lung and bronchiectasis.
3. Empyema opening into the lung.
4. Hepatic abscess, or hydatid cyst of the liver, communicating with the lung.
5. Collapse of the lower lobe from pressure on the main bronchus by a growth or enlarged and infiltrated mediastinal glands, followed by bronchiectasis.
6. Diffuse gangrene of the lower lobe resulting from a communication between the bronchi and the œsophagus, either directly or through the medium of a softened bronchial gland.
7. Chronic pneumonia and bronchiectasis following on the impaction of a foreign body in one of the bronchi of the lower lobe.
8. Unresolved and chronic pneumonia of the lower lobe.
9. Bronchiectasis secondary to catarrhal pneumonia and collapse. This lesion is rarely found except in children.

(b) *Non-Tuberculous Basic Disease complicated by subsequent Tuberculosis.*

Cases presenting basic lesions are occasionally met with in which the disease, originally non-tubercular, has had the tuberculous process engrafted on to it at some later period; the lower lobe being infected, either directly or, which is perhaps more common, subsequently

to the apex of the same lung. This complication is very likely to occur where bronchiectasis forms a part of the original lesion, but may also be found in cases of chronic pneumonia and in other forms of non-tuberculous basic disease enumerated above.

(c) *Basic Phthisis.*

1. Phthisis with physical signs most marked at the base, but the oldest lesions at the apex.
2. Phthisis with arrested lesions at the apex and at the posterior apex of the lower lobe, more recent lesions in the upper lobe and also at the base (*vide* Fig. 12).
3. Primary basic phthisis.

Cases illustrating several of the conditions here tabulated are described by Dr. Percy Kidd, in a paper on Basic Tuberculosis Phthisis,* from which some of the headings here used have been taken.

The mere enumeration of the many varieties of disease affecting the bases of the lungs is sufficient to show what caution is necessary before arriving at a diagnosis of primary basic tuberculosis.

Dr. Kidd narrates two such cases, being the only instances met with in 412 consecutive cases of phthisis examined post mortem; he is of opinion that a larger number of examinations would probably reduce the proportion of basic to apical phthisis to 1 in 500. During a post-mortem experience of six years not a single such case has been observed by the writer, and, as Dr. Kidd very rightly insists, none but pathological evidence can be accepted on this point, for it is only by a prolonged experience in the making of autopsies that one can become adequately impressed with the fallacies attendant upon physical diagnosis.

When the lower lobe is shown on post-mortem examination to have been the site of primary tubercular infection it will usually be found that its resisting power and functional activity have been diminished by previous disease either of the lung or pleura. In both of Dr. Kidd's cases, already referred to, firm pleuritic adhesions were found at the base.

In nearly all cases presenting lesions in unusual situations, it is possible by careful inquiry and examination to determine the cause of the departure from the normal course.

In such cases as show the arrangement here described most typically, it is pro-

bable that the disease spreads chiefly by inhalation of the virus from one point to another through the medium of the bronchi. Where, however, the blood or lymph vessels form the chief channels of dissemination, as for example in acute pulmonary tuberculosis, and probably also in the more acute forms of phthisis, it is difficult to recognize, either during life or on the post-mortem table, that the lines of extension of the disease are such as are here indicated. This does not, however, diminish the value of these observations, provided they are sound, for *the mere fact that no definite line of march can be made out is often in itself of the greatest importance in the prognosis of the case*, as it may indicate that the disease will run a rapid course. One of the chief dangers which beset the subject of chronic or arrested phthisis is the liability at any time to an outbreak of acute pulmonary tuberculosis. In such a case it is constantly seen, post mortem, that whilst the older lesions have followed the course here described, the remaining and previously healthy portions of the lungs have been rapidly infiltrated with miliary granulations arranged in no definite order. That in the interpretation of physical signs their exact site is a matter of importance has always been held with respect to lesions at the apices; this doctrine may be extended to all signs of disease, no matter in what part of the lungs they may be found.

J. K. FOWLER.

PHYSICAL EXAMINATION.—

In accordance with the plan adopted throughout this work such terms as are in common use and likely to be sought for independently (PALPATION, PERCUSSION, AUSCULTATION, MENSURATION) have been described under their proper headings. It is therefore only necessary here to indicate the order and method in which a physical examination should be conducted, and to describe the appearances observed on INSPECTION.

The presence of any given disease is determined by the existence of *signs*, which are either obvious to, or discoverable by, the observer, and of *symptoms*, which are subjective sensations appreciable by the patient alone. The word *sign* is generally qualified by the adjective *physical*, and the present tendency is to limit that term to such signs as are present in diseases of the lungs and heart.

A patient, for example, may complain of certain symptoms, and may present

* *Lancet*, October 2, 1886.

such signs as a flushed face, a high temperature, quickened pulse and respiration, but if, on examination of the chest, nothing definite be discovered, it is nevertheless common to state that these are no "physical signs."

To recapitulate here all the signs which may be present in conditions of disease of the various systems of the body would entail repetition of much that is stated elsewhere and would serve no useful purpose.

Regions of the Chest.—For convenience of description the chest is divided into certain regions, but, as the terminology is somewhat variable, it is best in all cases to indicate the position of any physical sign by reference to certain vertical lines and a given rib or interspace.

The vertical lines are as follows:—(1) The mid-sternal line, (2) the nipple line, (3) the anterior, mid and posterior axillary lines, (4) the posterior scapular line (vertebral border of the scapula), (5) the vertebræ. Other terms are used by some writers, but they are rarely employed in practice. The normal position of the cardiac apex is thus described: "In the fifth interspace one inch within the nipple line."

The following regions are commonly spoken of without their boundaries being accurately defined:—

Anteriorly.—The supra-clavicular, the infra- or sub-clavicular, the mammary, and infra- or sub-mammary regions.

The supra-sternal notch, the upper and lower sternal regions.

Laterally.—The axillary and infra-axillary regions, or upper and lower axillary.

Posteriorly.—The supra-spinous fossa, the infra-spinous fossa, the interscapular region, and the base.

For the relations of the lobes of the lungs to the chest wall, the reader is referred to the article on PHTHISIS, LOCALIZATION OF LESIONS OF.

Regions of the Abdomen.—The abdomen is divided into nine regions by the intersection of vertical and horizontal lines, the former drawn from the eighth rib to the centre of Poupart's ligament, the latter on a level with the lowest point of the costal arch and uniting the anterior superior iliac spines. The central regions are from above downwards, the epigastrium, the umbilical region, and the hypogastrium, on either side are the hypochondrium, the lumbar region, and the iliac region.

The examination of the lungs, heart and abdomen is conducted in the follow-

ing order:—(1) Inspection, (2) Palpation, (3) Percussion, (4) Auscultation, (5) Mensuration.

It may be confidently observed that, no matter how experienced the examiner, it is rarely advisable to depart from this order, as so doing may entail the necessity of recommencing the examination when half finished.

As already stated, all these subjects, except the first, are described under their proper headings.

INSPECTION.—This preliminary step, although much neglected by students, is certainly in importance equal to, if not greater than, any other part of the examination. So much is there to be learnt from inspection, that it is often possible in a case of phthisis, and even in some valvular affections of the heart, by simply looking at the chest to make a near approach to an accurate diagnosis.

Of the Chest.—The patient should be placed in a good light and the observer should stand opposite to him. Attention should be directed to the various points in methodical order.

The condition of the integuments and of the superficial vessels must be noted. The *shape* of the chest is of importance. The normal chest is well proportioned in the various diameters, the sternum has a slight curve forwards, the angle of Ludovici (junction of second cartilages with the sternum) is fairly marked.

In phthisis, on the other hand, the chest may be long and narrow, the upper interspaces wide, and the antero-posterior and lateral diameters diminished; or it may be fairly broad but flat in front. The point of the shoulder may be lower and the supra-clavicular fossa may be deeper on one side than the other, and there may be a depression beneath one clavicle, indicative of shrinking of the corresponding lung. In pleurisy with effusion a bulging of the affected side may be observed.

In emphysema the chest tends to assume a rounded outline, the "barrel-shaped chest," the antero-posterior diameter is much increased, and the sternum arched forwards. In rickets there is often a depression running obliquely downwards and outwards from the mammary regions to the costal margin, giving the transverse section of the chest the shape of a fiddle; with this the sternum may present the typical "pigeon breast." Again, the local bulging, due to an aneurysm of the aorta, may arrest attention on inspection.

Shoemakers often present a depression

of the lower part of the sternum, due to the manner of holding the foot when at work.

Behind.—It is important to notice the position of the scapulae, as any retraction of the upper part of the chest usually manifests itself by a drooping of the shoulder and lowering of the angle of the scapula, which is also seen to be nearer to the vertebral column. The long narrow chest is sometimes termed "alar," from the projecting wing-like position of the shoulder blades, due to the drooping of the shoulders.

Movement.—The expansion of the normal chest is equal on the two sides, and causes an increase in all the diameters. In disease it may, from various causes, be unequal, or absent, the enlargement being effected by the descent of the diaphragm, the chest only moving upwards "en masse."

If there be obstruction to the entrance of air, the intercostal spaces will be observed to sink in during inspiration, generally if the obstruction be in the larynx or trachea, locally if the obstruction be local.

Of the Heart.—The site of the apex beat will be first observed. The impulse may be diffused, and in emphysema is often most obvious in the epigastrium. The precordial region may be bulged in consequence of hypertrophy; this is not uncommonly seen in the case of children with valvular disease. Systolic recession of the interspaces or epigastrium, or even of the ensiform cartilage, may be present. The value of these signs in the diagnosis of pericardial adhesion is discussed under that heading. The heart may be uncovered by the retraction of the left upper lobe, and the apex may be obviously displaced from a variety of causes.

Of the Abdomen.—The condition of the superficial vessels will be noted, and the state of the abdomen as regards distension or retraction. Distension may be general or local. Peristalsis may be observed, and is sometimes indicative of gastric or intestinal obstruction. The attitude of the patient is of importance.

J. K. FOWLER.

PHYSOMETRA.—Distension of the uterus by air or gas. It may occur during labour, or in the puerperal state, or with atresia or blocking of the cervical canal, independent of pregnancy. It is rare, and cases apart from labour are so rare that their existence has been doubted; but authentic cases have been

published. It results from decomposition of a dead foetus, of the liquor amnii, or placenta, or of retained secretions. It is said to occur "in hysterical women." This means that hysterical women have sometimes passed wind from the rectum, and said it came from the vagina. Retention of air in the vagina, and its subsequent expulsion, sometimes with noise, is commoner than physometra, and has been mistaken for it.

Physometra is identified by the resonance on percussion of the distended uterus, and the escape of gas when the cervical canal is opened up.

The *treatment* is that of the condition on which the physometra depends.

PITYRIASIS.—A term formerly attached to various pathologically dissociated diseases of the skin, the most striking clinical feature of which is the presence of fine, branny desquamation or scurf. Thus, *P. simplex capitis* is now known to be a seborrhœa sicca; *P. versicolor* is due to a vegetable parasitic micro-organism, and is therefore now called *Tinea versicolor* (*q.v.*). Although the word had certainly better be abolished from dermatological nomenclature, it is still in general use to designate two diseases, which are therefore described here.

Pityriasis Rosea (vel Maculata et Circinata, Erythema Furfuracea, Roseola Circinata).—A trivial and comparatively rare but interesting affection, first described by Gibert of Paris in 1860, the identity of which has only recently been recognized in this country, and which Hebra even formerly regarded as an unusual form of ringworm of the body. Sometimes there are slight febrile and gastric prodromata to the rash.

Eruption.—This is patchy, and consists of bright pink macules and slightly raised papules, roughly circular or oval in form, which vary from $\frac{1}{16}$ to $\frac{1}{2}$ inch in diameter, and are covered with more or less fine greasy yellow or white scale. They invariably appear first upon the chest, abdomen or neck. Many remain discrete while increasing peripherally, whereas others coalesce to form irregular, gyrate areas, the centre of which is always slightly depressed as compared with the scaly spreading edge, which is also more vivid in colour, the centre becoming a dull yellowish brown. The disease often wanders from the chest and back over the lower part of the neck, abdomen (if not originally in these situations), and down the limbs

as far as the wrists and ankles, but exposed parts, *e.g.*, face and limbs, are hardly ever attacked. The various stages of the disease are usually present at the same time, and considerable patchy discoloration is apt to persist for an indefinite period after its subsidence. Generally, very little or no inconvenience is caused by it, but sometimes it may itch considerably.

The disease occurs in small epidemics, especially in spring and autumn, although it is not demonstrably contagious. It chiefly affects children or young persons of either sex, but has been seen in a patient aged seventy. It undergoes spontaneous arrest in a period varying from a fortnight to two months, its wanderings being apparently but little influenced by treatment. Much in the character of the rash suggests its origin from a micro-organism, but none to which it can with certainty be specifically attributed has as yet been identified.

Diagnosis.—The most important point about the disease is its similarity to papulo-squamous dermato-syphilis, for which it is often mistaken owing to the circinate configuration of the patches, the absence of itching and the subsequent pigmentation. It may also be confounded with *seborrhœa corporis* (*lichen circumscriptus*), *tinea versicolor*, *psoriasis gyrata* or *tinea circinata*, to the separate description of which attention is directed.

Treatment influences its duration very little. Sulphur, carbolic, boracic, and salicylic acids, resorcin and tarry preparations in the writer's hands have all proved inoperative. Calamine and weak tar lotions (*liq. carbonis deterg.* ʒj ad ʒviij) are, however, useful to allay itching. A condition of secondary exfoliative dermatitis may result from its treatment by strong irritants. J. J. PRINGLE.

PITYRIASIS RUBRA.—A name still most usually employed in this country to designate a large and important group of dermatoses to which the term "*dermatitis exfoliativa*" is more generally applied on the Continent; the latter designation is by far preferable, by reason of its greater descriptiveness and comprehensiveness.

The group includes various conditions of skin other than those produced by the exanthemata (especially scarlatina, erysipelas, measles and *rôtheln*) or by drugs (*e.g.*, chloral, belladonna, quinine, *copaiba*), whether primary or secondary to other cutaneous affections, in which universal

or almost universal dermatitis is present, with severe congestion and redness, but with little or no discharge, with slight or considerable infiltration and with profuse and continuous desquamation, either of fine, branny epithelium, or of extensive scales or sheets of epidermis.

From the foregoing it is obvious that the term exfoliative dermatitis is a very wide one, but the disease being thus conceived as an "entity," the following general observations may be made regarding it:—It occurs most frequently between the ages of forty and sixty years, but has been observed in early childhood and at the age of ninety years; it shows a striking predilection for the male sex; it is not hereditary. Arthritic affections—gout and especially rheumatism—strongly predispose to its occurrence, either spontaneously or as an epiphenomenon of other diseases; renal disease and chronic alcoholism do so to a less marked degree. It may supervene upon an eczema or a psoriasis, and may also arise from a lichen, an erysipelas, a *seborrhœa*, an *erythema multiforme*, a *pityriasis rosea*, or even a *dermatitis medicamentosa*. The amount of infiltration of skin varies within wide limits, as does the resulting hardness and the occasional subsequent atrophy or sclerosis of the skin. The amount of sweat secreted also varies considerably in different cases, although frequently it is surprisingly profuse. The characters of the desquamation generally depend upon its locality, that from the face being fine and branny, that from the scalp matted together—owing to admixture with sebum—that from the chest and abdomen in large thin scales and flakes, that from the hands and feet in thick sheets or moulds. As the greatest variety also obtains with regard to (1) the implication of the dermal appendages—hair and nails, (2) the amount of fever, the complications and general constitutional disturbance, and (3) the duration, course and prognosis of the malady, the recent writings of Dr. Brocq of Paris, which analyse and subdivide this extensive and inchoate group of diseases into various constituent "types," have their full justification, and these types, therefore, here receive separate—albeit brief—description. The writer is, however, unable to follow Dr. Brocq in his contention that exfoliative dermatitis is always and essentially a primary, independent disorder, and that the universal extension of an eczema, or of a psoriasis with an assumption of all the peculiar clinical, cyclical and pathological charac-

teristics of exfoliative dermatitis, is, nevertheless, not that disease, but a phase of the original disease. He is also of opinion that Dr. Brocq's writings are calculated to convey a false or exaggerated impression as regards the hard-and-fast delimitations of the various types or subdivisions which constitute the group, perhaps unduly neglecting—or it may be deferring for future study—the investigation of cases not in exact conformity with the types he has formulated, but which, indeed, represent connecting links between them which it is of the utmost value to recognize in order to obtain an harmonious view of the totality and essence of the apparently heterogeneous group.

(1) The relapsing, desquamative scarlatiniform erythema of Féréol represents the mildest form. It is commoner in children and young adults than the others. Its onset is brusque, with high temperature (102° – 104° F.), marked general febrile symptoms, an intense, universal, scarlatina-like redness of the skin without any infiltration, thickening or induration, and frequently even with sore throat. In the course of a day or two the febrile symptoms subside, all redness disappears, and copious general desquamation sets in; at the end of a week or a fortnight recovery is complete. Recrudescences repeating the characters of the primary attack often, however, occur, prolonging the duration of the disease over a month or more. The diagnosis of a first attack from scarlatina is generally difficult, if not impossible, but the subsequent course of the affection decides the point, as relapses invariably occur, often at regular seasonal intervals, especially in spring, when they are usually referable to exposure to cold, or in summer, when attributed to insolation. Sometimes a drug taken internally (especially mercurials) or an irritating external application may determine a first attack, which may be afterwards reproduced in the manner described. The disease never occurs in epidemics, is never infectious, and is never attended with albuminuria. The hair is never affected, but in most cases each attack leaves its mark on the nails in the form of a transverse groove upon them. In a small number of the severest cases the nails fall, constituting a connecting link with—

(2) The universal exfoliative dermatitis of Erasmus Wilson, which is a more frequent and much more serious condition than that just described. It is a

disease of temperate climates, occurring chiefly in warm weather and attacking healthy adult males in the great majority of cases. Although usually primary, it may be secondary to psoriasis, eczema or lichen. Its onset is acute, febrile, the temperature rising to 102° F. or higher. The eruption first manifests itself as erythematous patches, with some scaling, usually situated on the trunk and discrete, but rapidly extending and coalescing to cover the entire surface of the body in a week. The skin is then intensely and vividly red: it is infiltrated from the first, and large, white, imbricated flakes and sheets of epidermis are shed in amazing abundance, or remain attached to the skin only by their upper edge. Itching is usually severe, and scratching is naturally resorted to for its relief. There may be a little oozing from the flexures of the knees, elbows, axillæ and thighs, and in extremely exceptional cases small bullæ have been observed in these situations, suggesting to some writers a link with pemphigus foliaceus; but the rest of the surface is absolutely dry and harsh. Copious sweats are nevertheless observed from time to time. Severe seborrhœa of the scalp is always present. The buccal, lingual, pharyngeal, nasal and conjunctival mucous membranes are often congested, and severe vomiting and diarrhœa are not infrequent, indicating perhaps implication of the gastric and intestinal mucosa. Meanwhile the concomitant febrile symptoms are severe and intermittent in type, an evening rise of temperature to 102° – 103° F. being usually marked. Prostration is a prominent feature, and rapid emaciation occurs. Especially characteristic is the early complete loss of nails both from hands and feet, and of hair from all normally hairy parts; this may occur as early as the fourth week of the disease.

Almost all cases ultimately recover perfectly, the duration of the affection being generally about four months, but it may be prolonged for eight or twelve months owing to repeated recrudescences. Once thoroughly arrested the disease does not recur. Considerable pigmentation may persist for some time after the subsidence of the rash. Lymphangitis, adenitis, abscesses, boils or carbuncles often occur during the course of the disease, or they may interrupt convalescence. Albuminuria and pulmonary troubles are sometimes present in severe cases, especially towards the end of an attack, but they do not necessarily render

the prognosis unfavourable. Among various nervous sequelæ partial paraplegia, incontinence of urine, bed-sores, and functional ocular and auditory derangements may be especially noted.

(3) The chronic universal pityriasis rubra of Hebra represents a more severe and rarer type. Its onset is insidious and afebrile; it is generally primary, but may be secondary to other diseases, especially perhaps to psoriasis. Its spread is slow, but at the end of some weeks it becomes universal. The skin is then red, but not infiltrated or thickened. The desquamated epithelium is in the form of fine, white, branny scurf, which does not adhere to the surface; there is little or no pruritus. Gradually, however, in the course of months, or it may be years, the skin becomes infiltrated, hard and thickened, and when partially emptied of blood by pressure, deep pigmentation may be observed. Later on it slowly atrophies, becoming glossy, thin, yellowish, tightly stretched and often fissured over prominent bony points, as well as retracted round the openings of the orbits and mouth. Marasmus only sets in after years, when ulceration and gangrene may ensue, but death is generally the result of intercurrent tuberculosis or pneumonia. The hair and nails are only affected in the last stages.

(4) The pityriasis rubra pilaris of Devergie, the identity of which has recently been established beyond cavil by the works of Besnier, may here be briefly alluded to, although it is doubtful whether it ought to be included in the group, as its most intimate relationship appears to be with psoriasis. Any form of exfoliative dermatitis may, however, at a certain stage of recovery present a condition closely resembling it in its objective characters, although the clinical history in the two cases is entirely different.

Pityriasis rubra pilaris is an absolutely benign and local disease, unaccompanied by febrile or other constitutional disturbances. It chiefly affects young persons, and its onset is either sudden or gradual. It generally appears first on the face or hands, and other patches soon follow on the body. These may remain discrete or may coalesce; they are of a decided rose or coppery colour, are slightly infiltrated, covered with small, pityriatic scales and present little acuminate papular prominences, due to perifollicular accumulations of epidermic cells. These "epidermic cones" are eminently characteristic round the hair

on the dorsal surface of the first and second phalanges of the fingers and toes and on the backs of the hands and forearms; they never occur on the scalp or pubes. There is always marked seborrhœa capitis, but the hair is not shed; on the contrary, it generally is much increased in quantity all over the body, and the nails grow at a great rate, becoming ultimately like horns or claws. The disease is of quite indefinite duration, but in the long run the patient always recovers.

PATHOLOGY.—Of the intimate pathology of the group of exfoliative dermatitis we know nothing, and mere surmises would here be out of place. The pathological anatomy embraces congestion and dilatation of the vessels of the deeper, but more especially of the superficial longitudinal plexus of the skin, inflammatory leucocytic infiltration of the upper, papillary layers of the corium, great increase in size and depth of the inter-papillary processes of the rete and particularly great increase in thickness of the upper epidermic layers.

DIFFERENTIAL DIAGNOSIS.—This must be established from the exanthemata, medicinal rashes, urticaria, generalized eczema or psoriasis, the early stage of granuloma fungoides, and especially from acute lichen ruber. The foregoing description will suffice for this purpose as well as for a guide to prognosis.

TREATMENT.—Encouragement to vigorous and assiduous treatment is afforded by the more cheering prognosis gained by our present knowledge of the subject over that given by Hebra in his classical work, which, until recently, swayed all dermatological opinions. The value of general medication seems incontestably established. Absolute rest in bed is necessary; the diet ought to be nourishing but easily digestible, including milk, milk puddings, eggs, meat soups, juices or jellies, &c. Alcohol is, as a rule, contra-indicated, but cannot be withheld if there be much prostration. Cod-liver oil is beneficial in many cases of marked emaciation. The regulation of the bowels is of prime importance, and salines or mineral waters are most useful for this purpose. The writer is strongly convinced by personal experience that arsenic is in the great majority of cases absolutely deleterious, its discontinuance in several cases under his own observation having been attended with marked benefit. Some authors, however, consider arsenic useful in the most chronic cases. The writer also has found the eruption

aggravated by ferruginous preparations, whereas quinine has rendered signal service, given in full doses. The promotion of diuresis was strongly advocated by Tilbury Fox, and the subcutaneous injection of nitrate of pilocarpine (gr. $\frac{1}{10}$ — $\frac{1}{5}$ or more, with caution) has lately been advocated by Dr. Stephen Mackenzie; its diaphoretic action is aided by a hot-air bath.

Prolonged warm alkaline or bran baths are occasionally of service in relieving itching and removing scales, but, on the other hand, sometimes increase hyperæmia. Oily applications are more generally useful. The whole body must be swathed in soft linen cloths soaked in the application, the face being covered with a mask. The official linimentum calcis is useful, and the writer can confirm Dr. Crocker's opinion of the value of a liniment thus composed:—*R* Calaminæ $\mathfrak{D}\text{ij}$, zinci oxidi $\mathfrak{Z}\text{ss}$, olei olivæ et aquæ destillatæ ââ $\mathfrak{Z}\text{j}$. A lotion composed of an ounce of glycerole of lead and of glycerin in a pint of water is also serviceable when similarly applied. The patient ought to lie between the blankets and on a spring mattress or water bed.

J. J. PRINGLE.

PLACENTA, DISEASES OF.—

Myxoma of Chorion.—This disease, in its extreme development, is rare; in its slighter forms, not uncommon. There are two forms—(1) Myxoma, in the more literal sense, which is the so-called "hydatid mole," or "cystic degeneration of chorion." This occurs in the earlier months of pregnancy, before the placenta has been differentiated; (2) Myxoma fibrosum, which occurs in the later months, after the placenta has been formed.

Symptoms and Course.—The size of the uterus and abdomen increases out of proportion to the period of the pregnancy. Then follows hæmorrhage, which is often very profuse; it may be so great as to cause death before the expulsion of the mole. The hæmorrhage may begin as early as the middle of the second month of pregnancy; and it has been known to be postponed three or four months beyond the usual term of pregnancy. But, as a rule, hæmorrhage and the expulsion of the mole take place within the first six months. Either with the first hæmorrhage, or with some subsequent attack, some of the small "cysts," which have been aptly compared to "white currants floating in red currant juice," are expelled. This settles the

diagnosis, which cannot be made until these bodies have been seen.

Pathology.—Myxoma of chorion presents itself to us in the form of a loosely-connected heap of bodies looking like white currants, but of more various sizes, attached to one another by delicate semi-translucent threads. As a rule, no trace of a foetus can be found, nor can the foetal membranes be identified. The "cysts," as they used to be called, vary in size from a pin's head to a filbert. They are dilations of the chorionic villi, which, at the swollen parts are degenerated into myxomatous tissue. They are not true cysts, although they collapse when cut into. The condition of the uterus in different cases of this disease is various. Sometimes there is great overgrowth of the decidua, and the disease has been thought to be primarily due to this overgrowth. In other cases the contrary has been found, and the disease has been attributed to the chorionic villi not being able to take root in the badly developed decidua, and so hanging free in the uterine cavity and degenerating in consequence. It has also been attributed to the allantois failing to reach, or apply itself to the chorion. In some cases the diseased chorionic villi grow into the muscular wall of the uterus, splitting it into two parts, a submucous and a subserous part, and approach so near the peritoneum, that only a layer the thickness of paper separates the chorion from the peritoneal cavity. This condition has been termed "mola hydatitosa destruens."

Treatment.—While the diagnosis is doubtful, it is best to stimulate the uterus to contract by ergot and the hot douche. When the diagnosis has been made, the cervix must be dilated with tents (antiseptic precautions being taken), and, if necessary, the finger introduced to break up the mass. Uterine contractions will then usually expel it. Bearing in mind the possibility that the mole may have grown into the uterine wall, all rough usage, such as scraping the uterus or violent manipulation, should be carefully avoided. If hæmorrhage be profuse, the uterus may be swabbed with liq. ferri perch. diluted 1 : 6, or plugged with iodoform gauze.

Myxoma fibrosum affects one or more cotyledons of an otherwise normal placenta. These we find enlarged and studded with smooth, firm, roundish bodies, from the size of a hempseed to that of a hazel nut, arranged in stalks.

These knots consist of a vessel in the interior, surrounded by connective tissue resembling the Whartonian jelly of the umbilical cord. Myxoma fibrosum of the placenta may occur with a healthy and well-developed fœtus; often it goes with abortion or premature labour. It cannot be diagnosed before delivery, and therefore cannot be treated.

G. E. HERMAN.

PLETHORA.—A full habit of body. A condition frequently met with amongst those who eat and drink more than they require, and do not take sufficient exercise. Obesity, congestion of the face, sluggish bowels, general lassitude and undue drowsiness are the chief signs of this condition. It should be combated by careful dieting, regulation of the bowels, and the taking of such exercise as the age and other circumstances of the patient permit.

PLEURA, MORBID GROWTHS OF.—Several forms of morbid growth may be found affecting the pleura, but in most cases they occur as secondary to the same kind of growth elsewhere in the body. Lymphadenoma, lipoma, fibroma, fibro-chondroma and fibro-myoma, osteoma, scirrhus and sarcoma have all been found in the pleura. Primary cancer, sometimes described as endothelioma, but closely resembling epithelioma in structure, may sometimes occur. It begins in the endothelium of the small lymph-vessels, and may take the form of multiple nodules, or may aggregate into small flat patches—forms of distribution which are common to all morbid growths of the pleura. A nodule of growth on the costal or visceral surface will often, by direct contact, infect the opposite surface, either with or without inflammatory adhesion.

Fibroid thickening of the pleura may take place to an extent that may simulate the appearance of a morbid growth, but the localized fibroid tumours are generally secondary, and found in association with fibroid disease elsewhere. Secondary growths of the sarcomatous type are often met with in the lung, and hence may appear on the pleura, also when the surface of the lung is implicated. They are generally secondary to sarcoma of some other internal organ, or of bone.

Diagnosis.—Morbid growths of the pleura are so rare as primary affections that the diagnosis of them is almost invariably bound up with that of a similar condition in some other part.

Localized pain, and sometimes superficial tenderness, associated with dullness on percussion, and diminution in respiratory murmur, coupled with increase of vocal vibration, may serve to indicate the presence of a single patch of disease, but these signs are not by any means trustworthy, and must only be regarded in conjunction with the other features and general history of the case. In the cases of general thickening of the pleura, the principal indications are given by the physical signs; the whole of one side of the chest may be very dull to percussion, although the dullness is rarely so absolute as in the case of fluid. Vocal vibration is seldom altogether lost, although it is, as a rule, impaired. On auscultation, the breath sound is very much feeble than on the healthy side; but it is vesicular in character, unless some other condition be complicating the case. The transmission of the voice sound is variously affected, sometimes being increased and at others diminished. The presence of numerous small crackling râles will often be made out, and these, scattered over the whole dull area, are not unfrequently mistaken for evidence of acute mischief in the lung. They are, as a rule, but little affected by coughing, and may persist for a long time without undergoing any marked change. Bearing this fact in mind, their relative importance must be determined by the other features of the case.

Treatment.—Little can be done for these cases, the relief of pain and of any other troublesome symptoms being all that is possible.

E. CLIFFORD BEALE.

PLEURISY, ACUTE (Pleuritis).—Of all the serous membranes that cover the lungs and lining the chest walls is most often the seat of inflammation.

The attack may vary in severity from what is scarcely more than a sharp pain in the side to a most serious and rapidly fatal illness.

Symptoms.—After exposure to cold or wet, or perhaps independently of any definite exciting cause, the patient usually first complains of slight chilliness and pain in the side. The onset may be sudden, but is rarely marked by the severe rigor which commonly ushers in pneumonia, more often by a succession of chills which continue for two or three days.

The temperature quickly rises, and may range between 101° and 103° F. in

the early days of an acute attack. The respiration becomes rapid and shallow; there is a short dry cough; the pulse is frequent and often shows an increase of tension; the face is anxious, and there are signs of severe suffering.

The pain, or "stitch," in the side is aggravated by cough or a deep inspiration, whereby friction is produced between the inflamed surfaces of the pleura; the patient therefore usually leans toward the affected side, and by pressure and gentle breathing endeavours as much as possible to restrain its movements. The pain is usually felt in the lower axillary region, but may be referred to any spot in the course of the intercostal nerves most adjacent to the inflamed area, and even in rare cases to the opposite side of the chest.

On *palpation*, friction fremitus may be felt. *Percussion* may elicit a slightly altered note, but there will be no marked dulness. On *auscultation* the respiratory sounds are weak from the deficient expansion of the lung, and a friction sound is usually audible, but this may be absent, especially when the diaphragmatic pleura is alone involved. The disease may not advance beyond this stage, the temperature falling, pain in a few days ceasing, and the friction sound disappearing owing to the adhesion of the inflamed pleural surfaces.

More often, however, when the onset has been acute and the general symptoms severe an effusion of fluid of varying amount takes place.

This is usually followed by some amelioration in the patient's condition, the pain being less acute and the breathing easier than in the earlier stage of the disease, but should the fluid continue to increase dyspnoea may again become urgent.

The Signs of Pleural Effusion are generally first discovered at the base of the chest owing to the gravitation of the fluid and of any solid particles it may contain.

Inspection may reveal an apparent bulging of the affected side, although this is more often due to a rounding of the outline than an increase in the semi-circumference. Fulness of the intercostal spaces is a sign rarely present unless the fluid be purulent or the tone of the intercostal muscles lost owing to marked general prostration and wasting; it is on the whole more often seen in children than in adults. If the effusion be considerable and of long standing, the chest wall may be cedematous

and the superficial veins filled with blood. The heart may be seen to be beating away from its normal position.

On *palpation*, the vocal fremitus over the area of the effusion will be diminished or absent, and the heart will be found displaced towards the sound side to a degree varying with the amount of the effusion, the displacement toward the right, however, being usually more obvious than towards the left for an equal amount of effusion.

On *percussion* over the area of the effusion, resonance will be much impaired or there will be absolute dulness. The note yielded by a large effusion is more completely toneless than that elicited from consolidated lung, and the sense of resistance is greater.

The upper line of dulness is usually curved, the highest point being in the axilla, whence it slopes downward to the spine behind and across the median line in front where the dulness from fluid and displaced heart merge.

A tympanitic percussion note (skodaic resonance) is commonly present beneath the clavicle above the level of the effusion, if the latter be moderate in amount and the upper lobe of the lung be healthy.

On *auscultation*, the breath and voice sounds are generally weak or absent over the dull area, but the presence of tubular breathing and whispering pectoriloquy does not exclude the diagnosis of pleural effusion or prove that in addition to the pleurisy the lung is consolidated, as, under certain circumstances, the laryngeal sounds are well conducted through the fluid.

A natural result of the accumulation of fluid within the pleura is a partial contraction or complete collapse of the lung, which, receding towards its root attachments, may lie in contact with the mediastinum or spine. If in the latter position, the laryngeal sounds conducted through the larger bronchi, which, owing to the thickness of their cartilages, still remain patent, may be distinctly audible along the spine and may suggest a diagnosis of pneumonia.

If pleural adhesions over limited areas existed prior to the attack, the lung may be held in partial contact with the chest wall, and may act as a conductor of the laryngeal sounds to any point. About the upper level of the fluid a friction sound may be audible, and the voice sounds sometimes present a peculiar bleating quality, to which the term *ægo-phony* is applied. This sign is usually

most marked about the angle of the scapula in cases of moderate effusion. Over the opposite lung, if it be healthy, the breath sounds will be puerile in quality.

A loud systolic displacement murmur may be audible over the base of the heart when the effusion is considerable, and it may be audible at the apex also; this sound will disappear with the absorption or removal of the fluid. In the former case it is believed to be due to the displacement of the aorta and pulmonary artery.

Measurement may prove the affected side to be enlarged, but a cytometer tracing of the chest gives the most trustworthy evidence of any change in its size or shape.

Displacement of Organs other than the heart and lung may result from an effusion into the pleural cavity, but probably does not occur until there is a positive pressure within the thorax (Powell); the liver, stomach and spleen will then assume a lower position, and the displacement of the diaphragm is an important sign of positive intra-thoracic pressure, and indication of the necessity for paracentesis.

After a moderate amount of fluid has been effused, the temperature in favourable cases falls, the general symptoms improve, and the process of absorption commences. This is marked by a gradual diminution in the dulness of the percussion note, by the return of the breath sounds, and by the expansion of the lung. The friction sound which during the period of effusion disappeared, again becomes audible (redux friction), and the affected side moves more freely during inspiration; but though the absorption of the fluid be complete, some diminution of expansion, impaired resonance on percussion, and feeble breathing may remain for a time or permanently at the base of the chest. If, however, the case be severe, the effusion may increase to such an extent that the affected side becomes dull on percussion quite up to the clavicle, and the difficulty of breathing extreme—a condition requiring immediate relief.

If the temperature assume a "hectic" type, it may indicate that the effusion has become purulent, but no single sign can be looked upon as pathognomonic of that condition, the only mode of ascertaining with certainty the character of the fluid within the chest being to draw off a small quantity, for which purpose an instrument about twice the size of an

ordinary hypodermic syringe is the most useful.

Under the following circumstances, however, it is very probable that the fluid is purulent:

(1) When the pleurisy is part of a general disease of a septic nature, or

(2) Probably due to the escape of septic material into the pleural cavity.

(3) If there be sweating, rigors and marked emaciation; and

(4) The temperature assume the "hectic" type.

(5) If there be bulging of the intercostal spaces and œdema of the affected side.

Paracentesis may be required by the following conditions:—

(1) Urgent dyspnoea, palpitation or retching.

(2) Evidence of engorgement of the opposite lung.

(3) When the fluid has accumulated with great rapidity.

(4) When the dulness extend up to the second rib in front, and there is no skodaic resonance beneath the clavicle.

(5) Displacement of the diaphragm and abdominal organs, showing the existence of positive intra-thoracic pressure.

(6) When there be no signs of absorption of the fluid after a period of from two to three weeks from the commencement of the illness.

(7) If the fluid has been ascertained to be purulent.

Diagnosis.—The diagnosis of pleural effusion may be very simple, or present difficulties such as can only be solved by an exploratory puncture. In the early stage the diagnosis may be rendered difficult by the absence of a friction sound; this is especially likely to occur when the diaphragmatic pleura is alone involved. In the latter case, the presence of severe pain, high fever, and extreme respiratory distress would point to the true nature of the disease. The various painful affections of the chest wall, being unaccompanied by friction sound or fever, do not usually give rise to much difficulty. Close attention to the position of the heart will generally lead to a correct diagnosis; but when its displacement is prevented by previous adhesions, the most experienced may fall into error. Solid growths and a thickened pleura usually transmit the vocal vibrations, to some extent, whilst consolidation of the lung is rarely attended by a degree of cardiac displacement in proportion to the amount of dulness. Errors are not infrequent in the rare cases where

although a pleural effusion is present, the laryngeal sounds are distinctly audible over the dull area. Here, again, the position of the apex beat of the heart is the most trustworthy guide. Acute pneumonia, with fibrinous exudation into the larger bronchi (massive pneumonia), and the moderate degree of pleural inflammation which usually accompanies that condition, give rise to physical signs closely resembling those of pleural effusion; but by attention to the points already insisted upon, error may usually be avoided. If doubt still remain, no harm is likely to result from an exploratory puncture with a fine aspirator needle if it be clean, even should a growth or a thickened pleura or solid lung be struck instead of the expected fluid. If the fluid withdrawn be blood-stained, it must not be hastily assumed that the case is one of malignant disease or tubercular pleurisy, as a hæmorrhagic effusion is occasionally met with in simple pleurisy.

Pathology.—The pleura reacts to inflammation like any other serous membrane, and the changes which occur are in all respects similar. The early stage is one of hyperæmia and engorgement; then the glistening surface becomes dull and lymph is effused, and forms a thin coating to the membrane. New vessels extend from the pleura into the exudation, which consists of fibrin, leucocytes and serum, and shows a marked tendency to coagulate, semi-solid masses sometimes forming, and either floating in the fluid or sinking to the base of the cavity. Coagulation is promoted by a relative excess of fibrin, and retarded by an abundance of leucocytes; if these latter be in great excess, and have lost their vitality, the effusion may not coagulate at all, and will then assume the characters of a collection of thin pus. This is especially likely to occur if any septic element be present in the effusion. Adhesion of the inflamed surfaces is the natural mode of termination of pleurisy, and may take place either before any fluid has been effused or after its absorption or removal. From various causes the absorption of the effusion may be incomplete; if so, provided the effusion be aseptic, the solid portions may undergo fatty degeneration, leading to the formation of a caseous looking mass, which may ultimately become calcareous.

The fluid, if unabsorbed, may become loculated by adhesions; it tends after a time to become inspissated.

Ætiology.—It is probable that expo-

sure to cold, and wet, and a chill are not so commonly the cause of pleurisy as is generally supposed, and although in many cases little that is more definite can be made out from the history, post-mortem experience teaches that in the majority of cases there is some distinct cause for the attack. The attack may be due to local or general causes. Amongst the former, injuries, fractures of the ribs and strain of the chest wall constitute one class. In another group may be included all cases where the inflammation is set up by the escape of some material into the cavity, such as from a bronchial gland or a softening nodule in the lung; the latter, though tubercular, sometimes giving rise to a simple pleurisy. Cancer of the œsophagus again may give rise to simple pleurisy. Inflammation may extend from the pericardium or peritoneum to the pleura, and *vice versa*; and it may be secondary to various diseases of the liver. Disease of the spine or ribs may involve the pleura and cause inflammation. But in the majority of cases the affection is secondary to disease within the lung—*e.g.*, pneumonia, phthisis, or other pulmonary lesion.

Among the general causes septic conditions, such as pyæmia and septicæmia, and diathetic states, as gout and rheumatism, may be mentioned. Serous membranes are especially liable to be inflamed in the various forms of Bright's disease. Pleurisy may occur at any age, and at none is there either exemption from, or special proneness to, the affection.

Treatment.—Rest in bed and a liquid diet are essential measures in the treatment of a case of acute pleurisy. The pain may be relieved by linseed poultices, changed every two hours, leeches, or a blister or a subcutaneous injection of $\frac{1}{4}$ or $\frac{1}{2}$ grain of morphine. Strapping the affected side, as recommended in the treatment of "dry pleurisy," is sometimes efficacious if the pain be only moderate in degree, and the attack of a subacute character. The bowels should be freely acted upon, and the action of the kidneys and skin promoted by the administration of digitalis, nitrous ether, acetate and nitrate of potassium, and liquor ammonii acetatis. The use of aconite and antimony, and the inunction of mercurial ointment, is strongly recommended by some writers as of service in the early stage of pleurisy. The temperature is rarely sufficiently raised to require the adoption of antipyretic measures. Opium in some form may be

necessary if the patient be sleepless. When effusion has occurred, if the temperature remain high, the same line of treatment should be continued for at least a fortnight, no operation for the removal of the fluid at this period being as a rule advisable. Should the temperature fall, the use of counter-irritation to the side by means of iodine or blisters, and the administration of iodide of potassium and quinine is advisable.

Paracentesis having been decided upon, the operation may be performed with either the siphon-aspirator or a trochar and cannula; the former instrument is generally preferred. It is important to draw off the fluid slowly, as the lung is then more likely to expand, and the chances of a further effusion of fluid taking place are thereby diminished. The site to be chosen for puncture will depend upon the position of the fluid; but in the absence of special indications, the sixth interspace in the mid-axillary line is generally to be preferred. It is essential that the admission of air into the pleural cavity be prevented, and that the instruments be scrupulously clean, as neglect of these precautions may result in the conversion of a serous into a purulent effusion.

The pain of the preliminary incision of the skin of the puncture will be diminished by holding a piece of ice dipped in salt to the spot for a short time, freezing it with ether, or a few drops of a 6 per cent. solution of cocaine may be injected subcutaneously. It is well to draw off as much of the fluid as possible unless very severe cough, a sign of the expansion of the lung, be induced, as, although in some cases the withdrawal of a small quantity is followed by rapid absorption of the remainder, this result cannot be depended upon. When the flow has ceased, the skin is grasped between the fingers, the needle withdrawn, and a pledget of cotton-wool soaked in collodion applied, covered with lint, and held in position with a piece of strapping. If the first tapping be "dry," it will be advisable to puncture in another spot should there be clear indications of the presence of fluid.

Should the fluid re-accumulate, a second or third aspiration may become necessary; if, however, recurrence take place after repeated tapplings, it is generally advisable to allow the fluid to remain, as absorption occasionally occurs after long intervals, and if not, a simple serous effusion does little or no harm, whilst from the thickening of the visceral layer of the pleura which usually follows

the prolonged presence of fluid in the cavity, it is very unlikely that at this period the operation will be followed by re-expansion of the lung.

E. CLIFFORD BEALE.
J. K. FOWLER.

PLEURISY, DRY.—In this form of the disease the exudation from the inflamed surfaces of the pleura remains dry, little or no fluid being effused. It is especially common in rheumatic and phthisical subjects, and is probably in many cases of tubercular origin. It may precede, by a long interval, the development of pulmonary tuberculosis. Local injury and a chill are also amongst the exciting causes. The onset is rarely well marked, and the affection is often only discovered on examination of the chest, the patient's symptoms giving no clue to its presence, or slight pain in the side increased with the respiratory movements, may suggest the nature of the illness. Fever, if present, is usually only moderate in degree, and the general symptoms are not severe. There may be a short cough without expectoration.

On palpation, friction fremitus is often felt, and on auscultation a dry rubbing sound will be audible, often over a considerable area. This may soon disappear, or, as not uncommonly happens, may persist for a long time without causing much discomfort.

The most common site of the friction sound is the lower part of the axilla or infra-scapular region, but it is occasionally audible over the apex of the lung, or beneath the clavicles. Recovery from dry pleurisy occurs through the adhesions of the opposing surfaces of the pleura. Whether this be the invariable result is doubtful; the serous membrane, however does not return to its normal condition, some thickening and opacity inevitably remaining. Probably adhesion is the most desirable termination, as it prevents the recurrence of the affection at any rate in its original site, and a second attack is by no means uncommon.

After adhesion has taken place, creaking sounds may still be audible, and some pain may be felt on deep inspiration.

The best treatment for dry pleurisy is to firmly strap the affected side with emplastrum plumbi spread upon wash leather. The plaster should be cut into strips of about two inches wide and of sufficient length to reach from the spine to the sternum, and the strips, slightly overlapping each other, should be applied

over an area proportionate to the extent of the disease. By this means the movements of the affected side are restrained, the pain is relieved, and adhesion of the inflamed surfaces is promoted. In some cases counter-irritation is of service, for which purpose a blister or equal parts of the tincture and liniment of iodine may be used. The general health must be attended to, tonics and cod-liver oil being especially useful. In phthisical subjects a change of climate is to be recommended.

E. CLIFFORD BEALE.

J. K. FOWLER.

PLEURISY, TUBERCULAR. —

As stated in the preceding article, pleurisy of tubercular origin is very often "dry," but by no means always so, as such a case may present all the characteristics of an ordinary case of pleurisy with effusion, running on it may be to empyema, and terminating fatally, its true nature being only discovered on post-mortem examination. It is highly probable that many cases of pleurisy, which are believed to be of idiopathic origin, are really tubercular.

The *symptoms and physical signs* of tubercular pleurisy, whether dry or accompanied by effusion, do not in themselves differ sufficiently from those which are present in non-tubercular cases to permit of a differential *diagnosis* on those grounds alone. The suspicion of the tubercular nature of the disease generally arises from the family history or the previous history, or appearance of the individual, or from the fact of the presence of tubercular disease in the lungs or elsewhere.

Prognosis.—This is, as a rule, more serious than in simple pleurisy, but there is every reason to believe that, even should considerable effusion occur, absorption of the fluid may take place with complete recovery, and that in rare cases this may again happen when the opposite side is subsequently attacked. The chief reason for gravity in prognosis lies in the fact that, given the presence of tubercle within the body, it is impossible to predict what organs it will attack or to state what are the chances against a general outbreak of acute tuberculosis. As stated in the article on PHTHISIS (*q.v.*), one of the distinctive modes of onset of that disease is by the occurrence of an attack of pleurisy, which in all probability is, in many cases, tubercular.

Morbid Anatomy.—It is highly important to recognize the fact that the pleura may be so completely covered with

exuded lymph as to hide all trace of the tubercle with which the membrane is studded. This is especially the case at the base of the lung, where the affection most often commences. At the margin of the inflammatory changes, however, the granulations may often be observed, but in many cases it is only on separating the lobes and displaying the pleura of the interlobar sulcus that it becomes apparent that the membrane is thickly studded with miliary tubercles. The interlobar sulci are sealed up at an early period of the disease, with the result that there the appearances are faithfully preserved. The fluid, if any be present, may, on microscopical examination, prove to contain bacilli, and in like manner the fluid withdrawn by aspiration during life may also contain the specific organism. In cases of dry tubercular pleurisy the serous membrane is often found to be much thickened and covered with a tough layer of lymph; on removing this, the tubercles may generally be seen.

Etiology.—In the majority of cases the pleura is infected from the lung, but it may be attacked in common with many other organs in a wide dissemination of tubercle.

The writer has observed one case of tubercular pleurisy in an adult, in which careful post-mortem examination of all the organs of the body showed that the affection of the pleura was primary. The bronchial and mediastinal glands may be secondarily affected, and also in some cases are probably the starting-point of infection of the pleura. The peritoneum covering the under-surface of the diaphragm is especially likely to be affected secondarily to the neighbouring pleura, infection spreading through the diaphragm.

Treatment.—It is advisable in these cases to avoid operative interference unless imperatively called for; in other respects the treatment is not essentially different to that already detailed under PLEURISY, ACUTE, and PLEURISY, DRY. Lowering measures are not well borne by tubercular subjects, and a rather more liberal dietary may therefore safely be allowed.

J. K. FOWLER.

PLEURODYNIA signifies "pain in the side" and is usually due to rheumatism of the muscles of the chest wall. As it is often associated with cough, care must be taken to exclude pleurisy or other intra-thoracic disease; the possibility that the pain may be the precursor of shingles must be borne in mind. In

women, pain in the left side is often indicative of ovarian disorder. The pain, when due to a rheumatic affection of the chest walls, may be relieved by the local employment of linimentum saponis co., or, if very severe, by hypodermic injections of morphine. It is, however, generally best treated by fixing the chest with strips of lead plaster spread upon wash leather, applied from the spine to the sternum.

PNEUMOGASTRIC NERVE, DISEASES OF.

—The vagus or pneumogastric nerve, forming, with its fellow, the tenth pair of cranial nerves, according to Sömmering, arises from the medulla oblongata between the origin of the glosso-pharyngeal and the spinal accessory nerves, which are above and below it: its nucleus is situated in the floor of the fourth ventricle near the calamus scriptorius, and on its inner side is the hypoglossal nucleus. After its passage through the foramen jugular it is joined by the branches from the spinal accessory nerve.

The nerve may be affected either at its nucleus of origin or in its trunk, or in the terminal branches.

The disease in which the nucleus is most frequently affected is **BULBAR PARALYSIS** (*q.v.*) in which the neighbouring nuclei of the spinal accessory and the hypoglossal are also involved. It may be mentioned here that all the motor fibres of the vagus to the head and neck are supplied by the spinal accessory nerve. The writer, in conjunction with Mr. Horsley, found that, in the monkey, stimulation of the distal end of the cut vagus nerve inside the skull gave no motor results, whereas the accessory to the vagus produced elevation of the soft palate of the same sides as well as movements of the pharynx and larynx (see *Proc. Roy. Soc.*, vol. xlv.). Inside the skull the nerve is liable to be compressed by tumours, or by an aneurysm of the vertebral artery, or it may be involved in meningeal thickening, whether syphilitic or otherwise.

In the neck, being in the same sheath as the carotid artery, it may be similarly affected by an aneurysm of that vessel, or involved in a ligature, or compressed by glandular tumours in the neck. The frequency with which the recurrent branches, the right in its passage round the subclavian artery, and the left in passing round the arch of the aorta, become involved in the growth of aneurysms is to be remarked, the left being

more often affected than the right, as the aorta is more often the seat of aneurysm than the subclavian artery.

In regarding the phenomena produced when the nerve is divided or compressed, it will be necessary to remember that it contains the depressor fibres for the heart, accelerator and depressor afferent fibres for respiration, the former preponderating, the motor and sensory fibres for the œsophagus, the sensory and some of the motor fibres for the stomach; therefore the symptoms will be due to irritation or paralysis of these fibres according as they are irritated or destroyed.

The chief branches of the nerve are the

Pharyngeal, supplying the constrictors of the pharynx and the levator palati through the pharyngeal plexus, and producing, when affected, difficulty of swallowing.

Laryngeal branches, of which the superior laryngeal is sensory to the interior of the larynx, and also supplies one muscle, the crico-thyroid, while the inferior recurrent laryngeal supplies all the other intra-laryngeal muscles. Paralysis of the muscles of one side of the larynx is a prominent symptom when the trunk of the vagus in the neck, or the recurrent branch is affected, the symptoms being that the voice is hoarse, and coughing impossible, as the glottis cannot be closed, owing to one vocal cord being paralysed (see **LARYNX, PARALYSIS OF**).

Bilateral paralysis is produced in locomotor ataxia—where the spinal accessory nuclei of either side are affected—in diphtheria, and in bulbar paralysis. In the first-named disease paralysis of the abductors is especially apt to occur.

Besides paralysis, the muscles of the larynx are liable to spasm, which is always bilateral, unless brought about by irritation of one recurrent laryngeal nerve. Spasm is produced reflexly, in the form of cough, by irritation of the sensory branches of the superior laryngeal nerve in the larynx. In pertussis there is a series of expirations, followed by a spasmodic narrowing of the glottis during inspiration, and in laryngismus stridulus (*q.v.*) there is closure of the glottis without the muscles of respiration being affected. These two conditions are probably produced both reflexly and centrally (see **LARYNX, SPASM OF**). In epilepsy the cry which begins the fit is produced by tonic contraction of the vocal cords, similar to that of the limbs, and is part of the cortical discharge occurring centrally. In locomotor ataxia

"laryngeal crises" consist of spasm of the glottis, with dyspnoea and stertorous breathing, due to local irritation of the spinal accessory nucleus.

The pulmonary branches of the vagus which are distributed to the muscular fibres of the bronchi are generally believed to play an important part in the production of some of the phenomena of the asthmatic paroxysm, and through other pulmonary branches also, the trophic influence, which it is by some supposed to possess over the lungs, must be exerted.

Cardiac Branches.—In the remarkable cases of persistent extremely rapid action of the heart occasionally observed, these branches are necessarily concerned (see HEART, NEUROSIS OF). The influence of the pneumogastric nerve in the production of angina pectoris is discussed in the article on that subject (*q.v.*).

Besides the œsophageal, of the terminal branches to the abdominal viscera only those to the stomach need be here referred to. The vagus contains the sensory afferent nerves of the stomach and some of the motor, and the severe and persistent attacks of pain and vomiting—gastric crises—which occur in locomotor ataxia, are due to central irritation of the spinal accessory nucleus.

C. E. BEEVOR.

PNEUMONIA (Croupous, Lobar or Pleuro-pneumonia).—The term pneumonia is generally used to denote that form of acute inflammation of the lungs which usually runs a definite course, and tends, as a rule, to complete recovery after the fever which accompanies it has subsided. Other forms of pulmonary inflammation to which the name is occasionally given, are better described as secondary pneumonia, chronic or interstitial pneumonia and broncho-pneumonia.

Symptoms.—The onset of the disease is very frequently traceable to some exposure to chill, especially after violent exercise. A feeling of general malaise is soon followed by definite headache, a well-marked rigor and vomiting. Of these initial symptoms, the vomiting is the most constant, and is present in a large majority of recorded cases, especially in children. When the patient first comes under treatment, which is often not till about the third day, he is found with a peculiarly hot and pungent skin, flushed cheeks and dry coated tongue, and often a small outcrop of herpes about the lips. He usually lies very still

in bed with the head low, and very often flat on the back. The face has generally a flushed and dusky appearance with a slight icteric tinge, but at the same time the eyes are bright and there is an anxious expression of countenance. Respiration is rapid, and tends to become more so as the disease progresses, but the respiratory movements are cautious and shallow, as they are in most cases accompanied by localized pain, due to the inflammation of the pleura covering the affected lung.

The pain is increased by movement, especially by coughing, and sometimes when attempts are made to drink, and hence its speedy relief may become a matter of importance, as thirst is a very common and prominent symptom.

The pulse is regular as a rule, and ranges from 90 to 120, but does not maintain any regular proportion with the number of respirations, the latter sometimes ranging as high as 40 or 60 to the minute, showing a marked change in the normal pulse-respiration ratio of 4 (or 4.5) to 1. The temperature in most cases quickly rises to 103° or 104°, and shows a tendency to remain about the same level during the active period of the illness, the daily fluctuations being sometimes very slight or even absent altogether. In some cases a very irregular temperature has been recorded. More or less cough is generally present. It is always short and guarded to prevent any increase of pain. The expectoration which varies greatly in quantity, and may be absent altogether, is thick and viscid, and adheres closely to the sides of the vessel containing it, and is typically of a dull rusty colour from the admixture of a certain amount of blood. Pure blood is very rarely ejected in the course of pneumonia. The urine is high coloured, *deficient in chlorides*, deposits lithates on cooling, and may contain a trace of albumen. The action of the bowels is generally sluggish, but diarrhoea may occur. Delirium, especially in neurotic persons, is very frequent about the third day of the disease, and may persist as long as the fever lasts. In children, the onset is occasionally marked by convulsions in addition to, or in place of, a rigor.

The symptoms just described are apt to continue with little variation from five to eight days, but the appearance of the physical signs may be delayed for several days after the onset of the attack. In such cases it is probable that the inflammation has begun in the deeper parts of the lung and is slowly travelling to

the surface during the interval. In the majority of uncomplicated cases the disease remains limited to the lobe primarily affected, but in a very considerable number it extends to other parts of the same lung and may attack its fellow.

The recovery from pneumonia is usually rapid and complete, occurring by *crisis* on or about the seventh day of the disease. A sudden fall of temperature and the restoration of the healthy action of the skin mark the occurrence of "crisis," and with these signs the pulse becomes slower, the respiration easier, though still very rapid, and the patient quiet and sensible, often sleeping a great deal, especially if there has been much wakefulness before. The tongue gradually cleans and the appetite returns. "Crisis" usually occurs in the evening or at night, and is not delayed beyond the fourteenth day in uncomplicated cases.

Stages and Physical Signs.—The most characteristic sign of the first stage of pneumonia, that of *engorgement*, is the presence of crepitation audible only on inspiration; this may be preceded by a change in the quality of the breath-sounds which is usually described as an increased harshness with diminished intensity, but it is rarely possible to make a correct diagnosis until the appearance of the characteristic râle. The movements of the chest are shallow, and the expansion of the affected side diminished. The percussion note may have a somewhat tympanitic character, and the vocal fremitus is increased. The second stage, *red hepatisation*, is marked by dulness on percussion over the affected area, which may be the whole of one lobe, the right lower lobe being the most common seat of the disease, and the presence of high pitched tubular or "whiffing" bronchial breathing, a sound which closely resembles that heard on auscultation over the larynx in health. The dulness is rarely so absolute as that produced by the presence of an effusion into the pleural sac. Vocal fremitus is usually increased but may be quite absent if the larger bronchi, as sometimes happens in very acute cases, are filled with a solid fibrinous exudation continuous with that in the alveoli and smaller tubes. This is a condition likely to be mistaken for that of pleurisy with effusion. Crepitation may persist if the inflammation continue to spread, but is usually only heard in the earlier stages, and

before the lung has become completely solidified. The voice-sounds are altered and intensified to bronchophony or pectoriloquy, but they may at times acquire a peculiar nasal twang which is not heard over the trachea. A friction sound is often audible, but is very frequently absent, even when a considerable amount of pleurisy exists. Measurement may show the affected side to be slightly enlarged. The spleen can sometimes be felt and is usually increased in size. All these signs may persist during the acute stage of the attack. The third stage is that of *grey hepatisation*. The physical signs during this stage do not differ essentially from the above, and the presence of the condition can only be inferred from the severity of the constitutional symptoms and the non-occurrence of a "crisis."

The crisis is, as a rule, followed by the stage of *resolution*, which is marked by the presence of coarse liquid and bubbling râles (redux crepitation) audible with both inspiration and expiration, indicating that softening and absorption of the effused products is in progress; the bronchial character of the breathing becomes less and less marked and the sounds gradually return to the normal, although weeks and even months may elapse before the recovery of the lung is complete.

Course and Termination. — Recovery may be delayed, the temperature gradually declining (lysis) and certain sequelæ, leading to more serious results, may follow. The slower form of recovery is marked by the same symptoms occurring in gradual succession, but in many such cases it is not continuous. In old persons and those whose health has been previously broken down by any cause, such as alcoholic or malarial poisoning, recovery may be thus retarded, and a series of secondary changes may ensue, dependent in great measure upon the severity of the inflammation and upon the constitutional peculiarities of the patient. It is doubtful whether simple acute pneumonia ever terminates in abscess, but cases are on record in which, after a basal pneumonia, the lung has failed to recover itself, and has become the seat of a cavity, and, to all appearances, the starting-point of phthisis, of which the signs subsequently develop elsewhere in the lung. Such cases are in all probability tubercular from the first, and although the pneumonic process may have been predominant at the

outset, the specific character of the disease will have shown itself in the later stages, and have led to the disintegration of the inflamed patch of lung and the extension of tubercular disease to other parts.

In a few rare instances absorption is only partial, small islets of inflamed tissue being left which undergo disintegration. Such a change might be indicated by the presence of elastic tissue in the sputa; the condition, however, is rarely met with except in association with phthisis, and is probably to be attributed to specific influences.

The whole or part of a pneumonic patch in a lung may become gangrenous, but the condition is rare. It is probably caused by plugging of vessels in the inflamed area and around it, whereby the blood supply is cut off. The symptom indicative of this condition is an unmistakable fœtor, which resists the influence of all deodorising drugs. If the gangrenous area be very limited, it may ultimately be expectorated, but the occurrence of gangrene is generally the forerunner of a fatal termination.

Pneumonia is always a serious complication, especially when it supervenes upon renal disease or diabetes, œdema of the remainder of the lung being apt to ensue, a condition generally fatal in this connection.

Complications.—Inflammation of neighbouring serous membranes is very prone to occur. Some degree of pleurisy is present in nearly all cases of pneumonia, although much effusion of fluid is comparatively rare. Pericarditis is a most serious complication, especially in children. Local peritonitis may also occur.

Inflammation of the mediastinal tissues and enlargement of the mediastinal and bronchial glands have been frequently noted. Hyperpyrexia may at times supervene in the course of a case and then becomes the most serious condition, requiring active antipyretic treatment. Purulent meningitis occasionally occurs as a complication of acute pneumonia, and to it are probably attributable the irregular paralytic symptoms which sometimes complicate the most serious cases.

Prognosis.—Uncomplicated cases of pneumonia recover completely as a rule, even though they may have apparently approached very near indeed to a fatal termination. This is especially the case in young patients. To this rule, however, there are many exceptions, and

hence the prognosis should always be guarded. In the complicated cases, where pneumonia attacks intemperate persons or those who are the subjects of morbid conditions elsewhere, and especially of renal disease, the issue is more often fatal. Some doubt has, however, recently been thrown by carefully prepared statistics, upon the generally received statement that pneumonia is especially fatal in intemperate subjects. Marked delirium of the type of delirium tremens, hyperpyrexia (105° – 106° F.) extreme frequency of the pulse and respirations, the involvement of both lungs in the disease, the development of other acute inflammatory affections, such as pericarditis or meningitis, are all signs of danger, and, should œdema of other parts of the affected lung set in, the prospect is still more unfavourable.

Pathology.—The inflammatory changes taking place in a lung, the site of acute inflammation, may be roughly divided into three stages. The first stage is marked by hyperæmia and engorgement of the part about to be attacked; the second, by active inflammation with rapid effusion of fibrinous material into the pulmonary alveoli; and the third, by the various changes that may occur in the material thus effused and in the affected tract of lung tissue itself.

The pathological changes in the first stage of an acute pneumonia may sometimes be seen on the confines of an area in a more advanced stage of the process. The affected part is engorged and dense, but it is not solid. In the second stage, the lung is found to be almost entirely consolidated, and the layer of visceral pleura covering it is seen to be dull and dry and covered with a thin layer of lymph, which, on being stripped off, displays the injected surface of the pleura beneath. On section, the consolidated area appears of a dirty brick-red colour, the surface is granular, and exudes a yellowish-red fluid. It is airless, and sinks in water. Pressure with the finger easily pits the surface or breaks into the middle of the patch. Solid fibrinous cylinders of exudation are seen projecting from the small bronchi. This condition, generally described as red hepatisation, is brought about by effusion of fibrinous material from the hyperæmic vessels of the vesicular walls into the vesicles. A few leucocytes and many red blood corpuscles are effused at the same time, and as the fibrin coagulates, these are caught in the meshes

which it forms. Some swelling of the alveolar walls and of their epithelial lining takes place at the same time.

The next stage in the process has been called grey hepatisation, from the fact that the consolidated lung becomes yellowish-grey in colour, and is still more softened and friable than in the previous stage. This change of colour is in part due to increase in the number of leucocytes and to fatty degeneration of all the effused cellular elements, and in part also to the enlargement and multiplication of the cells of the alveolar walls, producing pressure upon the blood vessels and obstructing the flow of blood through them, thus rendering the whole tract of tissue more or less anæmic. Some authorities have doubted whether the lung is capable of recovery after this condition has once been reached.

These various stages of the disease may occasionally be found in progress simultaneously in different areas of the lung, so that the surface of a section may present a mottled appearance. The colour of the parts in the stage of red hepatisation varies with the quantity of red corpuscles effused. When the inflammatory process ends in resolution, it has probably reached its maximum intensity before grey hepatization has set in. The epithelial and blood cells then become granular from fatty changes, and gradually break up into a fine granular material, which is re-absorbed or expectorated, some of the colouring matter of the red corpuscles appearing as a red or brown stain in the sputa for some time after the symptoms of inflammation have subsided.

Ætiology.—Acute pneumonia is marked by a course which is very definite, the symptoms and the pathological changes which they indicate being more uniform and constant than is the case in any of the more common febrile diseases. This fact in itself seems to point to the probability that the whole affection is determined by the action of some micro-organism which has a definite and fixed period of activity. The identity of this micro-organism has not yet been demonstrated beyond dispute, although ascertained facts point strongly to two special forms as possibly the specific agents in acute pneumonia. One of these, known as Friedländer's pneumococcus, consists of elongated oval cells provided with a very marked capsule. These pneumococci when cultivated and injected into the lungs of certain animals have, in a large majority of cases, produced acute

pneumonia, the inflamed area containing the same form of micro-organism in abundance. The second form consists of micrococci which always occur in pairs, and are hence termed diplococci; these also have been shown to bear a definite relation to the development of pneumonia in man and certain animals. Their occurrence is not invariable however, and similar forms have even been found in the healthy air-passages, from which fact some observers are inclined to believe that the cocci may be occasional parasites of the normal mucous membrane of the air-passages which find in the inflammatory changes of pneumonia the best nidus for their development. (See Figs. 3 and 5, p. 521).

Many instances have occurred in which pneumonia has been epidemic in a district, and the disease may even recur many years afterwards if the dejects of a previous epidemic be brought to light again, as by the disturbance of soil, foul linen, or old stores. Although the great majority of cases occur singly, it may sometimes happen that the disease runs through a household almost as freely as an ordinary catarrh. In whatever way it may be set going, acute pneumonia usually follows a very regular course if it remain uncomplicated.

Pneumonia occurs most frequently in this country during the latter half of the winter—from January to March. It attacks persons of all ages and of both sexes, but males rather more often than females, and, although those of weak constitution are its most constant victims, yet its effects upon the strong and vigorous are often exceptionally severe. Pneumonia may occur in any part of the lung, but the lower lobes are the parts most commonly affected, and of these the right would seem to be more susceptible than the left. In children, however, apex pneumonia is by no means rare, or the disease may begin about the root and spread to the apex. Cases of bilateral pneumonia are less frequent and are not often simultaneous in their onset. The disease does not of necessity attack a whole lobe at one and the same time, although the inflammatory change is frequently limited by the great natural divisions of the lungs. It does, however, tend to attack large tracts of lung tissue, and is apt to spread beyond its first limits and gradually to extend over a whole lobe. One attack of acute pneumonia, so far from giving immunity from further recurrence of the disease, would seem to render the

patient even more susceptible to a second attack.

A form of inflammation closely allied in its morbid changes to acute pneumonia, may be set up by direct injury or contusion of the chest. The clinical course of the disease in such cases differs in many material points from that of the acute form, and is described in the next article (PNEUMONIA, SECONDARY).

Treatment.—It is important that the natural course of the disease should be interfered with as little as possible; careful nursing is essential, and a sharp watch must be kept for the onset of unfavourable symptoms. The patient must be confined strictly to bed, the bed-clothes should be as light as possible; a liberal supply of fresh air must be maintained in the room. The patient should be disturbed as little as possible, and hence all unnecessary examination is to be avoided and conversation must be prohibited. The daily sponging for cleanliness is best done in the recumbent position. If when the case is first seen the physical signs be not yet developed, it is always desirable to act freely upon the bowels. In rare cases, where the onset of the fever has been very rapid and severe, and before the physical signs of consolidation have appeared, the administration of small (3-minim) doses of tincture of aconite or of tartar emetic ($\frac{1}{10}$ of a grain every hour), will sometimes appear to cut the process short, the fever subsiding almost as quickly as it came on. This treatment, however, if not rapidly successful, should not be persevered with, but may always be tried when the case is seen in a sufficiently early stage, provided that the patient be not very weak. It is most successful in robust patients with a full and resistant pulse.

If these means fail or if the patient be not seen during the early stage, the affected side may be enveloped in a lightly made jacket-poultice of linseed-meal, which should be changed about every four hours, its use being continued so long as active inflammation persists either at its original site or elsewhere. Jackets of spongio-piline may be used for children, but are not so satisfactory as the linseed-meal poultice. Of late years, since more attention has been given to antipyretic measures in the treatment of disease, the use of poultices has in the practice of many physicians been superseded by the application to the affected side, when the temperature

reaches 103° or higher, of ice-water compresses, changed every half-hour. Relief of pain and a lowering of temperature generally attend this mode of treatment, and it is likely to become yet more firmly established in this country. When the disease is subsiding the use of any application can be discontinued, or layers of dry cotton-wool may be substituted for poultices.

The diet should consist of milk and beef-tea only. Alcohol is often of the greatest service, and in severe cases, where there is much delirium, or where the rate of pulse becomes excessive, it may be given in very large quantities, even to the extent of 12, 15, or more ounces of brandy in the twenty-four hours. As the disease progresses, digitalis may be given with advantage if the action of the heart becomes weak or irregular. Chloral may sometimes be required if the patient be sleepless. Such drugs, if they have to be used at all, should be used boldly. Hyperpyrexia should be treated with large doses of quinine (gr. xv-xx), by antipyrin (gr. x-xv), or antifebrin (gr. v-xv), or by the use of cold applications as above described. The action of the bowels should be maintained by saline purgatives with an occasional dose of calomel (gr ij). Local pain is often a serious feature, and may be relieved by the application of ice compresses or three or four leeches to the affected side.

The practice of venesection in acute pneumonia is rarely adopted in this country, although largely employed on the Continent. Cases are to be met with at times in which congestion of superficial veins and general slight cyanosis are present in association with a full and resistant pulse. In such the withdrawal of venous blood undoubtedly gives marked relief, and is sometimes followed by a general diminution in the severity of the disease itself, the range of temperature becoming lower, and the dyspnoea less marked. In most of the less congestive cases, however, the constant application of the jacket-poultice appears to act in much the same way by drawing a large amount of blood to the vessels of a wide surface area. Cough, if severe, should be relieved, as it usually aggravates the pain.

The occurrence of "crisis" is sometimes marked by very decided depression, and the free use of stimulants, such as brandy and carbonate of ammonia, is called for. After the subsidence of the fever it is usually only necessary to keep

up the action of the excretory organs, and to regulate the diet according to the patient's powers of taking food. Tonics, and especially iron and quinine, will aid recovery and convalescence, and a change of air is advisable before the patient resumes his usual habits of life.

The treatment of the cases which do not end in recovery of the lung must depend upon the course which the disease may take in each case. As a general rule, it is mainly necessary to keep up the patient's strength by all available means, relieving such special symptoms as may arise. It is not advisable to attempt the evacuation of an abscess or gangrenous cavity unless its position can be pretty clearly defined, often a matter of very great difficulty. A direct opening and the insertion of a large drainage tube is all that should be attempted, no advantage is to be gained by washing out the cavity. Experience of such cases does not indicate a hopeful prognosis, but the patient is generally saved from the annoyance of the constant evacuation of foul pus by the mouth.

E. CLIFFORD BEALE.

PNEUMONIA, SECONDARY.—

Certain forms of pneumonia are apt to occur as complications of pre-existent disease of some other organ, such as the heart, brain, kidneys or liver. Simple inflammation of limited areas of lung tissue may also be set up by direct injury.

In most of the specific febrile diseases, this form of secondary pneumonia may be met with, but it is especially common in association with typhus and enteric fever; it is also not infrequently a complication of acute and chronic nephritis. Pulmonary apoplexy following embolism may give rise to inflammation of the lung tissue around the infarction, and foreign bodies which may have been sucked into the smaller bronchi will, if they remain, certainly produce inflammatory changes.

A condition of lung closely allied to that of pneumonia is sometimes met with in the course of erysipelas of the face or head. In some cases the disease has apparently spread by direct continuity to the throat and then to the lung, but in others the lung has been attacked independently of the upper air passages. It is marked by acute hyperæmia and effusion of serum and some degree of fibrinous exudation into the lung tissue and is attended, like

erysipelas elsewhere, with considerable constitutional disturbance. Recovery, however, when it occurs, is more rapid than is the case in ordinary pneumonia.

The *symptoms* common to most of the forms of secondary pneumonia are cough, dyspnœa, more or less expectoration of tenacious muco-pus, and very commonly hæmoptysis of varying amount. In addition to the rusty sputa seen in simple pneumonia, there is often a considerable quantity of thick dark blood brought up, sometimes mixed with frothy sputa, and sometimes alone. The blood, which is derived from patches of congestion or of pulmonary apoplexy, may continue to appear for many days after the subsidence of the more active symptoms; it gradually alters in appearance, and becomes of a dark-brown colour, and may in some cases have a peculiarly offensive taste.

The range of the temperature of necessity varies much, but, as a rule, it is not so high as in the uncomplicated forms.

The onset of the pulmonary condition is in all cases much less marked than in the acute disease.

The *physical signs* of the disease are for the most part those of congestion. The entry of air into the affected part of the lung is feeble, the expiratory sound is more or less prolonged, and there may be crepitation or coarse crackling râles audible, according to the stage which the disease has reached. The amount of dyspnœa and pain vary greatly. The patient is usually more restless than is the case in acute pneumonia, and the cough is often very troublesome. When the disease is secondary to one of the specific fevers the symptoms of the two conditions become too mixed for differentiation. The gravity of the pulmonary condition is usually in direct proportion to its extent.

The *course* of the pneumonia will depend in great measure upon the nature and intensity of the disease of which it is a complication. Recovery may be satisfactory when the primary fever itself subsides quickly and completely, but when the latter is prolonged and the patient's strength exhausted, if the case should not end fatally the lung mischief rarely clears up satisfactorily. Septicæmic infection conveyed through a poisoned wound not unfrequently gives rise to a most rapid and dangerous form of pneumonia, which tends to spread through the lung with great rapidity and very commonly leads to a fatal termination.

Pathology.—The actual process of inflammation in secondary pneumonia is much the same as that observed in the acute disease. Its onset, however, is generally more insidious, the consolidation is less complete, and smaller areas are affected.

When the pneumonic patches are situated near the surface of the lung the pleura is very likely to become implicated, causing in many cases more or less pleuritic effusion.

Pneumonia as the result of injury or violence is generally limited to the parts of the lung in the immediate neighbourhood of the lesion. The pleura is almost always affected at the same time, and there is usually a certain amount of blood effused in the vesicular tissue before the inflammatory process sets in. The condition is generally followed by recovery, but the lung often remains scarred, and firmly adherent to the chest wall.

The *treatment* of the secondary forms of pneumonia must be of a more stimulating and active kind than that of the acute form. Brandy and carbonate of ammonia will be required at an earlier stage, and may be used with a freer hand. Poultices should be kept applied to the whole of the affected side. Quinine is sometimes of value, but large doses are required (3 to 10 grains three times a day). In the cases of traumatic origin, however, it is sufficient to keep the patient in as complete physiological rest as possible, using Dover's powder (gr. v, twice a day), if necessary, with that object. In septicæmic cases the only possible treatment is to maintain the vital processes by active stimulation. Strapping the side is advisable where there is much pleuritic pain.

E. CLIFFORD BEALE.

PNEUMOTHORAX.—The presence of air within the pleural cavity.

The condition may arise from—(1) Perforation of the pleura by the breaking down of a tubercular nodule in the lung; (2) the rupture of air-vesicles as in emphysema and from great efforts; (3) the discharge of an empyema through the lung or the chest wall; (4) gunshot and other wounds of the thorax. It may also occur (5) in abscess, gangrene and hydatid of the lung, and (6) after the operation of tracheotomy for diphtheria, and rarely in diphtheria when the trachea has not been opened; also (7) from perforation into the pleura of some part of the alimentary canal.

It has been proved that a very considerable amount of force is required to rupture the visceral pleura in its healthy state; but cases are recorded in which a violent act of straining has given rise to it, though these are extremely rare. In the vast majority of cases the point of rupture will be found to be the seat of some form of acute or chronic disease of the lung, leading to ulceration or sloughing of the pleura immediately in relation with it. Such lesions may be extremely small, and even isolated, and the most usual form which is met with in actual practice is the softening of a tubercular nodule on the surface of the lung. Simple rupture of the membrane, however, is not enough to cause the whole pleural cavity to become filled with air; a certain degree of pressure is requisite to separate the layers of pleura and overcome the elastic tension which holds them together. This force is supplied by the expiratory effort of coughing. In wounds of the parietal pleura the pleural cavity may be laid open to the air, but this is not followed by complete collapse of the lung, as used formerly to be supposed, until the layers of the pleura have been forcibly separated by some other cause.

The entrance of air from any of the abdominal viscera, involves the rupture of the diaphragm, and must be the result of excessive violence. The presence of air, whether it enter through the lung or through an external wound, usually gives rise to an effusion of fluid, which may be either serous or purulent. With the escape of air from a phthisical cavity there is often some effusion of its fluid contents at the same time, and the character of this fluid must materially affect the degree of irritation to which it gives rise. The air thus pent up within the pleura is always more or less altered in its composition, which approaches closely to that of expired air, being rich in carbonic acid. In some cases putrefactive changes may take place, and the air is then found to be charged with a large proportion of sulphuretted hydrogen.

Symptoms.—Pneumothorax sometimes occurs without giving rise to any symptoms whatever, but in most cases its occurrence is very clearly indicated. Sudden and acute pain is generally felt, followed at once by more or less urgent dyspnœa, a sensation of something running down the interior of the chest is very commonly complained of, and the patient may become almost collapsed

from shock. The pulse is usually small, feeble and rapid, and the affected side is sometimes extremely tender. The suddenness of the attack terrifies the patient considerably, and he becomes restless and anxious, frequently changing his position, but generally preferring to sit almost upright. The voice becomes feeble or whispering, and some amount of cyanosis may be present. The severity and duration of the symptoms will depend upon the extent of the disease in the lungs and the amount of healthy lung-tissue left available for respiration. Unless the case is about to end fatally, the more urgent symptoms usually pass off in a few hours, but a greater or less degree of dyspnoea will probably remain for several days.

Physical Signs.—The signs indicative of a general pneumothorax on one side are very definite. The whole side seems to be expanded and more rounded than before, the intercostal spaces are sometimes slightly bulged outwards, so as to be indistinct, and the respiratory movements are absent or greatly diminished. The percussion note is resonant and tympanitic in tone, the vocal vibrations are either absent or else much diminished, and the normal breath sounds are altogether absent. The heart is at once displaced to the opposite side, unless there be strong pleural adhesions on that side or some local disease of the lung. In some cases where a large opening is left through which air can pass freely in and out of the pleural cavity from the lung, amphoric breathing may be present, but this is dependent on the nature of the lesion in the pleura. The conduction of the voice sounds is not constant, being in some cases increased and in others diminished, but pectoriloquy resembling that audible over a phthisical cavity is rarely present. A peculiar metallic ring may occasionally be heard during the act of coughing, and if any fluid be present in the cavity there may be metallic r  le at the same time. The "bell sound" may also be elicited (*see AUSCULTATION*). A pneumothorax localized to any limited area of the pleural cavity by previous pleuritic adhesion is not so easily recognizable. The same physical signs are present as in the more general pneumothorax, but they are apt to be masked by the consonance of other healthy or morbid sounds in the lung-tissue immediately surrounding the affected part.

Additional physical signs are afforded when effusion has taken place, whether the

fluid be purulent or serous. Some amount of dulness is caused in the lower part of the chest, and this may be found to alter in level when the position is changed. Sometimes on listening to the chest and shaking the patient at the same time, very distinct splashing can be heard (succussion splash). As the quantity of the effusion increases, the signs of air will diminish and the hydrothorax or empyema will then become the chief feature in the case.

Diagnosis.—The conjunction of hyper-resonance, absence of the breath sounds and displacement of the heart, with partial or complete loss of tactile vibration, forms a group of physical signs not met with in any other condition. The symptoms of pneumothorax may be present in some cases of phthisis where acute congestion takes place in the last remaining area of healthy lung, but the physical signs will fully serve to distinguish between the two conditions. A very large excavation of the lung, especially if seated about the base, has occasionally been mistaken for pneumothorax, but the resonance is rarely so complete, and there are generally more adventitious sounds and a marked degree of pectoriloquy.

Prognosis.—Re-absorption of the air without the occurrence of any fluid effusion may take place if no septic matter has escaped into the pleural sac. In most cases some amount of fluid effusion follows the escape of air into the pleura, and as this increases the quantity of air is found to decrease. The gravity of any case of pneumothorax must essentially depend upon the extent of lung area which is left undisturbed for healthy respiration. In some cases, as effusion of fluid takes place, the lung becomes pressed upon and rendered incapable of further expansion, but, if the other lung be healthy, the compensatory changes which take place may render it quite sufficient for all the requirements of quiet respiration, whilst the enforced rest to which the diseased organ is subjected, may cause the disease to remain quiescent and the general health of the patient will be improved thereby. The duration of a case of pneumothorax may vary indefinitely from a few hours to a year, or more. In most instances the period is less than a year, but the condition of pyo-pneumothorax occasionally becomes chronic, and may then last for years.

Treatment.—It is not, as a rule, advisable to puncture the chest with a view to

withdraw the air, unless the dyspnoea be extremely urgent and there be immediate danger to life. The collapse and distress are best treated by absolute rest and by the administration of opium in moderate doses. Stimulants should only be given sparingly. Gentle purgation by means of salines is advisable. Dry cupping to the side will sometimes give relief to the dyspnoea in the less urgent cases, and fixation of the side with strong strapping is often useful in the same way. When serous effusion has taken place it is not advisable to attempt the removal of the fluid, especially if the case be one of advanced phthisis of the same side. A considerable amount of absorption of serous fluid is possible even when air also is present in the pleural cavity, and opportunity should always be given for this to take place in every case where it can reasonably be expected. The chances of re-expansion of the lung after the chest has once been opened for the relief of hydro-pneumothorax, are but small. In cases, which are, however, very rare, where the fluid has been shown by exploration to be foetid, free removal of it is advisable, a large opening being made in the chest wall so as to permit of thorough drainage and cleansing of the cavity.

E. CLIFFORD BEALE.

POISONOUS FOOD. — Idiosyncrasy and habit have much to do with the causation or prevention of poisonous effects from various articles of diet; thus certain kinds of fish are poisonous to some, whilst they may be eaten with impunity by others. Although in some countries food is chiefly prized when in a state of decomposition, anything in which putrefactive changes have commenced may prove poisonous; but apart from putrefaction there are other causes of danger. An animal may have been feeding on something poisonous to man. In this way the honey of wild bees or the milk of wild goats has become unwholesome; hares that have been feeding on the chrysanthemum, or pheasants fed on the laurel, are thus rendered unfit for human consumption. Again, the animal may have been suffering from disease—*e.g.*, anthrax, foot-and-mouth disease, pleuro-pneumonia or tuberculosis—and its flesh will then be unfit for food; or its flesh may be rendered poisonous through being impregnated with some medicinal substance administered during life. Sometimes no reason can be assigned for the poisonous symptoms; thus at times

mussels will induce retching, vomiting and an alarming state of collapse. Meat which has become putrid, and sausages under certain conditions, are believed to owe their poisonous properties to the development of certain alkaloids known as ptomaines, which are produced during the decomposition of animal matter. The poisonous symptoms which are sometimes met with in those who have partaken of tinned meats, vegetables, meat pies or fruits are to be explained on this hypothesis (*see* PTOMAINES).

The *symptoms* produced are those of an active irritant poison, violent retching and vomiting, with or without purging, being the most prominent. These may be accompanied by collapse, dilated pupils and a feeble pulse. Such cases sometimes result fatally.

The *treatment* would be the same as in the irritant poisons, the vomiting being combated by ice and iced drinks, and the purging by castor oil and opiates; stimulants, such as champagne or brandy, would probably be needed.

POISONOUS GASES. — 1. *Carbonic Acid.*—This accumulates in pits, wells, mines, fermenting vats, lime-kilns, &c., producing an atmosphere that may be absolutely irrespirable, a person placed in it speedily becoming suffocated, and even in crowded and ill-ventilated rooms the air may become so overcharged with carbonic acid and so deficient in oxygen as to produce headache, drowsiness, giddiness and loss of power, with quickened pulse and hurried breathing. After death the body presents all the outward appearances of death from asphyxia, the blood is dark and fluid, and the venous system engorged throughout the body.

2. *Carbonic Oxide* occurs in combination with the above, notably in charcoal vapour and in coal gas. It is a much more deleterious gas than carbonic acid, a smaller percentage of it sufficing to produce fatal symptoms; headache, giddiness, prostration, insensibility and death from coma being the usual sequence. The characteristic feature after death is the cherry-red colour of the blood and internal viscera. This appearance is due to the fact that the oxide forms a very stable compound with hæmoglobin.

3. *Coal Gas.*—The symptoms produced may vary from the slightest degree of malaise to a fatal coma with stertorous breathing and lividity ushered in by headache, vertigo, nausea and vomiting, and followed by loss of consciousness

and complete prostration. After death the blood is dark-coloured, the papillæ at the base of the tongue are injected, the lungs are light-coloured, extravasations of blood may be found in the spinal cord or its membranes, and rose-coloured patches on the thighs.

Treatment.—In all cases the patient should be at once removed from the polluted atmosphere and subjected to a free current of fresh air; this may suffice to revive him. The inhalation of oxygen may be tried; venesection and transfusion with arterial blood freshly drawn will be necessary in the case of carbonic oxide poisoning and would be beneficial in the other forms of poisoning also; artificial respiration may be performed; stimulants should be freely administered.

POISONS. — 1. Irritant Poisons are such as tend to produce inflammation or actual destruction of the part to which they are applied. In the latter case they are called corrosives; to this class belong the mineral acids, oxalic acid and the alkalies.

Symptoms.—The difference between the symptoms in irritant and corrosive poisoning is one of degree rather than kind. In irritant poisoning the symptoms may not come on at once; in corrosive poisoning they almost invariably begin immediately the poison is taken into the mouth. Most of the metals are irritant poisons. The more important of them will be found treated of under their respective headings. The vegetable irritants are elaterium, gamboge, savin, hellebore and ergot, whilst cantharides and certain kinds of foods must also be ranked amongst the irritants.

Corrosive Poisons.—The symptoms in the most severe form come on at once, and consist of a sour taste with burning pain in the mouth, throat, œsophagus and stomach, with eructations and vomiting of black frothy blood-stained matter. In the case of sulphuric or nitric acid there may be brown or yellowish stains about the lips, the mucous membrane of the mouth and tongue may become white and shreddy, the breathing is laboured, and there may be hoarseness especially when hydrochloric acid or ammonia has been taken. The vomiting is constant and the pain in the abdomen intense, there is also extreme thirst, constipation, tenesmus and dysuria. The pulse becomes exceedingly feeble and the skin clammy.

In the less severe cases where an irritant or only a small quantity of a corrosive has been taken the symptoms are less severe, there is not so much collapse and there is usually diarrhœa. Even when the patient survives the immediate effects of a corrosive poison he is liable to die at a later period from stricture of the œsophagus, and this is especially the case in poisoning by the alkalies. The intellect is generally unaffected in irritant poisoning, but convulsions or coma may be present at the last.

Post-mortem Appearances.—The changes will be most marked in the stomach and œsophagus, but lesions may be found more or less throughout the whole alimentary canal from the mouth to the anus. They may vary from the slightest degree of redness through all stages of inflammation to ulceration or even perforation, the stomach being invariably the part most affected. Where perforation has occurred some peritonitis will be found, but this may be present especially in corrosive poisoning without any perforation. In sulphuric acid poisoning the contents of the stomach and intestines will be black from altered blood, and in all severe cases of irritant poisoning blood will probably be found in the stomach or intestines. Sometimes, especially in the case of some of the metallic poisons, the large intestine will be affected whilst the small escapes. The other viscera may show signs of inflammation.

The *treatment* of a case of irritant poisoning resolves itself into an attempt to assist nature in her efforts to get rid of the poison, and in an endeavour to neutralize by antidotes what cannot be expelled. Vomiting is a constant symptom, and it should be encouraged. Where there is no contra-indication, the stomach should be thoroughly washed out with the stomach-pump until it is certain that no poison remains there. This cannot, however, be adopted in any case of corrosive poisoning, and it is also inadmissible in many of the metallic irritants. When there is no reason to fear ulceration of the stomach or œsophagus, emetics may be used if the vomiting be not sufficiently free. Of these, ipecacuanha in 20-grain doses or sulphate of zinc in 30-grain doses are the most reliable, or apomorphine may be used hypodermically (dose, gr. $\frac{1}{20}$ – $\frac{1}{10}$). Large draughts of tepid water or mustard and water will often prove efficient as an emetic where more active measures are contra-indicated, or the fauces may be tickled with a feather; but in the case of the corrosive

poisons not even these measures may be tried.

The best antidote for the mineral acids is carbonate of magnesia, but any of the alkaline bicarbonates may be used, or even chalk and plaster from the ceiling failing anything else. They should be given mixed with water, milk, or gruel, the object being to neutralize and dilute the poison as speedily as possible, for it is only when in a concentrated form that these poisons act as corrosives.

In the case of the alkalies, vinegar and water or lemon juice would be the best antidotes, or olive oil may be given in large doses. The antidotes to the metallic poisons will be found under their respective headings. The rest of the treatment would be symptomatic, the chief dangers being perforation of the stomach and peritonitis; the patient should therefore be kept in bed till all the irritant symptoms have passed off, and be kept on a light diet of milk, gruel, broth, &c. Opiates should be freely given, both by the mouth and hypodermically if there be much pain, and leeches to the epigastrium may be necessary. The dyspepsia or stricture of the œsophagus that might result from corrosive poisoning should be treated on general principles.

2. Neurotic Poisons.—Those which produce their effects either chiefly or wholly by their action on the nervous system.

Of these some produce almost instantaneous loss of consciousness and complete muscular relaxation; such are prussic acid, nitro-benzol, and the aniline group. Others produce convulsions or muscular spasms without loss of consciousness—*e.g.*, strychnine. Others, such as digitalis, aconite and carbolic acid, are both irritant and narcotic; whilst others are pure narcotics, the most important being opium, chloral hydrate, belladonna, conium, hyoscyamus and stramonium. The chief of these are separately described, but many of the narcotic poisons so closely resemble each other in their effects and in the treatment required that it will suffice to indicate a few points of difference. For instance, opium causes contraction of the pupils; several of the others, and notably belladonna, produce dilated pupils; delirium is a prominent feature of belladonna poisoning, though unknown in the case of opium; flushing of the face, too, so common in belladonna poisoning, is not met with in poisoning by opium.

Post-mortem Appearances.— Nothing

definite is found in cases of narcotic poisoning; congestion of the brain and its membranes is common, and also congestion of the mucous membrane of the stomach, but there is nothing characteristic.

Treatment.—In cases of narcotic poisoning spontaneous vomiting is not the rule, and, as the patient will be unable to swallow, emetics are not likely to be of much service. The stomach should be washed out without delay, and this should be continued until the fluid returned seems as pure as when it was put into the stomach, and is, as far as can be judged, free from any trace of the poison; nothing more will be gained by continuing the use of the stomach-pump after this. If the nature of the poison taken be known, and if there be any antidote, this may be administered by means of the stomach-pump, or preferably, if possible, by hypodermic injection, and in the latter case the treatment might be so commenced. For instance, in a case of belladonna poisoning, hydrochlorate of pilocarpine (gr. $\frac{1}{16}$ – $\frac{1}{8}$) might be injected or a small quantity of morphine. If these methods fail to rouse the patient, it will be necessary to try the effect of cold affusions or flicking the chest or feet with a wet towel; pouring hot and cold water alternately over the head is also a powerful method of reviving persons, and is sometimes effectual. The free use of the induced current, the poles being applied indiscriminately to different parts of the body, will often succeed when other measures fail. Mustard blisters to the calves, epigastrium or nape of the neck may be tried, and, if other treatment fail, artificial respiration, either by Sylvester's method or by galvanization of the phrenic nerves, should be tried. In a severe case these various measures will require to be persisted in for some hours before recovery is assured, and sometimes they will fail to arouse the patient from his coma. When the patient has been so far roused as to reply to questions, some hot strong coffee should be administered, which should aid in further rousing him, and the patient must then be kept moving about to prevent him from again becoming comatose, the greatest care being taken to avoid producing exhaustion or cardiac failure. Should he relapse, as is not infrequently the case, the treatment must be commenced over again, with the exception that the stomach-pump will not be required; but it must be remembered that the relapse may be due to exhaustion, and it would be well there-

fore, in all cases where such active treatment as is above described has been prolonged, that as soon as the patient is aroused he should be given strong beef-tea and a little brandy, either by the mouth or rectum. The inhalation of nitrite of amyl or of the vapour of ammonia through the nostrils may be useful when signs of returning consciousness begin to appear, but not before. The after-treatment does not call for special description.

JOHN ABERCROMBIE.

PORTAL VEIN, DISEASES OF.

Thrombosis.—The formation of a clot in the portal vein is generally secondary to compression from cirrhosis or the presence of tumours, abscess, &c.

Symptoms.—The symptomatology of this rare affection is not very definite. It may give rise to hæmatemesis, diarrhœa, bloody stools, ascites, enlargement of the spleen, diminished secretion of urine, and enlargement of the abdominal veins.

Its *duration* is usually short, and it almost invariably terminates fatally.

Morbid Anatomy.—In recent cases the liver is simple anæmic. In cases of longer standing it is atrophied, sometimes granular and anæmic.

Treatment is powerless to remove this condition and can only be palliative.

Inflammation (*Pylephlebitis*).—Inflammation rarely occurs as a primary condition in the wall of the vein but results from the extension to it of some neighbouring suppuration, but cases of obscure origin have been observed in which no such cause could be found.

Symptoms.—The clinical picture of this affection is that of septicæmia with abdominal pain. Rigors, followed by heat and sweating, great prostration, rapid emaciation, swelling of the liver and spleen, jaundice, scanty dark-coloured urine, diarrhœa, coma, delirium, convulsions, suppression of urine, and death. There may be generalized peritonitis.

The *duration* may vary from a few days to several months, but is usually about fourteen days.

Prognosis.—The condition is invariably fatal.

Morbid Anatomy.—The vein and its sheath are reddened, thickened and infiltrated with pus; on transverse section its lumen gapes, and on being slit up the intima is swollen, greyish-yellow and often ulcerated in places. The blood in the vein is coagulated and firmly adherent to

the intima. The branches of the vein are filled with pus, and there are numerous small purulent foci scattered through the liver-substance, which is softened, anæmic and discoloured.

Treatment can only be stimulant and anodyne.

Cancer may occur as a secondary condition, giving rise to symptoms exactly resembling thrombosis. The diagnosis must depend upon the evidence of the existence of cancer in the portal area.

Dilatation (*Pylephlebotaxis*) is usually caused by some obstruction in the liver, but in some cases no mechanical cause can be found, and it is suggested that some nervous defect may give rise to relaxation of the wall of the vein.

Calcification (*Chronic Pylephlebitis*).—This is always secondary to thrombosis.

Rupture.—This may result from injury, but Frerichs has described spontaneous rupture of fatty degenerated radicles of the portal vein.

Parasites.—*Distoma hepaticum* and *distoma hæmatobium* have both been found in the portal vein.

Gall-stones have been found within the portal vein, where they had no doubt arrived by a process of ulceration and perforation.

ROBERT SAUNDY.

POST-MORTEM EXAMINATION (Necropsy; Autopsy).

—For the performance of a necropsy a high table should be secured in a good light. The chief instruments required will be a long sharp section knife; a stout cartilage knife; three or four scalpels of varying sizes; scissors, large and small, probe-pointed and sharp; dissecting and bone forceps; a strong-backed saw and a couple of probes.

A careful external inspection should first be made, the natural orifices being examined for the presence of foreign bodies and the escape of pathological fluids. The stature should be recorded, the degree and distribution of rigor mortis, and the presence of discoloration or œdema. An incision into the deep blue patches often found on the trunk posteriorly will determine whether they are ante-mortem extravasations or simply livories.

The Skull should first be examined. The scalp is first reflected by an incision carried vertically over the skull from immediately behind the external auditory meatus to a corresponding point on the opposite side. A horizontal cut

should then be made with the saw completely round the cranium, the line in front being carried above the superciliary ridges, whilst behind a small V-shaped piece of the occipital bone should be left projecting upwards. This serves afterwards to fix the skull cap in its place and preserve the contour of the head. The less the chisel and mallet are used in removing the bone the less likelihood is there of damaging the brain. The dura mater should be left uncut, the skull-cap being forcibly detached from it. The characters presented by the bones forming the inner table should be noted, and the sutures, &c., carefully inspected. In children, in whom the dura mater is usually firmly adherent to the bone, it is convenient to remove both together.

The longitudinal sinus is now examined, and then the dura is divided on each side on a level with the saw cut and turned upwards towards the middle line. The amount of cerebro-spinal fluid and condition of the arachnoid and pia mater having been observed, two fingers of the left hand are inserted under the frontal lobes, and the olfactory bulbs separated with a scalpel from the cribriform plate. The brain being now further raised the nerves and vessels are divided in their order from before backwards; and, the tentorium cerebelli being divided on each side along the petrous bone by scissors, a long thin scalpel is directed downwards and backwards into the spinal canal, so as to secure as low a section of the cord as possible.

The surface of the brain is next inspected, and if tubercle be suspected the Sylvian fissures are opened up and the vessels in the pia mater covering the island of Reil minutely scrutinized.

The Brain is best examined by vertical transverse sections made from before backwards, after the method of Pitres. The first, or pre-frontal, section is carried down $2\frac{1}{4}$ inches in front of the fissure of Rolando; the second, or pediculo-frontal section, is made three-quarters of an inch in front of that fissure and divides the second and third convolutions near their insertion into the ascending frontal convolution. It shows the anterior extremities of the caudate and lenticular nuclei with the internal capsule between them, sections of the three frontal convolutions, of the anterior convolutions of the island of Reil, and of the orbital convolutions at their posterior ends. The third, or frontal section is made at the level of the ascending frontal convolution. It passes through

the middle of the lenticular nucleus, the hinder part of the caudate, the optic thalamus, the external capsule and claustrum, the island of Reil, the convolutions of the temporo-sphenoidal lobe, and nearly the whole of the ascending frontal convolution. The fourth or parietal section traverses the ascending parietal convolution, it passes through the posterior convolutions of the island of Reil and takes the hinder end of the lenticular nucleus and the claustrum. The fifth, or pediculo-parietal section is carried down an inch behind the fissure of Rolando and cuts the posterior extremity of the optic thalamus. The sixth, or occipital section is made a little less than half an inch in front of the parieto-occipital fissure, and exposes the corona radiata of the hinder part of the brain. A vertical antero-posterior incision should now be made through the superior vermiciform process of the cerebellum so as to open the fourth ventricle. The pons, medulla and cerebellum are then divided transversely by numerous sections and the precise situation of any lesion noted.

The brain being removed, the sinuses at the base of the skull may be slit up and examined; the dura must then be stripped off and the bones of the basal fossæ inspected, and any fracture traced. The orbits can be opened by removing the thin papery roof with bone-forceps, and the eye, for most practical purposes, can be satisfactorily examined by making a vertical transverse section of the globe with a sharp scalpel carried a quarter of an inch behind the sclero-corneal junction, the posterior part being removed and floated in water. The roof of the tympanum is likewise easily removed with bone forceps, and the auditory ossicula and membrane examined *in situ*.

The Spinal Cord may be examined either by removing the vertebral laminae from behind or preferably by the "Vienna method" from the front, in the following manner. The thoracic and abdominal viscera having been removed, the body of the fifth lumbar vertebra is first cut away with a strong knife and bone forceps. A strong, specially made chisel, armed with a blunt guide which travels in the spinal canal, is then taken, and with it the pedicles of the vertebrae are successively divided from below upwards, and the bodies being lifted off the spinal canal is exposed. The cord is then carefully removed surrounded by the dura, the latter is slit up in front

and behind, and transverse sections are made at short distances. Portions of brain and spinal cord required for hardening should be placed for twenty-four hours in alcohol and then transferred to a 2 per cent. bichromate of ammonium solution.

Abdomen and Thorax. — A long vertical incision should next be carried from the symphysis mentis to the symphysis pubis. The cavity of the abdomen should be opened, the character and quantity of fluid present noted and the position of the arch of the diaphragm observed.

The sternum should be carefully removed, the innominate veins being avoided in dividing the first rib, and the position of the lungs observed. The pericardium may be opened by an incision carried vertically down its right border, joined by a second at right angles to it, running along the base of the pericardial sac towards the cardiac apex; the flap thus formed should be turned up and the heart exposed.

The Heart is best removed by lifting the apex and dividing first the inferior vena cava, the quantity and character of blood escaping from it being noted; next the pulmonary veins and arteries are severed and finally the superior cava and aorta. The nature of the clot or fluid contents found in each of the vessels should be observed. The heart being emptied of its contents, the competency of the valves to the water test may be tried. The organ should be supported vertically and the water directed into it in a gentle stream. To measure the capacity of the various orifices a graduated cone should be used. The weight of the organ and any degree of dilatation and hypertrophy of the chambers should be then recorded. To examine the auricles and ventricles the heart is laid on its anterior surface with its apex towards the operator. Blunt-pointed scissors are then introduced into the inferior vena cava and an incision carried upwards parallel to the posterior inter-auricular groove and brought out at the superior cava. A second incision at right angles to this, beginning again at the inferior cava and carried to the right along the auriculo-ventricular groove into the apex of the appendix will completely expose the interior of the auricle and show the tricuspid ring. The ventricle may now be laid open from behind by an incision parallel to and half an inch to the right of the posterior inter-ventricular groove; this will

be found to enter the ventricle between the left and posterior segments of the tricuspid valve, the curtains of which should then be examined. To expose the pulmonary valve, the heart must be turned over on its posterior surface. A small ridge of fat will be seen coursing upwards over the front of the conus arteriosus of the pulmonary artery; if now, the apex being still toward the examiner, the scissors be entered into the front of the ventricle beside the anterior inter-ventricular groove and carried upwards immediately to the right of this ridge, it will be found that the instrument has passed precisely between the two anterior cusps of the pulmonary valve. This completes the examination of the right heart.

To examine the left side of the heart the organ should again be placed on its front, the scissors entered at the right inferior pulmonary vein, a vertical incision carried upwards and a second outwards to the appendix, similar to those on the right side. The interior of the left auricle and fossa ovalis can now be completely examined. A knife should next be placed in the posterior inter-ventricular groove and made to cut forwards and to the left, it will then enter the left ventricle between the aortic and posterior curtains of the mitral valve, will split the posterior papillary muscle and leave the chordæ tendineæ of each segment intact.

Finally, to examine the aortic valve the heart should be once more laid on its back and an incision made into the front of the left ventricle immediately beside the anterior inter-ventricular groove. When this cut reaches the base of the ventricle it should be turned at right angles across the inter-ventricular groove and continued upwards in the conus arteriosus of the pulmonary artery. If the scissors be now made to cut between the left anterior and posterior pulmonary cusps it will be found that the aortic valve-ring has been traversed exactly between the right and left coronary cusps. The cuts into the ventricles should not be carried completely to the apex, which thus serves to hold the heart together, like the binding of the book.

The Aorta should be laid open in its entire extent and the presence of atheroma or of fatty degeneration noted, the former change being especially common about the site of the obliterated ductus arteriosus and the origin of the renal arteries.

Pleural adhesions must be dealt with according to their density; if of recent formation, they are usually easily separated by the fingers, but if very firm the simpler way is to strip the parietal pleura from the thoracic wall and remove it with the lung.

The Lungs.—When the lobes of the lung are adherent, the organ is best examined by an incision carried from its outer border directly inwards to the root, for this not only gives the largest sectional surface but also the cut lies in the plane of distribution of the majority of the large bronchi and blood-vessels. Any further dissection can be carried on by incisions at right angles to the first. When the lobes are separate such a section is not easy to make, it is then preferable to enter the long knife in the septum between the upper and lower lobes and examine the former by an incision carried midway between its anterior and posterior aspects; the lower lobe can be dealt with by an incision beginning at its outer border and the middle lobe by one passing directly backwards horizontally. The relative size of the lobes, the amount of vascularity of the parenchyma and the presence of consolidation or oedema are then carefully noted, and the blood-vessels and bronchi slit up.

The Pharynx, Larynx and Structures in the Neck should be removed together. The knife is entered below the mental symphysis and the floor of the mouth divided. The tongue is then depressed with the finger and the soft palate divided at its junction with the hard. The knife should then be made to cut back on to the cervical vertebræ and the posterior pharyngeal muscles divided from above downwards. The soft palate having been examined, the pharynx is laid open from behind and condition of the glottis noted. The larynx and trachea can then be opened by a posterior incision.

In examining the abdomen the rule of removing first those organs the ablation of which will give rise to least disturbance of the relations of the remainder should invariably be followed.

The Spleen is first drawn forwards and removed by cutting the gastrosplenic omentum. The best section of the organ is obtained by a cut carried midway between its hilum and its convex external surface.

The Supra-renal Capsules and Kidneys should next be taken out; the for-

mer may be examined by several transverse cuts across the shorter diameter, while the kidneys should be divided into two equal halves by a vertical incision from the external border to the hilum, opening the infundibulum of the ureter.

The Ureters may now be followed to the bladder and slit up.

It is most convenient to remove the **Pelvic Organs en masse**. For this purpose the sigmoid flexure is first ligatured in two places and then divided; the rectum is then drawn forwards, and the peritoneum overlying the brim of the true pelvis is separated all round. The knife should now be directed to the hollow of the sacrum and the posterior attachments of the pelvic viscera separated; it is then brought round on each side of the pelvis to the front, and the urethra being pulled well backward beneath the pubic arch, is divided as far anteriorly as possible. In laying open the **Urethra and Bladder** the upper wall should be divided with scissors, while the **Rectum** is best opened from behind. The **Uterus** may be divided by a vertical lateral section which completely exposes its cavity. The **Testes** are now brought upwards to the external ring and then freed with the knife. They are best opened from behind so that the section completely traverses the epididymis and body of the organ. Two ligatures being now placed on the first part of the jejunum, the **Intestines** are removed and opened along their mesenteric attachment. The **Stomach and Duodenum** may well be examined *in situ*, the former being opened by an incision carried along its anterior surface midway between its greater and lesser curvatures, while for the duodenum the scissors should be carried along the inner attached border. The **Gall-duct and Portal Vein** are then slit up as far as their entrance into the liver. The stomach must be drawn upwards and the **Pancreas** opened by a cut horizontally across the organ from its head to its tail, its duct being laid open with scissors.

The Liver may be examined by a series of vertical antero-posterior incisions carried nearly to the posterior border; the condition of its vessels and ducts on section being especially noticed.

Attention should next be paid to the lymphatic glands occupying the mesentery and the retro-peritoneal space. After the organs have been removed, the

great vessels and receptaculum chyli are laid open with scissors in their whole length. Finally, any lesion of the parietes is to be followed up, and any required dissection of the joints or bones of the extremities made.

LEOPOLD HUDSON.

PREGNANCY, DISEASES OF.

—The occurrence during pregnancy of the following affections is here described:—

1. Salivation.
2. Heartburn.
3. Excessive or Pernicious Vomiting.
4. Varicose Veins.
5. Hæmorrhoids.
6. Leucorrhœa.
7. Pruritus.
8. Anæmia.
9. Progressive Pernicious Anæmia.
10. Leukæmia.
11. Renal Disease.
12. Dilatation of the Ureters.
13. Heart Disease.
14. Phthisis.
15. Retroversion of the Gravid Uterus.
16. Ovarian Tumour.
17. Cancer of the Cervix Uteri.
18. Hydramnios.
19. Relaxation of the Pelvic Joints.

1. Salivation is an occasional phenomenon of pregnancy. It may be so excessive as to lead to the discharge of from 3 to 4 quarts of fluid daily. The salivation of pregnancy is distinguished from mercurial salivation by the absence of sponginess or soreness of the gums. It may be only transitory, or may last throughout gestation. It is apt to recur in successive pregnancies. The only drug that has any effect upon the action of the salivary glands is atropine, gr. $\frac{1}{16}$, which may be injected into the neighbourhood of the gland. This drug has a special effect, exerted through the chorda tympani nerve, in checking the secretion.

2. Heartburn is a frequent and troublesome symptom, especially in the latter months. A familiar popular remedy, and a very good one, is half a teaspoonful of sal volatile with as much carbonate of soda as will go on a sixpence, in water. Tablets made of carbonate of soda with peppermint are also much used. Liq. mag. carb. ʒij to ʒij is disagreeable, but sometimes useful.

3. Excessive or Pernicious Vomiting.

ing.—The vomiting of pregnancy deserves the title of “pernicious” when it reaches the point that the patient is unable to retain *any* food, and therefore if it be not checked her life will be in danger. The practitioner must form his own judgment as to this, for it is not uncommon to be told that the patient keeps nothing down, when at the same time her condition shows that she is not suffering from defective nutrition. These cases of excessive vomiting during pregnancy fall into three groups—(1) Excessive vomiting of pregnancy, *i.e.*, cases in which the ordinary vomiting of the first months of pregnancy is more severe than usual, and more persistent, not ceasing at about the middle of gestation, but steadily getting worse; there being no cause for the vomiting, save the pregnancy. The vomiting is a reflex neurosis: and is most apt to occur in weakly women of nervous temperament.

(2) Vomiting in pregnancy. By this name are denoted cases in which pregnancy co-exists with some other condition and itself tending to produce vomiting, which it increases and renders intractable. Thus cases of pregnancy with disease of the stomach or bowels, and with whooping-cough and sea-sickness have proved fatal: the combined effect of the vomiting and the disease exhausting the patient.

(3) Certain rare and at present imperfectly understood cases, in which the vomiting seems to depend upon acute degeneration of glands; or a degenerative change in the liver allied to, or perhaps an early stage of, acute yellow atrophy; or a degenerative change in the kidneys allied to, and possibly an early stage of, that found in certain cases of puerperal eclampsia.

Fatal vomiting of pregnancy, of any kind is rare. When it occurs the patient dies from starvation. With the continual vomiting, and the non-retention of food, there is marked wasting, irritability, restlessness, and want of sleep. At last an apathetic condition supervenes, with a dry brown tongue, small and frequent pulse, and epigastric tenderness. There is a steady diminution in the quantity of urine, which contains more or less albumen. On the first appearance of symptoms of this kind, abortion should be induced; this prevents the patient from falling into the grave condition above described.

Treatment.—As a preliminary, the bowels should be cleared out, and the condition of the abdominal and pelvic

organs, not omitting the kidneys, investigated. (1) If there be no sign of disease, and the vomiting be not severe, medicinal treatment may be enough. There is no drug which is a specific for all cases: but there are many which in individual cases will be found to check the vomiting. Among these are—effervescing draughts: bismuth carbonate or nitrate gr. x; oxalate of cerium gr. x; carbolic acid gr. j; vin. ipecac. ℥j; or atropine gr. $\frac{1}{100}$. When there is anæmia, and discomfort after food, iron, and the preparations of pepsin do good. If there be epigastric pain and tenderness, a mustard poultice to this region may be useful. The bromides are indicated in conditions of great nervous irritability. If there be flatulence and a furred tongue, a mercurial purge will be beneficial. Regulation of diet is not of much importance in these cases, for appetite is very capricious, and articles of diet usually difficult of digestion may, if they excite appetite, be better assimilated than simpler food. The patient's inclination is therefore in this respect the best guide.

If treatment by drugs fail, the next remedy to be tried is *recumbency*. In most cases the vomiting ceases while the patient is lying down, and in bad cases it may be necessary to compel her to remain in bed. If, notwithstanding this, the patient still vomits whenever she takes food, the next resource is to *keep the stomach at rest*, by giving nothing by the mouth, supporting the patient by nutrient enemata. If this measure fail in improving the patient's condition, the *cervix may be dilated*. This is an empirical remedy, which often succeeds, but often induces abortion. If it fail, then *induction of abortion* is the last resource: and it should not be postponed until the patient's condition is hopeless.

Cases of vomiting in pregnancy are recognised by the presence of signs and symptoms of the disease which, combined with the pregnancy, is causing the vomiting: and the treatment will be dictated by the nature of that disease.

In any case in which there is reason to fear that acute atrophy of the liver, or one of the allied glandular degenerations which have been mentioned, is commencing, when, for example, besides excessive vomiting, there is headache, irritability, restlessness, great prostration, diminution of liver dulness, or albumen in the urine, abortion or premature labour

should be induced without delay, for it offers the only hope for the patient, and there is but little likelihood of a favourable result unless the operation be performed at an early period.

4. **Varicose Veins** of the lower extremities and of the pelvis are often met with in pregnancy, especially in multiparæ. The usual results of the varicose condition are present: dilatation, tortuosity, thinning at some parts, thickening at others. They usually begin to be troublesome about the fifth or sixth month, causing aching and slight swelling of the lower limbs; when there is already varicosity, it often perceptibly increases from the very beginning of pregnancy. Some patients describe similar symptoms without there being any conspicuous varicosity of the superficial veins to account for them. In such, varicosity of the deep veins has been assigned as a cause for the aching in the limbs. The veins commonly diminish in size after delivery. Varicosities of the superficial veins may lead to *ulceration* and to *rupture*. The favourite seat of rupture in the leg is just above the inner malleolus. The hæmorrhage from this accident is often great, and may be fatal. It is to be stopped by elevation of the limb, and pressure on the bleeding spot. The varicose condition may also lead to *thrombosis* and *phlebitis*. Simple thrombosis is not common in pregnancy. Phlebitis often is more common, ending in suppuration. The attack ends in the bursting of the abscess, subsidence of the inflammation, and obliteration of the vein. It may lead to embolism or pyæmia, but these results are not frequent. A vein may burst subcutaneously, and form a swelling called a *hematoma* (*q.v.*).

During pregnancy no radical treatment for the cure of varicose veins should be carried out. Support may be given to the limb by a bandage, strapping, or an elastic stocking. Phlebitis should be treated by rest, elevation of the limb, and evaporating lotions, and the patient must be warned against friction, lest a clot be detached.

Varicose veins of the vulva or vagina sometimes form tumours so large as to attract the patient's attention, and cause much annoyance by producing intolerable itching, impelling the patient to scratch or rub the part. Either from such scratching, or from some slight local violence, they may burst—a very dangerous accident, for in most cases of the kind the patient has died before medical

help could reach her. Bursting during labour is less serious, because, then, help is usually at hand. In these cases, to prevent accidents and to relieve symptoms, the recumbent position should be maintained.

5. **Hæmorrhoids** are apt to arise during pregnancy, and it is still more common for small piles, which have not attracted notice before, to cause a good deal of trouble then. Their cure by operation is better not undertaken during pregnancy. For the relief of the symptoms they cause, the essential points are the avoidance of constipation, and the recumbent posture when discomfort is present. The rectum should be washed out with an enema of cold water every morning, and if the piles come down during defæcation they should be pushed back and the patient should remain recumbent until all discomfort has passed off.

6. **Leucorrhœa.**—Some amount of leucorrhœa is frequent during pregnancy, the increased vascularity of the parts leading to increased secretion.

7. **Pruritus** is a not uncommon trouble. It is best treated by frequently washing away all irritating secretions, and by the application of a sedative. These two purposes are accomplished by the use as a vaginal douche of a solution of borax (5j ad Oj).

8. **Anæmia in Pregnancy.**—The composition of the blood is altered during pregnancy. It contains more water, more fibrin, fewer red corpuscles but more white corpuscles, less albumen, and less hæmoglobin. It is increased in quantity. The condition has been described by the term "serous plethora." It departs from the standard of health in the direction of anæmia. Some amount of anæmia during pregnancy may, therefore, be regarded as an exaggeration of a physiological change. It should be treated exactly in the same manner as anæmia occurring in a person not pregnant. There is an old belief—it is difficult to say on what founded—that there is danger of bringing on abortion by giving iron during pregnancy. Iron may be given freely in pregnancy, and in an anæmic patient tends to prevent abortion rather than to favour it.

9. **Progressive Pernicious Anæmia** sometimes comes on in the second half of pregnancy. If it be allowed to run its course, it produces, first, death of the child, and then premature delivery; and this is soon followed by the death of the mother. When this disease is well

established, all treatment—iron, food, transfusion—quite fails to check it. The rapid progress of the disease as pregnancy advances, and the known tendency to anæmia therein, warrant the conclusion that in these cases the pregnancy is an important ætiological factor, and the induction of abortion the most hopeful treatment. In any such case, therefore, when, in spite of treatment no improvement results, abortion should be induced without delay.

10. **Leukæmia.**—This disease has been observed along with pregnancy, but the two conditions do not appear to have any effect on one another, except that the co-existence of the enlarged spleen and the pregnant uterus causes more than usual abdominal enlargement and consequent discomfort.

11. **Renal Disease in Pregnancy.**—

In a small number of cases of normal pregnancy, some albumen is present in the urine, due either to slight cystitis or to venous congestion of the kidneys, produced by pressure. But comparing the frequency of renal disease in pregnancy with its frequency in females at the same ages who are not pregnant, it is clear that pregnancy brings with it a special liability to nephritis. Between 0.5 and 1 per cent. of pregnant women suffer in this way. It is a dangerous complication, both for mother and child, for it may lead (1) to puerperal eclampsia, a complication which occurs in about 20 per cent. of cases of renal disease; and (2) to renal disease which persists after the pregnancy and soon proves fatal. It is probable that one in five of such cases die within two years. In pregnancy with nephritis the child often dies *in utero*; and if eclampsia supervene, and the child have survived till then, it is likely to die from asphyxia, produced by the convulsions.

Pregnancy may take place in patients already suffering from renal disease, no matter of what kind. In that case the course of the disease is likely to be accelerated by the pregnancy, and there is danger of eclampsia.

Of renal disease coming on during pregnancy, three forms may be distinguished—(1) *Acute Nephritis*.—This is rare during pregnancy, as it is rare without it. It is mostly followed by delivery, and accompanied it by eclampsia; but may occur without eclampsia. The mortality is high, but if the disease does not prove fatal, recovery takes place quickly and completely. The symptoms and treatment are the same as those of

acute nephritis in patients who are not pregnant (*see* BRIGHT'S DISEASE, ACUTE).

2. *Subacute Chronic Nephritis* is commoner. The disease comes on gradually, without any evident cause. It usually begins about the fifth month. Anasarca appears, and is often great, the lower extremities being usually the first affected; there may also be effusion into the serous cavities. Bronchitis, and œdema of lungs, disturbances of sight, and retinitis are symptoms commonly observed. The quantity of urine is diminished, and it contains abundant albumen and casts. Labour comes on prematurely in the majority of cases. Eclampsia is present in about 25 per cent. Often the nephritis terminates after delivery, and the patient gets well. But it may go on to the production of chronic and ultimately fatal kidney disease; and it may recur in subsequent pregnancies.

The *treatment*, speaking generally, is the same as that of nephritis apart from pregnancy. It is mainly dietetic. If the case be seen early, and treatment diligently carried out, the disease may be held in check, and the pregnancy go to term. But if the disease be pronounced, the only effective treatment is to induce labour. If this step be opposed on the ground of the danger to the child's life, it may be pointed out that death of the child *in utero*, and its spontaneous premature delivery, frequently occur; whereas, if the renal disease can be arrested, a future pregnancy which may go on to term is rendered possible, thus giving a better chance of a healthy child.

(3) There are cases of *eclampsia*, with scanty urine, loaded with albumen, in which the symptoms come on quite suddenly, without the slightest warning, in the midst of apparent health; and on post-mortem examination no macroscopic changes are found in the kidneys. It has been suggested that the disease in these cases is an acute atrophy of the kidneys analogous to the acute atrophy of the liver to which pregnancy predisposes; and a few cases have been described in which the results of microscopical examination supported this view. But the cases are so few in number that it cannot yet be said to be established.

12. *Dilatation of the Ureters*, from the pressure of the gravid uterus, has been shown to occur in a minority of pregnant women, and puerperal eclampsia has been ascribed to this condition. But

the amount of dilatation found is slight, and such as, apart from pregnancy, is not known to produce any similar effects.

13. Heart Disease and Pregnancy.

—There is no doubt that a large number of patients with valvular disease of the heart go through pregnancy and labour without suffering more than others whose hearts are sound. But in some cases—it is difficult to say in what proportion—the increased strain thrown upon the heart leads to its gradual failure during the latter half of pregnancy. This failure is manifested by the usual symptoms, œdema of the lower extremities, dyspnoea, cough, and hæmoptysis. The quantity of blood which the heart has to propel is increased, and there is a difficulty in the return of blood from the lower limbs caused by the augmented pressure within the abdomen. To these two causes the hypertrophy of the heart, which is by some believed to take place during pregnancy, is attributed. There is further danger from the straining which accompanies the second stage of labour when the heart is unsound; and also lest the sudden alteration of the conditions under which the circulation is carried on which follows delivery, should lead to cardiac failure, although the exact mode in which these altered conditions act is not known.

Bearing in mind these facts, it is our duty, if consulted prior to the marriage of a patient with cardiac disease, to warn her that pregnancy and labour will, in her case, be attended with more risk than usual. Should pregnancy take place, and slight symptoms of cardiac failure appear, they should be treated with digitalis and rest, in the same way as similar symptoms apart from the pregnant condition. Should such treatment not relieve, and the symptoms, as pregnancy advances, increase in severity, then labour should be induced without waiting for the patient's condition to become perilous. Rapid improvement in these cases follows the induction of labour. During labour, to prevent injury to the heart from straining, chloroform should be given.

14. *Phthisis and Pregnancy*. — It was formerly believed that during pregnancy the progress of pulmonary phthisis was retarded or arrested. The tendency of recent observations is to show that it is not so, but that such influence as pregnancy has upon phthisis, and upon patients predisposed to it, is unfavour-

able. Phthisis in pregnancy does not appear to exert any unfavourable influence upon the development or health of the child, beyond that the child inherits the mother's predisposition to the disease.

15. Retroversion of the Gravid Uterus.—This is one of the most important diseases of pregnancy. The body of the uterus is incarcerated in the hollow of the sacrum, being prevented from rising by the projection of the overhanging sacral promontory. The cervix uteri is raised, and presses the urethra upwards and forwards, so compressing it as to cause retention of urine. The causes of this displacement are (1) pregnancy taking place in a uterus already retroverted or prolapsed. This is probably the most common cause. For this reason the displacement is more common in multiparæ. (2) A sudden and violent effort when the bladder is full. The bladder, when full, carries the uterus upwards and backwards. If at this time the patient makes a great effort, the force of the intra-abdominal pressure, transmitted through the bladder, falls on the anterior surface of the uterus, and may drive it down below the sacral promontory. (3) Contraction of the pelvis, of the flat or rickety kind, in which the sacral promontory unduly overhangs, so that the uterus, if it once gets below it, finds an unusual difficulty in rising again.

Two aphorisms may be laid down, which epitomize the important facts in the clinical history of this condition:—*(a) Incarceration is everything: displacement nothing.* The mere retroversion of the uterus causes little or no trouble; it is only when incarcerated that symptoms arise. *(b) The bladder is everything: the uterus nothing.* All the trouble and danger of this disease come from the pressure on the bladder. It is important solely as a cause of retention of urine.

When the retroverted and incarcerated uterus comes to press on the urethra, it leads to distension of the bladder, and thus to pain and abdominal swelling. The retention then sets up cystitis. When the bladder has become greatly distended, the pressure in it becomes so great that it imperfectly overcomes the obstruction, and the urine dribbles away. This has been called "ischuria paradoxa." It thus often happens that the patient complains, not that she cannot pass water, but that she cannot retain it. It should never be forgotten that *incontinence of urine may be a symptom of retention.*

From the cystitis the urine becomes mixed with pus and blood. The cystitis may reach such a degree that sloughing of the vesical mucous membrane may take place; or the membrane may be extensively separated, dissected off, as it were, from the muscular coat, so that the whole of it lies in the bladder like a loose bag, or a large piece of it may lie loose in the bladder. This is called *exfoliative cystitis*. Or the sloughing may take place at one point, and extend through first the mucous, then the muscular coat, and then the peritoneum may give way, and so rupture of the bladder and extravasation of urine into the peritoneum may take place. More commonly the inflammation extends from the bladder along the ureter up to the kidneys, and pyelitis results. This may prove fatal long after the retention has been relieved. When either from cystitis or pyelitis, the patient becomes very prostrate, abortion is likely to ensue; but except in these circumstances, retroversion of the gravid uterus does not, as a rule, cause abortion. Cases have been described in which ulceration has occurred, and the uterine contents have been discharged by perforation of the uterine body through the vagina; but these were probably instances of mistaken diagnosis, being really cases of extra-uterine gestation. No case of this occurrence has been so well described as to remove all doubt about its nature.

The *clinical history* is usually this:—A patient who thinks herself in the fourth month of pregnancy, gives a history of retention of urine, accompanied by increasing abdominal pain and swelling, followed, after a few days, by incontinence of urine. There is often also obstruction to the bowel, but the symptoms from this cause are so much less urgent than those of the bladder, that they sink into the background. On examination the abdomen is distended and fluctuating. Per vaginam, a large rounded elastic tumour is felt, filling the hollow of the sacrum, and pushing the vagina forwards, leaving, it may be, only room for one or two fingers to pass between the tumour and the symphysis pubis. The cervix uteri is high up, above and behind the pubes; it may be so high as to be out of reach of the finger. The meatus urinarius is dragged backwards, and flattened by the tension on it, so that it may be very difficult or even impossible to pass a catheter without the aid of sight. The first step, in the examination of any fluctuating abdominal swelling, should

be to pass a catheter, and empty the bladder. When this has been done, bimanual examination will show that the body of the uterus is not in the abdomen. This will distinguish the case from one of extra-uterine gestation, pelvic hæmatocele, pelvic abscess, or ovarian tumour, for, in these conditions, if the cervix be high up close behind the symphysis, the body will be felt immediately underneath the anterior abdominal wall. The diagnosis between a retroverted gravid uterus and a retroverted uterus containing a fibroid will be made from the presence or absence of the signs and symptoms of pregnancy.

Treatment.—In nine cases out of ten it is enough to keep the patient in bed, and pass the catheter every six hours. If this be done, the uterus will generally ascend into its normal position within forty-eight hours. Should it not, it must be replaced, or circumstances may indicate immediate reposition as the best course. This can be usually done by pressing the uterus upwards by two fingers in the vagina, the patient being in the left lateral position. Should efforts thus made fail, the patient may be put in the knee-elbow position, and an attempt thus made. If that be unsuccessful, the patient must be anaesthetised, and upward pressure made by two fingers in the rectum. In this way, if the uterus be not adherent, it can be replaced. It is seldom that a pregnant uterus is adherent; for adhesions, firm enough to prevent the uterus from rising into the abdomen, usually produce early abortion. In whatever way applied, the pressure should be made not directly upwards, but towards one side, so as to avoid the projection of the sacral promontory. Should the uterus be so adherent that reduction is impossible, abortion should be induced, by passing a curved sound into the uterus. If this cannot be done, the size of the uterus may be reduced by puncturing it through the vagina, and drawing off the liquor amnii. Cases are infinitely rare in which this can be required.

After the retention has been relieved and the uterus righted, a copious diuresis usually takes place, but after a day or two the secretion of urine gradually sinks to the normal quantity. The cystitis must be treated by the usual methods. Exfoliative cystitis may be inferred if the cystitis does not yield to treatment, and if the catheter seems to impinge on something resistant in the bladder, and when this takes place the

flow of urine sometimes stops. In that case the bladder should be opened by an incision from the vagina in the middle line, the exfoliated mucous membrane removed, and the opening left patent for a few weeks.

In rare cases, recovery may take place without reposition of the uterus, the organ continuing to enlarge by expansion of its anterior wall upwards into the abdomen; so that, at the full term of pregnancy the cervix uteri is above the symphysis, and the cavity is partly above it, in the abdomen, partly below it, in the hollow of the sacrum. In these rare cases, the cervix descends during labour, and comes to occupy its normal position.

16. Ovarian Tumour.—This involves much additional risk. The distension of the abdomen is greater. The tumour, if small, may obstruct delivery. There is special liability during pregnancy to twisting of the pedicle of ovarian tumours, and they are also liable to become inflamed or ruptured, from the pressure exerted. Therefore if an ovarian tumour be discovered in a pregnant woman, or even during labour, the proper course is to remove it without delay.

17. Cancer of the Cervix.—When pregnancy is thus complicated the progress of the cancer is accelerated. The best means of prolonging the patient's life, as well as saving her from the dangers of labour obstructed by the cancer, is to induce abortion as early as possible. This may be done the more readily, because cancer often leads, when allowed to go to term, to the death of the child *in utero*. But if the cancer can be removed, this should be done.

18. Hydramnios means excess of liquor amnii. Its chief interest is obstetrical. But it requires notice here because it may be difficult to distinguish from (1) ascites or (2) ovarian dropsy. (1) In ascites there is resonance in front, dulness in the flanks, the line between resonance and dulness changing with the position of the patient. In hydramnios, there is resonance in the flanks, dulness in front, and no alteration from position. In hydramnios there are the signs of pregnancy and ballottement is very distinct. In ovarian dropsy without pregnancy, there will not be softening of the cervix or other signs of pregnancy, and the uterus, by careful combination of rectal, vaginal and bimanual examination, can be made out apart from the tumour. In ovarian dropsy with pregnancy there will be a sulcus between the pregnant uterus and

the tumour. No such sulcus is felt in hydramnios, even if there be twins. In some cases, especially when ascites complicates the other conditions named, diagnosis may be very difficult, and an exploratory incision the best course.

19. Relaxation of the Pelvic Joints is normal in pregnancy, but it may go on to such an extent as to prevent the patient from walking. The joints, of which the softening is important, are the sacro-iliac and the pubic. The condition is detected by putting the patient on her back, putting the thumb and finger respectively above and below the symphysis pubis, and bidding the patient draw up first one leg, then the other. When this is done, any movement at the symphysis will be perceived. The sacro-iliac joints may be examined by putting the hands on the bones forming them, and in a similar way testing their mobility; also by testing whether the iliac crests can be at all moved to and from the middle line. The treatment is to apply a strong bandage, of unyielding material, round the hips, embracing the trochanters and the iliac bones.

G. E. HERMAN.

PREGNANCY, SIGNS, SYMPTOMS, AND DIAGNOSIS OF.—

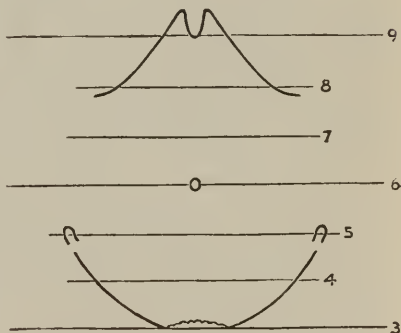

The signs and symptoms of pregnancy may be thus classified:—(a) Signs useful to the mother; (b) Signs valuable when combined; (c) The certain signs; (d) Phenomena of no diagnostic value.

Signs Useful to the Mother.—(1) *Amenorrhœa*.—The especial value of this is, that it is the *first* symptom; and it is therefore by its aid that we estimate the date of delivery. It has no diagnostic value, for hæmorrhages may take place throughout pregnancy, amenorrhœa may occur from other causes than pregnancy, and pregnancy may occur in a patient who is not menstruating regularly. But it is the symptom which usually announces to the patient that she is pregnant.

(2) *Morning Sickness*.—This is the symptom by which women usually judge whether their not having menstruated is due to pregnancy or not. It usually begins as nausea about the fourth or fifth week, reaches its height about the tenth or eleventh week, and ceases at about the middle of pregnancy. It is not invariably present, and, as vomiting may occur from many causes, it will be clear that it has no diagnostic value, but it helps the patient to form her own opinion.

Signs Valuable when Combined.

—(1) *Enlargement of the Uterus*.—This enlargement is practically confined to the body of the uterus, the enlargement of the cervix being very slight. As the body of the uterus enlarges, the shape of the uterus, taking the body and cervix together, becomes more and more that of a pear; but in the second half of pregnancy, the enlargement of the body is so much greater that the cervix may be left out of account, and the uterus described as egg-shaped. The size of the uterus at different periods of pregnancy can be easily remembered, if gestation be divided into periods of three months each. At the end of the first three months the uterus reaches to the pelvic brim, at the end of the second three months to the umbilicus, at the end of the final three months to the ensiform cartilage. If then, each of the spaces intermediate between these points be divided into three, the divisions will mark the height of the uterus at the fourth, fifth, seventh, and eighth months of pregnancy respectively (see diagram).

The lines indicate the upper level of the pregnant uterus at the various months.

(2) *Intermittent Contractions of the Uterus*.—Throughout pregnancy the uterus alternately contracts and relaxes, at intervals varying from five to twenty minutes. During contraction it slowly hardens, becoming soft again when relaxation follows. The recurrence of these changes is characteristic of uterine enlargements. It does not take place in any other kind of abdominal tumour. It is not peculiar to pregnancy, for it may occur in the uterus when enlarged by fibroids. It is useful in the diagnosis of pregnancy, for it assures

us that the tumour which we feel is the uterus.

(3) *The Uterine Souffle*.—This is a blowing sound, synchronous with the maternal pulse. It is usually heard best low down and at the sides; but it is heard at various places in different patients, and at various times in the same patient. While the uterus is contracting it gets louder, diminishing when the contraction reaches its height, increasing again as the contraction is passing off, and becoming a soft sound again when relaxation is complete. It is not affected by the position of the patient. A murmur of the same kind, and varying rhythmically in the same manner, is often heard over uterine fibroids. A blowing murmur, very much like this, may sometimes be produced by the pressure of the stethoscope over other abdominal tumours. This does not vary rhythmically, but is altered in intensity by increase or decrease of pressure, and by the position of the patient. A blowing murmur, varying rhythmically tells us that the tumour is uterine, but nothing further.

(4) *Mammary Changes*.—As these to some extent persist after the first pregnancy, they are of no diagnostic value in any pregnancy except the first. They begin early in pregnancy and gradually become more marked up to the end. They consist in enlargement and vascularity of the glands, and pigmentary changes. The enlargement is due to increase of the gland tissue. From the increased vascularity the connective tissue becomes looser, the lobules can be more easily felt and moved upon one another, and the gland acquires a knotted feel. The large veins are plainly visible through the skin. The nipple is enlarged, its colour deepened, and the areola becomes wider and darker, extending from half an inch to 3 inches outwards from the nipple. The size and colour vary: in brunettes, it is very dark, almost black; in blondes, it is light. During the last three months of pregnancy in the outer part of the areola white spots appear in the dark ground; this is called the secondary areola. In the last few months the nipple becomes covered at the apex with branny scales. From about the fifth month onwards, a drop of opalescent fluid can be squeezed from the nipple; in the last month or two this can be expressed more abundantly, and the fluid contains cream-like globules. These changes, when well marked, in a woman who has never been pregnant, are almost conclusive. They are not ab-

solutely so, because it is possible for them to be produced without pregnancy, by giving suck. But in England it is so extremely rare for a virgin to suckle a child that these changes in the breasts form very strong evidence of pregnancy. They have especial practical utility, because the state of the breasts can be ascertained under pretext of auscultating the chest, without suggesting suspicions that might give offence.

(5) *The Colour of the Genital Mucous Membrane*.—In pregnancy the pelvic organs become very vascular, and, in addition, the increased pressure within the abdomen leads to distension of those veins which return their blood through the inferior cava, and frequently to a varicose condition of them. The result is, that the mucous membrane of the cervix uteri, vagina, and vulva, instead of being the same pink tint as the buccal mucous membrane, becomes a dark bluish purple. This change goes on progressively throughout pregnancy, and is very marked towards the end. Occurring in a young woman who presents no sign of serious ill-health this is an important sign of pregnancy. The bluish colour may also be produced by great venous obstruction owing to heart, lung, or liver disease. But change in colour as great as that in pregnancy is only produced by disease of such magnitude that it could scarcely be overlooked.

(6) *The Softening of the Cervix*.—The cervix becomes enlarged, its texture looser, and, owing to the great vascularity, it becomes softer. The vagina is altered in a similar way, but the change is more easily recognized in the cervix. The softening becomes more and more marked as pregnancy goes on. It is well described by the comparison, that the consistence of the unimpregnated cervix is that of the tip of the nose; the consistence of the cervix at the full term of pregnancy that of the lip. Like the bluish colour, the softening may be produced by great venous congestion, and what has been said of the value of that sign of pregnancy applies also to the softening of the cervix.

(7) *Ballottement*.—This sign consists of two sensations—(a) That of a solid body retreating from the fingers when they are suddenly pressed against the uterus; (b) That solid body again falling back on to the fingers. To obtain this sign it is necessary that the fingers should press where there is a resisting part of the child in contact with the uterine wall. There are two chief ways of obtaining the sign.

First, the patient being on her back, by palpation it is ascertained to which side the back of the child appears to be turned. The patient then lies on that side, and one hand is placed beneath the abdomen, the other above it, and with the lower hand the back of the child is sharply pushed up. If the conditions are favourable the child's body is felt to move upwards, and to strike against the upper hand. When it sinks down its impact is felt by the lower hand. Second, the patient being supported in a position midway between sitting and reclining, so that the axis of the uterus is vertical, pressure is made with two fingers per vaginam on what is thought to be the child's head, the other hand being placed on the fundus uteri, the sensation of the child's moving upward and then sinking down being felt as in the former method. This sign cannot be obtained until the fifth month, because not till then is the child big enough to give a perceptible shock, and as a rule it cannot be attained after the seventh month, because then the child is so large in proportion to the uterine cavity that it cannot move freely enough. The sign is not free from error, as an ovarian tumour, with a pedunculated growth inside it, or a movable tumour with ascites, may simulate it. But, taken with other signs, it is sometimes useful.

The signs that have been mentioned, viz., a tumour, shown to be uterine by its intermittent contractions and by the rhythmically varying *souffle* heard over it, and presenting *ballotement*, softening of the cervix, and a bluish colour of the genital mucous membrane, in a woman not seriously out of health, taken together, warrant the diagnosis of pregnancy in a case in which the certain signs cannot be perceived.

The Certain Signs.—In the second half of pregnancy, if the child be living, the sounds of the *fœtal heart* may be heard. The sound is double, and varies in frequency from 120 to 180 per minute. It is heard best over the back of the child's chest; and this, in the usual position of the child, is below and to the left of the umbilicus. It is quicker as a rule in female children than in male. If over 145, the probability is that the child is a female; if under 135, male. The action of the *fœtal heart* is slightly accelerated when a uterine contraction is coming on, it is retarded during the height of the contraction, and is again accelerated as it passes off, subsequently returning to its average frequency. The action is accelerated by febrile conditions of the

mother. This sound is absolute proof of pregnancy.

In the first half of pregnancy, we may attain practical certainty if, by examining the patient more than once at intervals of two or three weeks, we can ascertain the *regular increase* in size of the uterus, together with the gradual development of the other signs.

Phenomena of no Diagnostic Value.—Among these are, the appearance after the urine has stood of an iridescent pellicle on its surface, called *hiestein*. This occurs in other conditions and even in men. Its import is unknown. The development of *pigmentation* of other parts beside the mammary areola, as along the middle line of the abdomen, on the perineum, in the axillæ, on the face, &c. *Fœtal movements*, which are of no use for diagnosis, because if they are felt the *fœtal heart* ought to be heard. *Atrophic lines* on the skin of the abdomen and breasts, from stretching of the skin by enlargement of the parts it covers. These may be produced by any condition which stretches the skin. *Longings*, that is, cravings for particular articles of diet, generally either fruit or highly flavoured things, such as pickles, salted fish, or meat. There is an old superstition that it is necessary to gratify these longings; it is baseless, but there is no harm in gratifying them.

Twin Pregnancy may be diagnosed if over different parts of the uterus two *fœtal hearts*, not beating synchronously, can be heard. G. E. HERMAN.

PROGNOSIS.—The forecasting of what will probably be the result of a disease is amongst the most important of the duties of the physician. A prognosis, if it is to be worth anything, must be founded on an accurate diagnosis, which in its turn must depend not only upon a close investigation of the symptoms and signs of the disease but upon an accurate knowledge of its pathological relationships, as well as upon a careful analysis of the past history of the patient. The prognosis will often depend upon the results of treatment, and on the obedience of the patient to instructions.

PROGRESSIVE MUSCULAR ATROPHY (Wasting Palsy; Chronic Anterior Poliomyelitis).—A disease characterized by progressive wasting of individual muscles or physiological groups of muscles, and by an associated and proportional amount of paralysis.

The morbid change consists of degeneration and atrophy of the multipolar cells in the anterior grey matter of the spinal cord, with consecutive degeneration of the anterior nerve-roots and muscles.

Symptoms.—The disease commences slowly, and usually the earliest indication is wasting of the muscles of the hand with impairment of power, often first noticed in the act of writing or in the performance of some other delicate action. Occasionally, these symptoms are preceded by pain, of no great severity, in the muscles subsequently affected. Although the hand, usually the right, is most frequently the part first attacked, the disease sometimes begins in the shoulder muscles, the muscles of the back, the extensors of the forearms, and, very rarely, in the lower limbs. In the hand, the muscles of the ball of the thumb are the earliest to undergo atrophy, the interossei and the hypothenar eminence soon following. Of the thumb the opponens and adductor are the first affected. The hand soon takes on a peculiar claw-like form (*main en griffe*), and from the wasting of the abductor indicis the thumb assumes a position nearly parallel with the index finger. The muscles of the forearm are usually next attacked, and with them not uncommonly the supinators. The deltoid often now suffers, with the muscles of the upper arm and of the scapula, the triceps retaining its normal bulk longer than the rest. The second arm is usually attacked in the same manner as, and soon after, the first, often before the atrophy has spread beyond the muscles of the hand on the side first affected.

Of the muscles of the trunk the middle and lower parts of the trapezius are first invaded, the upper part of this muscle remaining normal. The pectoralis major, the serratus magnus, the latissimus dorsi, the rhomboidei, the extensors of the head, the other muscles of the back, the sterno-mastoid, and, more rarely, the levator anguli scapulæ become involved. The sternal and clavicular parts of either the pectoralis major or of the sterno-mastoid may be affected separately. The platysma myoides is said always to escape. The intercostals and the diaphragm sometimes suffer, and occasionally the muscles of the abdominal wall; under such circumstances danger to life from interference with respiration may arise.

The lower limbs are usually affected

late in the course of the disease. The muscles first attacked are the tibialis anticus group, the glutei and the extensors of the knee. Dr. Gowers asserts that the lower limbs not unfrequently become paralysed with little or no wasting, the loss of power which is gradual, being accompanied by increased knee-jerks and clonus.

Towards the end the facial muscles may become involved, and symptoms of glosso-labio-laryngeal palsy may supervene.

In children attacked by progressive muscular atrophy, the muscles of the face are the earliest affected, and hence ensues an expressionless and almost idiotic aspect. It is believed by many observers, however, that this "juvenile" form of muscular atrophy is really a variety of "simple idiopathic muscular atrophy."

In the advanced stage, the wasting becomes extreme, so that bony prominences normally concealed become obvious. At this period the fatty tissue may disappear, though earlier in the disease it may be abundant, and on this account the muscular wasting may be not apparent.

The loss of power in the affected muscles progresses gradually and is proportional in amount to the wasting. Hence complete paralysis does not take place until the atrophy has become extreme. The muscles respond with undue readiness to mechanical stimulation, and fibrillar movements of the muscles may very frequently be seen and felt. Such movements, however, are not peculiar to progressive muscular atrophy, although undoubtedly more common in this affection than in any other.

The galvanic and faradic irritability of the muscles diminishes as the muscular atrophy progresses, and when the latter becomes extreme, no reaction can be obtained with either form of stimulation, even with the strongest currents.

The galvanic irritability may, however, persist after the faradic has disappeared. The nerve-trunks remain excitable for a longer time than the muscles.

Vaso-motor disorders are often present in the limbs, the affected parts becoming cold, livid or pale. In the early stages the temperature of the parts involved is said to be slightly elevated, later on a distinct lowering of the temperature occurs. Trophic changes in the skin are sometimes present, but they are rarely extreme. In exceptional cases

articular swellings chiefly of the phalangeal joints have been noted. Changes in the pupil have been rarely described, but they are especially likely to occur when the muscles supplied from the lower cervical region are implicated. The reflex actions of the atrophied limbs become enfeebled and finally disappear. Cutaneous sensibility is not affected, though subjective sensations of numbness, coldness and the like may be present. The functions of the sphincters remain unimpaired, and there is no tendency to the formation of bed-sores. Sexual power is not uncommonly lost. Lordosis, and various deformities, of which club-foot is the most common, are occasionally seen in progressive muscular atrophy.

Diagnosis.—It is important to bear in mind that the muscular wasting, unlike that occurring in many spinal affections, is not diffuse. The muscles, as has already been pointed out, are affected according to their physiological grouping. Chronic meningitis or any condition giving rise to pressure on the nerve-roots may be followed by muscular atrophy; but in such cases the posterior roots are usually involved, and hence severe premonitory pains are common, and anaesthesia subsequently appears. In amyotrophic lateral sclerosis the wasting is widespread, and is preceded and accompanied by rigidity, with exaggerated reflexes. The diagnosis between progressive muscular atrophy, multiple neuritis and pseudo-hypertrophic paralysis presents little difficulty. In lead palsy the onset is comparatively abrupt, the electrical reactions are profoundly changed, and the paralysis precedes the atrophy.

Prognosis.—The disease, although usually progressive, is essentially chronic. Occasionally the affection becomes stationary, and this may occur at any stage. Arrest is said to be more common in cases arising from over-use of the affected muscles. The outlook is very serious when the respiratory muscles are attacked, and when symptoms of bulbar paralysis make their appearance.

Morbid Anatomy.—It is now admitted that the most constant morbid change is degeneration with atrophy of certain of the multipolar cells in the anterior grey matter. The lesion is almost always more marked in the cervical region than elsewhere. Dr. Ross believes that the disease begins in the central grey column and extends outwards and forwards into the anterior cornua. The anterior nerve-roots become atrophied, and their fibres

degenerated and subsequently replaced by fibrous tissue. In some few recorded instances the destruction of the anterior grey column has apparently resulted from dilatation of the central canal (hydromyelia).

In many cases sclerosis of the direct and crossed pyramidal tracts in the cord, and sometimes of the entire system of these fibres as high as the cortex, has been described. Dr. Gowers is of opinion that the pyramidal tracts are invariably degenerated. The posterior horns and roots are always intact. In the early stage of the disease the vessels of the cord are enlarged and their walls thickened. Degeneration of the peripheral nerves, sometimes limited to the minute intra-muscular branches, sometimes affecting the large trunks, has been found by several observers. The affected muscles are wasted, pale or buff-coloured. The fibres are narrowed granular or fatty, and the striation indistinct or absent. Scattered among these degenerated fibres there are often many which present little or no deviation from the normal. Some interstitial change, with accumulation of fat, is not uncommon. Lastly, it may be mentioned that changes have occasionally been found in the sympathetic ganglia and nerves, but it is now almost generally allowed that such alterations have no share in the causation of the disease.

Ætiology.—The disease is much more frequent in males than in females, and it is mainly an affection of adult life. A history of nervous affections in the progenitors is found in a large proportion of cases, but direct transmission of the disease itself is much less common. Excessive muscular exertion is believed by many to be a potent exciting cause. Exposure to wet and cold, mental emotion, injury to the spine or to a limb, are occasional antecedents. Syphilis probably plays an unimportant share. The disease occasionally follows one of the specific fevers.

Treatment.—Drugs are often of little service. When there is a possibility of a syphilitic taint, mercury and iodide of potassium should be tried for a few weeks. Gowers speaks favourably of arsenic and strychnine. He recommends that the latter be administered subcutaneously in the form of the nitrate of strychnine once daily, and that the dose be $\frac{1}{16}$ grain, gradually increased to $\frac{1}{4}$ grain. Electricity is occasionally of service, though in many cases it entirely fails. The galvanic current is usually more efficacious than the

faradic, but both may be used alternately.

The electrodes may be applied to the muscles themselves, or one pole may be placed on the spinal column in the region corresponding to the diseased part of the cord. Duchenne preferred the use of the induced current, and recommended that it be applied to the affected muscles. Passive movements and massage may also be employed. Hydro-therapeutic measures are of no service. Unfortunately, in a considerable proportion of cases all remedies fail. Amelioration, however, often occurs spontaneously, and arrest of the disease is by no means uncommon.

W. B. HADDEN.

PROPHYLAXIS signifies the means of preventing disease; thus the practice of disinfection is prophylactic against the spread of zymotic disease.

PRURIGO.—A chronic disease of the skin which begins in early childhood, presents an extensive eruption with special characters and distribution, is accompanied by intense itching, and secondary dermatitis due to scratching.

The affection is closely allied to chronic papular urticaria (*lichen urticatus*), and may be regarded as the head of the urticarial family, the various members of which present considerable differences of character and severity. It is slightly commoner in the male than in the female sex. It appears first in early infancy in the form of urticarial wheals of the ordinary type, of various size and shape; these develop in successive crops indiscriminately all over the body. Generally in the second year of life, small, hard wheals appear, which have a predilection for the trunk and outer sides of the limbs, and which become more and more numerous as time goes on. The large wheals, on the other hand, become less numerous till about the fifth year, when the condition termed "prurigo" is usually established, but exacerbations with crops of large wheals occur from time to time throughout life, especially in cold weather.

In a typical case of moderate severity (*P. mitis*) the lesions consist mainly of pale or pinkish papules, varying in size from a pin's head to a hemp-seed, never arranged in groups, situated deeply in the skin, and therefore often more perceptible to touch than to sight. Their seats of election are, in order of frequency and severity, the outer sides and backs

of the legs, the front and outer sides of the thighs, the buttocks, loins, thorax and abdomen, the extensor surfaces of the fore- and upper arms. A few papules are generally present on the face, especially on the cheeks and forehead. A still smaller number exist generally on the neck and scalp, although the hair is lustreless and dry. The regions conspicuously free from them are the soles and palms, the hams, but especially the popliteal spaces, axillæ, and the bends of the elbows. Where the papules are closely studded together the skin feels rough, and has been compared to a nutmeg-grater. As the result of the intolerable itching the tops of the more prominent papules are scratched off, and blood crusts form upon them. The "pruriginous habit" is thus established, and fresh lesions are constantly produced outside the originally affected areas. In consequence of constant scratching other secondary lesions are evoked, and, if severe, the case then corresponds to Hebra's description of *P. ferox*, the wholesale acceptance of which, as typical of the disease, gave rise to the false impression—only dispelled at the International Congress held in London in 1881—that the disease does not exist in this country. These secondary lesions comprise linear excoriations, severe dermatitis with chronic congestion, vesication, serous discharge, pustulation, scabbing and ecthymatous sores, deep pigmentation with infiltration, thickening, and exaggeration of the normal lines of the skin, loss of lanugo hairs and sympathetic enlargement of the lymphatic glands, especially of those in the inguinal regions, which may form large prominent tumours. In the ultimate stages the skin becomes leathery, dry and shrunken, both sweat and sebaceous functions being abolished. The course of the disease is never continuous, but the fresh exacerbations which constitute its progress are generally less frequent in summer than in winter—probably owing to the better regulation of the temperature of the skin produced by perspiration—the rule being, however, by no means an invariable one. The disease described, however, by some authors as summer prurigo (*P. æstivalis*) is a form of relapsing bullous eruption much more closely allied to the vesicating erythema than to that under discussion. As the result of want of sleep from itching the patients are always pulled down, miserable, pale and emaciated. In a few cases fatal marasmus is estab-

lished, but in the great majority death results from independent causes.

The *diagnosis* is only a matter of difficulty when the secondary lesions are sufficiently accentuated to mask the real nature of the disease, and even in the severest cases their distribution is eminently suggestive. The affections with which prurigo is most likely to be confounded are pediculosis, scabies and eczema, especially in xerodermatous subjects (Crocker). In establishing the differential diagnosis the history must be borne in mind and too much stress must not be laid on the discovery of the so-called typical sub-epidermic papules. These are often absent, being destroyed by scratching immediately after their formation.

The *prognosis* depends mainly on the stage of the disease when the case is first seen, and on the general surroundings of the patient. In old standing cases in adults it is unfavourable.

Pathology.—Nothing is known of the essential pathology of the affection. Its "nervous" origin is generally admitted, and some authors even maintain that the initial, as well as the secondary, lesions, are the result of scratching, thus making the disease a pure neurosis or sort of essential pruritus. The characteristic initial "sub-epidermic" papule is due to inflammatory infiltration into the substance of the corium, spreading to its upper papillary layer. Subsequently the epidermic layers hypertrophy, the rete cells multiply, are the seat of excessive pigmentation, and become enormously involutioned, causing exaggeration of papillation. The *musculi arrectores pilorum* hypertrophy, and contribute to the formation of the papules. The vessels of the corium dilate, and a fibrosis of that layer occurs, which may result in the destruction of the sweat and sebaceous glands.

Ætiology.—Prurigo seldom affects persons of the upper classes who are able to treat its earliest manifestations in infancy; it prevails among the poor, the badly nourished and the squalid, and probably in all countries, although commoner in temperate and cold climates. No recognized diathesis predisposes to its development or modifies its course.

Treatment, to ensure success, must be vigorous, assiduous and applied to the earlier manifestations of the disease. The patient must be placed in good hygienic surroundings; the diet must be simple and digestible, although generous. Crustacea, molluscs, dried and salted

fish, pork, tinned meats, strawberries, and other common excitants of nettlerash must be sedulously avoided. Digestive derangements must be treated on the ordinary lines. The regulation of the bowels is of special importance, and is generally best accomplished by a morning saline draught. Cod-liver oil is of great value as a reconstituent, and iron is often a useful adjunct. Arsenic is of undoubted value in some cases, the amount of itching being diminished during its administration, while in others it is inferior to carbolic acid (best given in pill form). Sulphate of atropine and pilocarpine have both their adherents, but as both are best administered subcutaneously, they are seldom applicable in the case of children. Salicin and the salicylates have also been recommended.

Prolonged warm bathing is of the greatest use; a bath of 30 gallons of water at 90° F. may be taken for twenty minutes night and morning, and the addition of sulphide of potassium (3ij) tends further to diminish irritability and lessen the frequency of urticarial outbreaks. After the bath the body must be carefully dried with soft towels. A weak lotion of liquor carbonis detergens (5j ad 5vii) may then be sponged on all over, but ointments are generally preferable. Of these probably the best is vaseline containing 2 per cent. of salicylic acid or from 2 to 5 per cent. of β -naphthol. In the aggravated cases in adults sulphur baths may be too irritating, when bran, mucilage or linseed baths may give relief.

J. J. PRINGLE.

PRURITUS signifies merely itching (*i.e.*, a functional disorder of sensation or paræsthesia), although the word is often erroneously used as synonymous with prurigo. It is a symptom of many diseases of the skin, especially of the urticarial group—including acute and chronic urticaria, lichen urticatus and prurigo—of pediculosis and scabies, and of eczema, especially in its papular and squamous phases. In other affections—*e.g.*, psoriasis and lichen ruber—although it is usually present and sometimes a very marked feature, its intensity varies within very wide limits. Too much stress is usually laid upon its absence as characteristic of dermatosyphilis, as squamous "specific" manifestations are not infrequently accompanied by considerable pruritus.

Itching may accompany jaundice from whatever cause proceeding, lithiasis, diabetes and albuminuria, probably as the result of irritation of the peripheral

nerves or of the sensory centres by the toxic substances circulating in the blood. In the same category may be placed the itching which in some cases follows the administration of morphine or quinine. When secondary to digestive derangements, intestinal worms, pregnancy, organic or functional uterine or ovarian disturbances—especially about the menopause—or to genito-urinary diseases, it is generally regarded as “reflex.” Pruritus may, however, exist independently of all ascertainable cause, especially in advanced life, when the skin becomes thin, pale, dry, wrinkled and often warty, and in persons suffering under depressing mental or moral emotions. Frequently it follows exposure to cold or exists only in winter (*P. hiemalis*) especially in dry climates.

The sensation of itching needs no description; it may be universal or local, and may vary in position from time to time. It presents all grades of severity and may attain the utmost degree of torment, driving the patient to the use of all imaginable sorts of rough instruments for the accomplishment of the irresistible scratching which alone alleviates it, or even to insanity and suicide. The secondary dermatitis resulting from scratching includes the production of linear excoriations, urticarial wheals, thickened, pigmented skin, papules crowned with blood-crusts, vesicles, pustules, &c., and may mask the real nature of the malady, but the history of the case and the distribution of the lesions as contrasted with those of the above-mentioned diseases which it may complicate, generally render the diagnosis easy. The regions most affected by the secondary lesions are those most readily accessible to the hands; thus the back is seldom their seat; the inner sides of the legs and thighs are more affected than the outer and posterior sides, and the clavicular regions more than the shoulders. Not infrequently, however, patients who complain even of severe itching exhibit no scratch marks. Others entertain an ineradicable delusion that they are the subjects of some parasitic affection; the fantastic description of their symptoms and of the nature of the parasites they imagine to have discovered soon give an unmistakable clue to the nature of such cases. The local forms of pruritus are more frequent than the universal, and merit a few words of special description.

Pruritus of the Nostrils is popularly associated with the presence of intestinal

worms in children, or may be the precursor of an asthmatic attack.

Pruritus of the Anus and Neighbouring Parts occurs in children as the result of the presence of oxyurides in the rectum, but is commoner in adults, especially in those whose occupations are sedentary. It is frequently associated with hæmorrhoids, enlarged prostate, fecal accumulation, proctitis, or anal fissure. Its intensity may be extreme, and the secondary lesions are often very severe.

Pruritus of the Genitals in either sex may be the result of diabetes or vesical calculus. In females leucorrhœa or varix of the labial veins is often present, and the condition may exist only during menstruation as the result of mistaken neglect of cleanly precautions (*see also PRURITUS VULVÆ*).

Pruritus of the Feet occurs chiefly between the toes. It appears to be the result of sweat detention or decomposition.

Treatment must always be directed towards the cause of the disease, a complete examination being made with regard to all the conditions enumerated as sometimes underlying it, the examination of the urine being of paramount importance. The bowels will require careful regulation, and errors of diet or digestive derangements must be rectified. The use of alcoholic stimulants and of tea or coffee are decidedly contra-indicated. Of the remedies recommended for the alleviation of itching it may be truly said that their name is legion—than which there can be no more eloquent expression of their general inefficacy or unreliability. Only those which appear to the writer to be of real service are here alluded to.

Internally, arsenic is occasionally useful but it is wise to administer it in small doses. The tincture of cannabis indica (m_x increased with caution to m_{xxx}) is perhaps of greater service, but disagreeable cerebral effects are sometimes observed from it. Jaborandi in the form of the infusion and its alkaloid, pilocarpin (gr. $\frac{1}{10}$ or less hypodermically), merit further trial. Bromide of potassium has yielded unsatisfactory results, but the tinctures of hop, hyoscyamus and belladonna, and the sulphate of quinine seem sometimes of decided value, and given at bedtime may secure a good night's rest. In menopausal cases ichthyol (m_v or more in capsule thrice daily) occasionally acts with remarkable success.

Prolonged warm baths are generally to be recommended; they should be

taken at bedtime, and the addition of sulphide of potassium (3ij) or of borax, bicarbonate of soda or potash (of either 3vj or more) to 30 gallons of water often increases their efficacy. After careful drying various lotions containing tar or its derivatives may be employed, such are: R Liq. carb. deterg. 5j, spir. vini rect. 3j, aq. dest. ad 3vj; R Acidi salicylici 5ij, spir. vini rect. 3iv, aq. dest. 3x; R Acidi carbolici gr. v-xv, aq. dest. 3j; R Thymol 3ij, liq. potassæ 3j, glycerini 5iij, aq. dest. 3vii; R Hydrarg. perchlor. gr. ¼-1, spir. rosmarini 5ij, aq. dest. ad 3j; &c. Oily applications and ointments are less often useful, but an ointment of naphthol, 2-5 per cent., in vaseline and lanoline is to be recommended. For the local forms of pruritus, scrupulous cleanliness must be observed. It is generally serviceable to apply warm water freely on a sponge or piece of flannel, afterwards drying the parts with care. Mercurial ointments are of special value, particularly the red oxide ointment of the B.P. diluted with an equal quantity of benzoated lard; and black or yellow wash is often useful. Painting the parts with compound tincture of benzoin or a solution of nitrate of silver in spirit of nitrous æther (gr. x ad 3j) is invaluable in cases depending upon varix, while suppositories of cocaine (gr. ½) are most effectual in some cases of pruritus ani. J. J. PRINGLE.

PRURITUS VULVÆ.—Itching of the vulva may arise from various causes. (1) The presence of an irritating discharge. Almost any discharge may, under certain undefined conditions, cause troublesome itching. Thus, pruritus is often present before and after menstruation, and during pregnancy and in cancer, gonorrhœa, endometritis, and leucorrhœa of any kind. (2) It may arise from wearing pessaries, the effect of which seems to depend on some idiosyncrasy, a metal pessary causing pruritus in one patient, an india-rubber one in another. (3) Vulvitis may act as a cause, especially in children. Also skin diseases, such as eczema of the vulva, which is more especially met with in gouty subjects; erythema of the vulva, a frequent accompaniment of diabetes; also herpes of the vulva, furunculus and warts. (4) Parasites, *e.g.*, the pediculus pubis, scabies, ascarides. The pediculus pubis only causes itching when recently acquired: patients in whom the insect is habitually resident cease to notice it. (5) Nervous pruritus,

as in degenerative cerebral or spinal changes.

Treatment consists in keeping the parts very clean; frequently washing away by a douche all irritating secretions, and then applying some sedative application. The douche may be a saturated solution of borax. Greasy or glycerin applications are best for after-use, as they do not evaporate. The following are useful: ung. calomel., ung. zinci, ung. plumbi acet., glyc. boracis, and boric acid 3j, ad vaseline 3j. For class (2) the treatment is that proper for the underlying disease. The pediculus pubis must be killed either by ung. hyd. amm. chlor., or by the application of chloroform. Ascarides may be treated by washing out the rectum daily for a fortnight with inf. quass. Oj, ferri sulph. 5j. In any case of pruritus the patient should be instructed that the effect of friction is to aggravate the condition on which the itching depends. In children it may be desirable to secure the hands during sleep, lest bad habits should be acquired. G. E. HERMAN.

PRUSSIC ACID, Poisoning by.—Prussic or hydrocyanic acid is chiefly obtained from the cherry laurel or bitter almond plants or from the kernels of peaches or apricots. Compounds containing the acid, such as essential oil of almonds, laurel water, bitter almond water or cyanide of potassium are almost as poisonous as the acid. Nitro-benzol, nitro-glycerin, and aniline produce poisoning in much the same way as prussic acid and call for the same methods of treatment.

Symptoms.—Sometimes the patient becomes insensible almost immediately, and dies within two or three minutes, but some cases do not prove so instantaneously fatal, though, as a rule, death, when it does occur, takes place early. A slow and irregular action of the heart and difficulty in breathing are at once apparent, then follow convulsions, ushered in, it may be, by a shriek; the pupils are widely dilated; the expiration laboured; cyanosis, vomiting and involuntary passage of urine and fæces, and complete loss of muscular power will be observed; finally, there is extreme collapse, pulselessness, cold clammy skin, stertorous breathing and death. Occasionally there is time for voluntary acts not requiring many seconds for their accomplishment to be performed. If the patient survive the first half-hour there is fair hope of his recovery, whilst, after an hour, re-

covery is almost assured. The almond-like odour of the poison may be noticed in the breath, but the absence of the odour would not militate against the diagnosis.

Post-mortem Appearances.—Cadaveric rigidity comes on early. The eyes are glassy, the pupils dilated, the nails livid, the fingers and toes contracted. The odour of the acid may be noticeable either before or after the opening of the body. The right side of the heart is generally engorged with blood, dark and fluid, sometimes thick; the lungs are engorged and œdematous; the bronchi contain frothy mucus. The brain, the stomach and intestines may or may not be congested.

Fatal Dose.—From 40 minims to 1 drachm of the pharmacopœial acid is usually a fatal dose. Scheele's acid is rather more than twice as strong.

Treatment.—To have any chance of success treatment must be prompt. Cold affusion to the neck and spine, or alternate douches of hot and cold water constitute the best means of stimulating the respiration, which is the main object of treatment. Stimulants may be given by the mouth if the patient can swallow, and ammonia should be held to the nostrils. Emetics should be given or the stomach pump used. Artificial respiration and the application of the induced current to the cardiac region are useful measures. The poison so soon gets into the blood that chemical antidotes can rarely be of any benefit, but a mixture of a proto- and a persalt of iron, followed by an alkaline carbonate, has been recommended, and might be given if at hand. But there would be no time to spare to make up such a mixture. The hypodermic injection of atropine $\frac{1}{16}$ gr. may be tried, but the other treatment above recommended is far more important.

PSEUDOCYESIS (Spurious Pregnancy).—It is not uncommon for women to be in doubt whether they are pregnant or not. But spurious pregnancy means more than this. The patient not only thinks she is pregnant, but has symptoms which to some extent justify the belief; and the spurious pregnancy is often followed by spurious labour. That the disorder is not simply the result of imagination is shown by the fact that similar phenomena have been observed in birds and other animals. The patients generally have some irregularity in menstruation; they say that the abdomen is enlarged and that they have had to let out

their clothes; that there has been sickness in the morning, and that the movements of a child have been felt. Sometimes the breasts have enlarged, and, if the patient have had children before, it may be possible to squeeze milk from them. In some cases these symptoms persist long after the expected date of delivery, and the patient seeks advice to ascertain the cause of the delay. Sometimes spurious labour comes on; there is a vaginal discharge, nurse and doctor are sent for, and find the patient in paroxysmal throes of pain. On physical examination, it is at once discovered that the patient is not pregnant. But it may not be easy, owing to the resistance of the abdominal muscles, to make a thorough examination, and it is generally difficult to convince the patient that she is in error. In a case in which absolute certainty is necessary, but its attainment difficult, an anæsthetic may be administered. When the patient is anæsthetized, the uterus can be grasped between the hands, and the absence of uterine enlargement, or the presence of any other tumour, satisfactorily established.

G. E. HERMAN.

PSEUDO-HYPERTROPHIC PARALYSIS.—A disease characterized by progressive muscular weakness, usually associated with an enlargement of some of the affected muscles. The morbid change is an interstitial fibrous overgrowth of the muscles, frequently accompanied by an accumulation of fat.

Symptoms.—Impaired muscular power and clumsiness, especially of the lower limbs, are usually the earliest appreciable symptoms. Very shortly, enlargement, usually symmetrical, of certain muscles supervenes, the disease then presenting the features to which it owes its name. Increased bulk, however, is by no means constant. In the course of time many of the muscles undergo diminution, sometimes differing little from the normal in size, sometimes becoming markedly atrophied.

It is important also to remember that enlargement is in rare cases absent throughout, the muscles either retaining their natural bulk, or exhibiting a variable degree of wasting.

The muscles of the calf are most commonly the earliest to undergo enlargement, the increase in bulk being sometimes extreme. The glutei, the extensors of the knee, the lumbar muscles, the infra-spinatus, the deltoid

and the triceps are especially liable to be affected. The muscles on the front of the leg, the supra-spinatus and the biceps are less frequently involved. The flexors of the knee and the muscles of the forearm usually escape, and the serratus magnus is rarely implicated. With the exception of the clavicular part of the sterno-mastoid, the muscles of the neck are rarely involved. The muscles supplied by the cranial nerves never suffer, with the exception of the tongue, which is occasionally enlarged. The pectoralis major is never enlarged, but its lower part, usually in conjunction with the latissimus dorsi, and sometimes also with the teres major, is frequently wasted. The weakness of this muscular group causes inability to depress the raised arm, and the atrophy gives rise to diminished size or almost complete absence of the posterior fold of the axilla. Occasionally these muscles appear to be entirely wanting, and it has been suggested that they may be congenitally absent. The masseters and temporal muscles have in rare instances been enlarged, but otherwise the face is rarely affected. The muscles of the hand almost always escape. It not unfrequently happens that portions of muscles are involved, and this has been particularly observed in the triceps, in the component parts of the muscular mass in front of the thigh, and, as has already been noticed, in the pectoralis major and sterno-mastoid. Impairment of power is said to be more marked in the wasted muscles, and as enlargement gives place to atrophy, the loss of power progressively increases.

The attitude and gait in pseudo-hypertrophic paralysis are characteristic. In the upright posture the legs are wide apart, the shoulders thrown back and often projecting beyond the buttocks, the lower part of the back strongly curved, and the abdomen pushed forwards. During progression the legs are widely separated, and the body swayed to one or other side. The gait thus presents a peculiarly awkward and waddling character. Great difficulty is experienced in rising from the floor, and the method which the patient adopts is almost pathognomonic. First he rests on the hands and knees with the head down, then by extending the knees the buttocks are raised and protruded. The hands grasp the thighs, and then by pushing upwards with each hand alternately, the trunk is gradually extended. When the extensor muscles of the knees are profoundly affected, the patient is unable to rise.

In course of time distortions of the joints are apt to occur. When the calf muscles diminish in bulk, talipes equinus and sub-luxation of the ankle-joints may supervene. The knee sometimes becomes permanently fixed from the unopposed action of the flexors, and by the contraction of the biceps the elbow may also become flexed. The antero-posterior curve of the spine, with the concavity backwards, has already been noticed. Dr. Gowers believes that it is due to weakness of the extensors of the hip, which permits the pelvis to incline forwards, carrying with it the lower lumbar vertebrae and the abdomen. The shoulders and upper dorsal spine are thrown backwards, in order to bring the centre of gravity over the feet. Lateral curvature from weakness of the spinal muscles may occur.

In the early stage of the disease, the reaction of the muscles to electricity is not altered. Later on, the faradic irritability is diminished, and, according to some observers, the galvanic contractility is normal or increased. Dr. Gowers, however, asserts that the latter is lowered, and that the reaction of degeneration is never present. The knee-jerks at first are feeble, and finally disappear. Sensation remains unaffected. The power over the sphincters is preserved, except in rare cases, when towards the end some difficulty in retaining or voiding the urine is experienced. Mental weakness, sometimes congenital, sometimes supervening during the course of the disease, is frequent.

Course. — Pseudo-hypertrophic paralysis is a slowly progressive malady. Its duration is variable, and life may be preserved for twenty years or even more. But long before death, often after the lapse of ten years or thereabouts from the onset, there is inability to stand. Death usually results from pneumonia or phthisis.

Diagnosis. — When there is enlargement of the calves and buttocks, there is little or no difficulty in arriving at a correct diagnosis. The gait and the mode of rising from the floor are also very suggestive. Dr. Gowers asserts that enlargement of the infra-spinatus muscle, combined with wasting of the latissimus dorsi and lower part of the pectoralis major, is rarely absent.

The attitude of the lower limbs and the gait in infantile spasmodic paraplegia sometimes suggest pseudo-hypertrophic paralysis. In the former, however, the legs are in a state of active spasm, the knee-jerks are commonly

exaggerated, and the peculiar method of rising from the floor is absent. Serious difficulty in diagnosis, however, only arises in those exceptional cases of pseudo-hypertrophic paralysis in which the muscles are wasted and when there is no history of antecedent enlargement. Under such circumstances, confusion is apt to arise between this disease and various forms of muscular atrophy of spinal and idiopathic origin. In infantile paralysis, the sudden invasion, the acute wasting, the electrical reactions and the distribution of the paralysis, are the main distinguishing characters. In other forms of atrophy from spinal disease, the seat of the paralysis, the altered reactions to electricity, and the frequent implication of the muscles of the hand, are usually sufficiently distinctive. In the disease known as "idiopathic muscular atrophy," believed by many to be allied to pseudo-hypertrophic paralysis, several members of the same family are often affected, there is no antecedent enlargement of muscles, and the muscles of the face are sometimes affected.

Morbid Anatomy and Pathology.—After death the muscles are found pale or yellowish, and often appear to be replaced by fatty tissue. Under the microscope an abundant nucleated fibrous tissue, usually with an excessive amount of fat, is seen between the muscular fibres. Adipose tissue may however be scanty or absent, especially in the late stage, and occasionally even throughout the disease. The muscular fibres at first present no marked changes. Later on they become narrow and irregular. The transverse striation often persists until an advanced stage, though occasionally, even in the early stage, it is faint here and there or the intervals between the striæ are wider than normal. Eventually, the fibres may become granular or fatty, finally dwindling until nothing is left but empty sarcolemma sheaths. The destruction of the muscular fibres is said to be more general when the interstitial tissue is almost entirely fibrous. Many normal fibres are seen in those muscles in which there is an abundant amount of interstitial adipose tissue. The motor nerves have always been found normal. In a few instances changes have been described in the spinal cord. It is now, however, admitted by nearly all authorities that the disease is a primary affection of the muscles, and that the wasting of the fibres is due to an interstitial growth.

Ætiology.—Males are much more fre-

quently affected than females, the proportion being about six of the former to one of the latter. The disease is often noticed shortly after the child begins to walk. In the great majority of cases the onset occurs before the age of ten, but a few cases have been recorded in which the disease began in adult life. Several members of a family are often affected, and, as in hæmophilia, the disease is always transmitted through the mother, although she is not herself affected with it.

Treatment.—Various drugs have been recommended, such as arsenic, phosphorus, strychnine, and cod-liver oil, but these remedies have little influence over the course of the disease. Friction, massage, passive movements, gymnastics, have sometimes been used with advantage. Duchenne strongly recommended the faradic current, which is especially effective in the early stages. When the calf-muscles become so contracted that the patient is unable to stand, division of the tendons should be performed. Great care should be exercised to guard the patient from intercurrent maladies, especially of the respiratory organs.

W. B. HADDEN.

PSORIASIS (Lepra; Dry Tetter).—

A chronic inflammatory disease of the skin, characterized by the presence of silvery white scales adherent to and covering dry, reddish, primarily rounded, raised patches. It occurs chiefly on extensor surfaces and is very prone to relapse.

Eruption.—The disease begins as minute red papules which rapidly become surmounted by pearly scale (*P. punctata*). These spread peripherically and soon resemble drops of mortar (*P. guttata*); when they attain the size of a coin, the name *P. nummularis* has been applied to them. By coalescence of these, larger patches are produced (*P. diffusa*), the outline of which is festooned, convex outwards. Recovery begins in the centre of the patches causing a ringed appearance (*P. circinata*), composite patches thus assuming serpiginous outlines (*P. gyrata*). The patches are always distinctly raised, and in old-standing cases are often markedly so; they are well defined and sometimes form a distinct rim outside the scale. Their colour is at first a vivid red, but afterwards it becomes duller and brownish. Pigmentation is often very deep—like that of Lichen planus or dermato-syphilis—in very chronic cases, in cases treated

freely with arsenic and in lesions situated below the knee. The scales are most abundant and most typical in recent patches; they are pearly white, lustrous, dry not greasy, and are easily separable from the subjacent raised patch, the surface of which presents numerous small, reddish points, from which a little blood may ooze, but which never discharge serous fluid. In a variety of the disease, to which the name of *P. rupioides* has been given, the scales are excessive in quantity and piled up like the shell of a limpet, but confusion with syphilitic rupia is, after careful examination of all the features of the disease, hardly possible. Itching is a frequent but by no means invariable symptom of the disease. As a general rule, its severity is proportional to the acuteness of the inflammatory process, and it is seldom so troublesome in the young, as in old, possibly gouty, persons.

The *Sites of Election* are the fronts of the knees, just below the patellæ, and the tips of the elbows, in both of which situations patches may persist for years, before a general outbreak occurs over the body, or between such outbreaks. Generally speaking, extensor surfaces are far more prone to be attacked than flexor surfaces, and the eruption as a rule presents remarkable symmetry. The scalp is a frequent seat of the affection; the circular outline of the patches there is generally masked by surrounding seborrhœa, but if the disease spread to the forehead or behind the ears, as it often does, its nature is revealed. On other parts of the face it is rather rare. Patches often occur on the trunk, especially on the front of the chest and over the sacrum, particularly in the psoriasis of advanced life, in which the distribution is often asymmetrical, scaling inconspicuous and itching excessive (Liveing). The scrotum and penis are seldom involved: very rarely, also, the palms and soles. So-called *palmar psoriasis* is almost always a dry eczema or squamous syphiloderm; a few cases of true psoriasis of the palms and soles have been observed, and there seems some reason to think that it is specially liable to become the starting-point of a pityriasis rubra, or, after having become "verrucose," to develop malignant, epitheliomatous characters. When psoriasis affects the nails they become opaque, thickened and brittle, the matrix beneath being much heaped up; the condition is specially intractable. Occasionally the distribution appears to be determined by

pressure, e.g., of garters, or by previously existing skin lesions, such as the scars left by varicella.

The *course* of the disease is essentially a very chronic one; its tendency to recur, sometimes after perfect recovery and at regular intervals, varying in different cases, is very marked, and must compel one always to give a guarded prognosis. The occasional supervention of general pityriasis rubra even in mild and localized cases must also be borne in mind.

The *diagnosis* is seldom a matter of difficulty, but an ill-developed or abnormally distributed eruption, or one under treatment of any sort, may be mistaken for one of the following diseases—viz., dermatosyphilis, lichen ruber, chronic dry eczema, pityriasis rubra, ichthyosis, lupus erythematosus (of the face), tinca tonsurans or seborrhœa (of the scalp), pityriasis rosea. Into the several points of differential diagnosis it is here impossible to enter.

Morbid Anatomy.—The pathological changes begin in the rete Malpighii, where rapid cell-formation occurs, resulting, on the one hand, in enormous increase in the cells of the upper horny layers of the epidermis, from premature conversion and imperfect cornification of the rete cells, and on the other, in increased development of the rete layers, except over the papillæ. The result is great downgrowth of the inter-papillary processes, with consequent hypertrophy, congestion, œdema and diapedesis. The upper part of the corium, especially round the hair follicles and sweat-ducts is also the seat of moderate inflammatory changes, almost certainly secondary to those in the rete. In very chronic cases the deeper layers of the corium may become involved.

Ætiology.—Very little is really known of the ætiology of psoriasis. Heredity is certainly the most powerful factor. Whilst generally appearing in persons in perfect health, it not infrequently attacks those suffering from lowering conditions, e.g., pregnancy, lactation. On the other hand, plethora may produce it, and alcoholism certainly generally aggravates it. Spring and autumn seem more favourable for its appearance than summer or winter. Psoriasis is very rare before the age of five years. Whether or not the psoriasis of advanced life is to be attributed to gout or "the gouty condition" is a subject of dispute. The arguments *pro* and *con* appear to the writer about equally balanced, nor does his personal

experience justify any decided expression of opinion upon his part. Of course, micro-organisms of a supposed specific nature have been found in the scales, but some few clinical facts and inoculation experiments reported from Germany which seem to support this view of the ætiology of psoriasis, have been received with scepticism in this country.

Treatment ought to be both constitutional and local, many cases in which subjective symptoms are absent and local remedies not employed, yielding readily to the former alone. Any marked derangement of the general health (anæmia, plethora, dyspepsia, constipation or gout) must be dealt with in the ordinary way. Among drugs considered as specific, arsenic holds the first place, and it certainly exerts a potent influence over the disease; it must, however, be used with due caution and full knowledge of the limitations of its applicability. It is unsuitable, even deleterious, in acute, inflammatory cases, and, generally speaking, is more useful in psoriasis of the young than of the old. It ought never to be prescribed unless the tongue be clean, and the digestive functions in order. Then it may be administered in small doses at first, rapidly increased until the maximum dose is attained, individual susceptibility varying greatly as to its tolerance. Itching of the eyelids, diarrhœa, gastric pain or uneasiness are indications to diminish the dose; bronchial catarrh is certainly a frequent result of its administration, but there is some doubt as to the asserted frequency of the development of herpes zoster during its use. The deep pigmentation of the patches produced by its prolonged employment has already been alluded to. The liquor is the preparation most generally employed, usually in combination with alkalies and a bitter infusion, but arsenious acid (gr. $\frac{1}{30}$ or more) and arseniate of soda (gr. $\frac{1}{12}$ or more), are perhaps equally efficacious and may be conveniently prescribed in pill form with sugar of milk and compound tragacanth powder. Arsenic is always best given after meals accompanied by a copious draught of water; opium may be combined with it to prevent or counteract gastric irritation. Hebra's well-known "Asiatic pill" is seldom borne by the English stomach. Antimonial wine is sometimes of use when liq. arsenicalis disagrees.

Carbonic acid internally (gr. j to gr. iij in pill) is occasionally of value, and oil of turpentine has lately been highly

lauded by Dr. Crocker. He gives from 10 to 30 minims with 2 minims of oil of lemon in half an ounce of mucilage of acacia and of water, immediately after meals, three times daily, the last dose not later than 6 P.M., and directs that during treatment at least a quart of barley water be drunk daily.

In strumous persons cod-liver oil and iron are of special service, and with them arsenic may be easily and conveniently combined, a liberal diet being allowed. In gouty conditions colchicum, iodide of potassium, and alkalies may be prescribed with advantage, and due dietary restrictions must be observed. In such cases vegetarianism is sometimes attended with the best results. In inveterate cases a prolonged stay at La Bourboule, Buxton, Harrogate, Strathpeffer, or Kreutznach may prove efficacious.

Local treatment is, however, necessary in the great majority of cases, and may, of itself, prove curative, although, of course, in no sense preventive of future relapses. Acute outbursts must always be treated by perfect rest, the affected parts being covered with rags soaked in olive oil or calamine liniment. It is also important to remember that psoriasis in advanced life is much more liable to be irritated by stimulating applications than in early life.

If the disease be chronic the first condition necessary for the successful application of local remedies is the removal of all scales. Hebra's method, of rubbing in soft soap vigorously until all crusts are removed and some bleeding produced, is unnecessarily severe and by no means more successful than prolonged bathing, say for half an hour or more, every night and morning in a warm alkaline bath containing about three ounces of carbonate of potash; the body ought to be well soaped afterwards and friction with a soft towel employed. For the scalp a shampooing liquid, consisting of equal parts of soft soap and alcohol (Hebra's spiritus saponis kalinus), is especially applicable for the same purpose.

Afterwards stimulating applications are suitable, the most frequently employed being the preparations of tar. It is also advisable to use them at first over a limited area and dilute, their strength being gradually increased according to the tolerance of the patient and the amount of stimulation necessary. The official unguentum picis liquidum is a powerful but disagreeable remedy, and other more elegant preparations are now generally employed. Liquor carbonis

detergents may be painted on to very chronic patches with a hard brush, may be used dilute (5j ad 3vj) as a lotion, or combined with lard, lanolin, vaseline, or other convenient vehicle as an ointment. The oleum rusci, oleum cadini, and oleum fagi—in strength varying from 5ss to 3iv ad 3j—are also excellent. Naphthol and thymol (5j or more ad 3j) are useful, either in ointments or lotions, to allay itching.

The red oxide of mercury ointment is often very efficacious, especially for the scalp and exposed parts, as it causes no disfigurement, and the other mercurial ointments have some value as stimulants. Chrysarobin is certainly the most powerful local remedy we possess against psoriasis, but it requires careful watching, and should always be applied over a small patch at first, as it is apt to cause severe dermatitis. It also has the disagreeable property of staining the skin, clothes, and everything with which it comes in contact a bright yellow. It may be used in the form of the official ointment, but is more efficacious, less dangerous, and not at all dirty when a ten per cent. or stronger solution in traumaticine is painted over the part—traumaticine being a ten per cent. solution of gutta percha in chloroform. Unna's chrysarobin mull-plasters may also be used with advantage in some localised cases.

A somewhat similar remedy is pyrogallie acid, which is much used, but causes conspicuous black discoloration. It is employed as Jarisch's ointment (gr. xx to 3j ad 3j); its absorption sometimes gives rise to hæmaturia and other toxic symptoms.

Localized excessive thickness of scale may be removed by salicylic acid in collodion (gr. xx ad 3j).

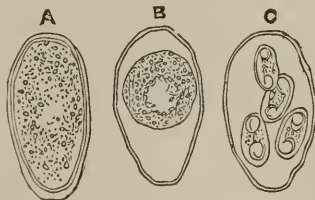

Finally, wrapping the part affected—if limited—in an elastic bandage or other form of impervious india-rubber covering is often of itself curative.

J. J. PRINGLE.

PSOROSPERMIA.—It has long been known that rabbits are liable to a disease which often assumes epidemic proportions in warrens. Its chief clinical symptoms are the following:—The animals are noticed for some weeks to be sickly, to become thin, and to lose their activity and appetite; breathing is quick and violent, convulsions set in, and are followed by death. On examining rabbits dying in this way the liver will be found dotted with small white nodules, varying

in size from a mustard seed to a hazel nut, but they rarely exceed the dimensions of a split pea. Adjacent nodules may be connected by bands of tissue resembling cicatrices. The nodules are especially abundant beneath the serous membrane, but they also occur in the substance of the organ and in a well-marked specimen the cut surface of the liver will present numerous white dots. This circumstance induced some writers to describe the nodules as tubercle, others regarded them as cancer. To Leuckart we are indebted for the discovery of their true nature. When a piece of liver containing such nodules is hardened and sections prepared for the microscope, we find that they consist of dilated bile-ducts. The walls of the central cavity are lined by epithelium and processes often project from the lining membrane into the cavity, giving it a villous appearance. The true lining of the cavity is separated from the liver substance by a capsule of dense connective tissue. The interior of the nodule is occupied by a multitude of oval bodies, known as *coccidia oviforme*. The coccidium is described by Leuckart as egg-shaped, 0.033 to 0.37 mm. long and 0.015 to 0.02 mm. wide, with thick smooth shells, possessing at one end, usually the narrower, a micropylar opening. The coccidia resemble very closely the eggs of certain entozoa; some observers regarded them as the eggs of *Distoma lanceolatum*, some still believe them, not without reason, to be the eggs of parasites. Leuckart rejects this view and describes them in their early stages as non-capsuled inhabitants of the epithelial cells of the bile-ducts. This is very questionable. As the coccidia develop they become invested with a tough membranous capsule. At first they are filled throughout with granular material as Fig. 1, A; at a later

FIG. 1.

Coccidium oviforme in its various stages.

stage this becomes collected into a ball, as in B. This change is probably accompanied by an alteration in their composi-

tion, for in the early stage A they stain with methyl violet, whilst stage B stains best with fuchsin. Staining with any material is a matter of difficulty, on account of the thickness of the capsules. The coccidia undergo no further change in the tissues; they may escape from the bile-ducts into the intestines and be thus evacuated. In the rabbit the escape from the bile-duct is rendered possible by the fact that the cavities in the various nodules are connected by intervening passages. After escaping from the rabbit either by accidental expulsion, or, more commonly, when the animal dies, the coccidia, after a period of incubation varying from a few days to several weeks (the difference in time depending on temperature and the nature of the medium), undergo metamorphosis and the capsule is found to contain four ovoid spores, or psorosperms as they are sometimes called, Fig. 1 C. At this stage the spores so strongly resemble the pseudo-navicellæ of an encysted Gregarine that many have been content to regard coccidia as Protozoa. The shells of the coccidia possess considerable power of resistance, and it has been found that when placed in preservative and hardening media such as weak solutions of chromic acid and Müller's solution, development proceeds as usual, and even seems to be carried on with more vigour than when simply placed in water.

The term psorosperm seems to have been introduced by J. Müller, *Archiv*, 1841. "Ueber eine eigenthümliche krankhafte parasitische Bildung mit specifisch organisirten Samenkörperchen" (Psorospermia). The derivation of the term is obvious, for the parasitic disease about which Müller wrote affects the gills, skins, and muscles of fish and frogs as well as the kidneys and bladder. The Greek word, $\psi\omicron\rho\alpha$ or $\psi\omicron\rho\eta$, signifies a cutaneous disease, the itch, scab, or mange, and its Latin equivalent is *scabies*. The French use the word *Psore* as a generic title for vesicular and pustular maladies of the skin. The skin disease of fish and frogs described by Müller consisted of small sacs containing oval bodies, some of them with and some without tails, hence he termed them psorosperm-sacculi.

To return to the coccidia, whatever they be, whether immature forms in an intermediate host or Gregarinidæ, they are the cause of this destructive disease of the rabbit, and are so frequent among them, that out of five hundred rabbits imported from Holland for dis-

section purposes sixty to sixty-six per cent. had an abundance of coccidium nodules in the liver.

This disease occurs in other mammals and in birds; it is occasionally seen in the human subject. One of the earliest cases was recorded by Gubler in 1858. The patient, a stone-breaker forty-five years of age, suffered from disordered digestion, bad appetite, sour stomach, and anæmia. He had a dull pain over the liver, and was of cachectic appearance. The liver was enlarged, and a spherical tumour could be made out in the neighbourhood of the gall-bladder. The anæmia increased; the man had violent pain in his body, fever, feeble pulse, bilious vomiting; collapse and death followed a night of delirium. At the post-mortem examination the immediate cause of death was found to be peritonitis. The liver contained twenty tumours, some of the size of chestnuts, others as big as an egg. The large tumour felt in the liver during life was about 15 cm. in diameter. The encapsulated tumours contained thick fluid of greyish-brown colour, containing countless egg-like bodies, which are now known, thanks to Leuckart, to be coccidia. Gubler (*Mém. Soc. Bio.* 1858) regarded these bodies as the ova of *Distomum* (liver-fluke). The brief history of this case is sufficient to show that the symptoms induced by coccidia in man are similar to those displayed by the affected rabbits.

Cases in man similar to the one described by Gubler have been reported in Germany by Dressler, Perls, Eimer, and others. One of Perls' cases was a preparation from Sömmerring's collection at Giessen. The earliest case recorded in our home literature is described by Dr. Hadden, in the *Transactions of the Pathological Society*, vol. xxxiv. (1883), under the title "A Case of Disseminated Sarcoma." This, in the light of subsequent events, we know to be a fatal instance of psorospermia. Its chief features are briefly these:—A gentleman thirty-eight years of age had long complained of occasional pain in the region of the heart. When admitted into St. Thomas's Home he was dull and heavy, with slight occasional elevations of temperature; the drowsiness and dullness increased, followed by low muttering delirium and partial unconsciousness, ending in death. The case was under observation fourteen days. At the post-mortem examination the visceral and parietal layers of the pericardium were

found dotted with numerous slightly raised round white nodules of new growth. Similar nodules existed throughout the muscular substance of the heart and endocardium; the valves were free. The parietal layer of the pleuræ, both surfaces of the diaphragm, mesentery, and omentum were dotted with nodules. The liver and spleen contained several sub-capsular deposits; a few existed in the substance of these organs. Similar nodules were found in the kidney, in the arachnoid and convex surfaces of the brain. The nature of the case was detected by Dr. Cobbold, to whom the Morbid Growths Committee submitted sections of the nodules. Cobbold pronounced them to be psorospermial sacs.

In 1889 Mr. Eve exhibited at the Pathological Society, London, a specimen of psorospermia of the ureter and kidney from a woman aged fifty-one years who was taken suddenly ill. The chief symptoms were hæmaturia and frequent micturition. Death took place from anæmia and exhaustion on the seventeenth day.

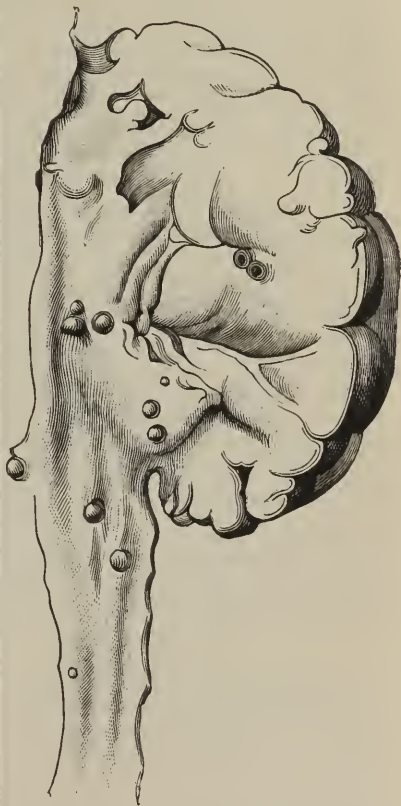

The general appearance of psorospermial saccules in the ureter may be gathered from Fig. 2, taken from a specimen in the museum of the Middlesex Hospital, where it has long been preserved as an example of mucous cysts of the ureter. The parasitic nature of the nodules was suspected by the writer of this article, and on submitting them to microscopical scrutiny they were found to contain coccidia; a few of the nodules were calcified. Mr. Targett has detected in the museum of Guy's Hospital a similar specimen from a young man aged thirty years who was under Dr. Bright's care fifty-three years ago.

As yet we are imperfectly acquainted with the clinical symptoms of psorospermial affections of the ureter. In addition to the functional disturbance they set up, they may produce mechanical effects, for Dr. Joseph Griffiths, of Cambridge, has met with a case in which these nodules in the ureter induced hydronephrosis.

By far the most complete case of psorospermia yet described in Great Britain is one reported by Mr. Q. Silcock. A woman aged fifty-three years was admitted to St. Mary's Hospital seven days before death. She was thought to be possibly suffering from typhoid fever. The illness dated from a chill taken seven weeks before death. The symptoms consisted in pains in the limbs, nausea, and occasional sickness, tenderness over the liver

and spleen, fever of remittent type, the temperature reaching 103° , and slight diarrhoea. The urine was albuminous; the splenic and liver dulness increased; the tongue coated with brown fur, becoming dry; the breath foul. Death resulted from cardiac failure. The liver was much enlarged, weighing eighty-three ounces. In its substance were a

FIG. 2.

Portion of a kidney and ureter showing nodules due to *Coccidium oviforme*. (From the Museum of the Middlesex Hospital.)

number of aggregations of caseous foci, for the most part near the surface, there being generally a well-marked red ring of congestion or capillary hæmorrhage around each caseous area. The spleen was enlarged, weighing sixteen ounces, and exhibited similar caseous foci varying in size from a pin's head to that of a pea, arranged in aggregations, and with

a red inflammatory zone around each nodule. In the ileum were found six papule-like elevations, with red bases and circumferential inflammatory zone; also in the large intestine, as well as in the ileum, were red patches of infected mucous membrane, from one to three inches square. A small pneumonic area existed in the anterior border of the left lung; the other organs and tissues presented no noteworthy change, except those associated with fever. The macroscopic appearances to a certain extent resembled those of tuberculosis, but differed in the character, situation, and generalisation of the lesions. On microscopic examination the nodules were found to contain coccidia, and in their relation to the bile-ducts corresponded to the disease as seen in rabbits.

These constitute all the cases of psorospermia in man which have been recognised in this country.

There is reason to believe that psorospermial infection is not confined to internal organs, for M. J. Darier gave in the *Annales de Dermatologie et de Syphiligraphie*, 25 Juillet 1889, under the title "De la Psorospermose folliculaire végétante," reasons for the belief that man is liable to certain cutaneous affections due to the presence of psorosperms and coccidia. These parasites may invade the orifices of the follicular ducts of the skin, and, by their accumulation, plug the orifices of the follicles. Among other things, Darier thinks that chronic eczema of the nipple and molluscum contagiosum may be due to this cause. These statements are very suggestive, and require thorough investigation.

J. BLAND SUTTON.

PTOMAINES (Animal Alkaloids).—Alkaloids produced by the decomposition of animal substances.

The word *ptomaine*, which is derived from *πτῶμα*, a corpse or dead body, and *inus*, belonging to, was at first restricted to alkaloids produced by cadaveric decomposition, but it is now also employed to designate alkaloids of animal origin formed during life as a result of chemical changes induced by some agency or other acting within the organism.

The term *leucomaine* has recently been introduced to particularise the animal alkaloids formed during life from those produced by decomposition of dead animal matter; it is probable, however, that in the near future the terms *ptomaine* and *leucomaine* will be dropped,

and that these bases of animal origin will be classed in one category as *animal alkaloids*.

It is only within the last few years that the existence of the ptomaines has become known. In 1866, Dupré and Bence Jones found an alkaloidal substance, resembling quinine in some of its properties, in the liver. In 1868, Bergmann and Schmiedeberg obtained from putrid beer a nitrogenous crystalline substance, which they called *sepsine*, and which was subsequently thought to be present in septicæmic blood. In 1870, Gautier commenced his researches on putrefying albuminous substances. In 1877, Selmi announced that by subjecting pure albumen to putrefaction he had been enabled to produce and separate two new alkaloids. Since then, Gautier has made a series of elaborate and prolific researches, as the result of which several animal alkaloids have been discovered.

Creatinine, xanthine, hypoxanthine, guanine, carnine and betaine, all genuine alkaloids, were found in the tissues of animals or in their excrementitious products. Creatinine, discovered in urine by Liebig and Pettenkofer, was the first body of animal origin acknowledged to be an alkaloid. Later on, Liebrich detected the already known vegetable alkaloid betaine in normal urine. In 1880, Pouchet detected carnine in the urine of man, and this was confirmed in 1881 by Gautier, who showed that it possessed the general properties of a ptomaine. In 1882, Bouchard demonstrated that not only were alkaloids present in appreciable quantities in normal urines, but that they augmented notably in the course of certain maladies, typhoid fever for instance; and later, Lepine and Aubert concluded that these alkaloids in the urine increase in quantity until the crisis of a disease is reached, after which they diminish (no alkaloid was isolated in connection with any disease in sufficient quantity or sufficiently pure to admit of its ultimate composition being determined). It has also been shown that in the course of uræmia there is a notable increase of creatinine in the urine. Since 1882, Gautier, as the result of his investigations, has affirmed, that the incessant production of alkaloids at the expense of albuminoid materials is a function of all the animal tissues, and is an essential concomitant of the vital phenomena of all living things, animal and vegetable.

The following ptomaines have been ex-

tracted from human corpses and their composition determined by analysis:—

Putrescine ($C_4H_{12}N_2$).

Cadaverine ($C_5H_{16}N_2$).

Neurine ($C_5H_{13}NO$).

Choline ($C_5H_{15}NO_2$).

Putrescine and cadaverine have also lately been found by Jauksch in fæces.

The following is a list of the principal animal alkaloids that have been extracted from the secretions of living beings, and from animal tissues:—

Creatinine ($C_4H_7N_3O$).

Pseudoxanthine ($C_4H_5N_3O$).

Sarkine ($C_5H_4N_4O$).

Xanthine ($C_5H_4N_4O_2$).

Crusocreatinine ($C_8H_8N_4O$).

Xanthocreatinine ($C_8H_{10}N_4O$).

Guanine ($C_5H_5N_5O$).

Carnine ($C_7H_8N_4O_3$).

Betaine ($C_5H_{11}NO_2$).

Some of these alkaloids are toxic, inducing somnolence, purgation and vomiting.

Animal alkaloids have also been detected in the liver, brain, heart, lungs, spleen, and saliva of man. The poisonous effects of certain shell-fish (mussels, &c.) have been shown by Brieger to be due to a ptomaine which he has named *mytiloxine* ($C_6H_{15}NO_2$).

The animal alkaloids that are being incessantly produced within our bodies as a result of the normal physiological processes of life are eliminated by the bowels, kidneys, liver, skin and lungs, but if from any cause these eliminating organs fail to perfectly fulfil their excretory functions, then an accumulation of these alkaloids in the circulation occurs, and a toxic action is exerted by them on the nervous centres. In this way can be explained the headache resulting from constipation, and the more serious nervous symptoms resulting from deficient excretory action of the kidneys in certain diseases of those organs. But it is not only on the excretory organs that the removal of these animal alkaloids depends, for a powerful agent is at work, in the oxygen of the blood, which is continually oxidizing them and burning them up, and it seems probable that this combustion, to a large extent, occurs in the liver.

If, the emunctories remaining sound, there be excessive production of animal alkaloids, but inadequate elimination—a condition which is obtained in all forms of over-exertion, as in a prolonged march—then accumulation of material, elaborated in excess and imperfectly eliminated, occurs, an auto-infection, a temporary poisoning of the system results,

the poison affecting the nervous centres and producing the fever of over-exertion, the fever of prostration.

With regard to the possible relation of the ptomaines to the infectious fevers, one view is, that after the admission of the specific micro-organisms into the body, and provided they find the conditions suitable, they live and multiply, and that, as a result or as a residuum of their vital activity, a powerful alkaloidal poison is produced, the toxicity of which is the cause of the symptoms of the disease. If this view be correct, then each infectious fever is the result of a fermentative decomposition of albuminous matter within the body, induced by a special micro-organism manufacturing its own peculiar poison for each disease. But in many non-contagious diseases it seems probable that, without the intervention of micro-organisms, abnormal chemical changes may result in the formation of poisons which exert a toxic influence on the body within which they are produced.

The facts and experiments that can be brought forward in support of these views are necessarily, at the present time, meagre, but they are suggestive. Pouchet has extracted from the fæces of a cholera patient an alkaloidal body, which injected into animals produces slowing of the heart, and later, death, followed quickly by rigor mortis. The same author, and also Nicati and Rietsch, have obtained from cultivations of Koch's cholera bacillus traces of an alkaloid which appeared to be identical with the preceding one. Again, from cultivations of the typhoid bacillus Brieger obtained a small quantity of a poisonous alkaloid that he calls *typhotoxine*, and which yielded reactions different from the alkaloids he had previously isolated from putrefying animal matters. Quite recently Dixon Mann has extracted from the abdominal and thoracic organs of a patient dying of typhoid fever during the third week of the attack, an alkaloid which, however, differed in some of its reactions from the typhotoxine of Brieger. Dixon Mann has also extracted from the organs of a patient dying of septicæmia, of unknown origin, a small quantity of an alkaloidal poison. Brieger from cultivations of the tetanus bacillus extracted four ptomaines, all of which when injected into mice produced tetanus. Lastly, and most recently, the writer has extracted from the urine of typhoid-fever patients a ptomaine, and also one from the urine of scarlet-fever patients. Both of these ptomaines are

absent from normal urine, and in their properties and reactions they differ from any previously known ptomaine.

ARTHUR P. LUFF.

PTOSIS.—A drooping of the upper eyelid and inability to raise it, from paralysis of the levator palpebræ superioris. It is seldom so complete as to conceal the whole of the eyeball. In the majority of cases, when the lid is raised the pupil will be found dilated and the eyeball turned outwards, the whole being due to paralysis of the third nerve. Partial drooping may be caused by chronic inflammation of the lids (granular lids), or it may be the result of a blow, and is then usually transient, or it may depend upon paralysis of the sympathetic nerve in the neck. It is often congenital, and is then commonly bilateral (see **FOURTH NERVE, DISEASES OF**; **THIRD NERVE, PARALYSIS OF**).

PUERPERAL FEVER (Metria).

—A severe and generally fatal febrile disease occurring after delivery. The term "metria" has been proposed and adopted by the Registrar-General as equivalent to it, and is less open to objection. Many different theories have been held as to its nature, and still find defenders. Before describing what puerperal fever is, it will conduce to clearness to state what it is *not*.

1. It has been, and still is, maintained that puerperal fever is a *specific disease*, peculiar to lying-in women, not occurring in any other subjects. This view now has very few supporters, and their number is diminishing.

2. It is thought by some, that many cases of puerperal fever are due to the poison of *zymotic diseases*, more especially *scarlet fever*, which, when introduced into the body of a lying-in woman, produces a peculiar disease closely resembling septicæmia, and, indeed, not to be clinically distinguished from it. The evidence adduced in support of this view, consists of cases of illness resembling septicæmia, in which, after the illness, a search for some way in which the patient might have been infected with septic poison, resulted in failure to discover it; while inquiry directed to finding a possibility of infection from a scarlatina case, revealed some way in which this might have happened. It is concluded, from such cases, that the illness was due to scarlatina, and could not have been ordinary septicæmia. It will be seen that, for the validity of this

argument, it must be assumed that if a source of septic infection was not found, none existed. It is not possible to assert that this is the case, and, therefore, arguments based on such cases are far from conclusive. Against them there is the evidence of epidemics of scarlatina observed in lying-in hospitals in which proper precautions against septicæmia were taken. In these epidemics, the only illness scarlatina produced in lying-in women, was a disease differing in no important respect from scarlatina in other persons. The conclusion follows that the cases in which scarlatina was supposed to have produced septicæmia, were either cases of ordinary septicæmia or of scarlatina complicated with septicæmia. *Scarlatina produces in lying-in women scarlatina and nothing else.*

3. Many observers think that there is a close connection between *erysipelas* and puerperal fever. They have undoubtedly this in common, that the propagation of each disease is favoured by bad ventilation and uncleanness: and therefore, in places, and at seasons, when these conditions occur, these diseases, if once introduced, are apt to spread, and thus the apparent epidemic prevalence of the two is likely to coincide. The question of their relationship has been rendered obscure by the fact that under the term "*erysipelas*," two diseases have been included, which modern research has shown to be different from one another; and one of these diseases produces a form of puerperal fever, the other does not. One of these diseases is called "simple" or "cutaneous" *erysipelas*. It affects the skin only; is transmitted by contagion through the atmosphere; is characterized by redness of the skin with a distinct margin; and is produced by a definite microbe (the *erysipelas coccus* of Fehleisen), which is found in the lymphatic vessels of the skin at the advancing edge of the disease, but seems to be destroyed in the morbid process, for it is not found in the parts where the disease is older. This disease, when given to puerperal women, produces the same symptoms, and runs the same course, as in non-puerperal patients. *Simple cutaneous erysipelas produces in puerperal women erysipelas and nothing else.* The other disease is called "cellulo-cutaneous" or "phlegmonous" *erysipelas*. This affects the cellular tissue, and not the skin only. It is not produced by atmospheric contagion; the redness of the skin has no defined edge; the diseased parts contain micrococci which

are different from those of cutaneous erysipelas, and are found in all parts affected by the disease, and not at the advancing edge only. This disease may occur in puerperal women, and is one of the diseases classed under the term puerperal fever.

4. Puerperal fever has been ascribed to epidemic influences, that is, to an atmospheric or telluric influence or contagion, such as produces epidemics of smallpox, scarlet fever, influenza, &c. But examination of mortality records shows that epidemics of puerperal fever are unknown. This disease is present at all times of the year, and in about the same frequency at each season. It is slightly more common in winter and spring, when variable weather leads to neglect of ventilation.

5. Among causes to which particular cases are often assigned, are the following: chills, grief, excitement, shame (in the case of unmarried mothers), blood changes, such as hyperinosis, hydræmia, suppression of milk, deficient excretion, &c. All these causes occur just as often in lying-in hospitals where antiseptics are used as they do anywhere else, but in these hospitals they are not found to cause fever.

All accurate knowledge of puerperal fever dates from the time of Semmelweis, who, in 1847, showed that puerperal fever was caused by inoculation of the patient with decomposing organic matter, and that by taking precautions to prevent such inoculation, puerperal fever could be prevented. At that time, the influence of micro-organisms in causing the decomposition of organic matter was not known. Since then, the researches of Pasteur and Sir J. Lister have carried our knowledge further, and we now know that puerperal fever is due to the access to the patient of certain micro-organisms. The precautions introduced by Semmelweis were very rough as compared with those now in use, and therefore, some cases of fever occurred in spite of them. Semmelweis supposed that these patients infected themselves, and he therefore divided cases of puerperal fever into two classes, those infected from without, and those self-infected. These terms, translated into Greek, appear in some text-books of to-day as "heterogenetic" and "autogenetic." This classification is a delusive one, because (1) all our present knowledge goes to show that there is no such thing as self-infection; (2) if there be, we cannot in any way distinguish an

"autogenetic" from a "heterogenetic" case, and (3) if we could, it makes not the slightest difference in treatment or in prognosis. It may therefore be confidently stated that *puerperal fever is a wound disease*.

In the process of parturition, the cervix uteri, the vagina, and the vulva, are often, indeed usually, torn. The same diseases may result from these wounds, as result from wounds elsewhere. The wounds caused in parturition are more likely to become the seat of diseased processes caused by microbes than wounds of similar size elsewhere, because they are bathed with the copious lochial discharge which offers a fertile soil for the multiplication of germs. The wounds of the vaginal orifice are probably those through which poison generally gets into the blood. The researches of bacteriologists show that the secretions in the lower part of the vagina always contain abundance of microbes, the secretions in the uterus usually none, and those in the upper part of the vagina very few. It will be evident that, if decomposition of the lochia take place, this process will be most advanced in the lochia lying in the lower part of the genital tract. Clinically, it is found that syringing the vagina is, as a rule, enough to keep the secretions healthy; it is but seldom necessary to wash out the uterus.

The diseases which affect wounds of the genital passage received in delivery are the same which affect wounds elsewhere. Certain morbid states of the wounds themselves must be first described.

1. So-called "diphtheritic" ulcers.—An unhealthy condition, in which the wound becomes covered with a whitish or greyish pellicle, whilst the healthy discharge of pus ceases, and is replaced by a slight serous exudation, is known by this name. The surrounding tissues are swollen and reddened, and healing ceases. The pellicle is a superficial slough, and contains abundance of micrococci. Febrile disturbance is always present. It is to be regretted that the adjective "diphtheritic" should have been applied to this and the following condition, for they have no relation to true diphtheria. This disease, before the introduction of antiseptics into midwifery, was quite common in lying-in hospitals, at least in those of Germany, so that this state of laceration of the vaginal orifice has been given the name of "puerperal ulcers." In this country, at least in private practice, it is rare, but the writer has seen it. It ought never to be met with, for it can

be prevented by antiseptic precautions. The *treatment* is to dust the unhealthy surface of the wounds with iodoform, and to syringe the vagina twice daily with a 1 in 2000 solution of corrosive sublimate.

2. Diphtheritic Inflammation.—In some cases the disease reaches a greater degree of severity. There is not merely the greyish pellicle over the wound, and inflammation around, but the ulcer spreads by molecular sloughing of its edges. There is a higher degree of fever and greater prostration. This condition is identical with the disease known as hospital gangrene, or phagedæna. It is scarcely ever seen except in badly managed lying-in hospitals; and as it can be prevented by antiseptics, it ought never to occur.

The *treatment* is to anæsthetize the patient, clean away the slough, wash away all discharges, and freely mop every part of the ulcerated surface with strong nitric acid, and then use vaginal injections of 1 in 2000 corrosive sublimate, twice daily.

3. Spreading Traumatic Gangrene.—This is a still more formidable condition, attended with high fever, and with, at first, redness and swelling round the wound. The redness becomes dusky, then purple, then black, till the tissues are converted into a black pulpy mass, and the gangrene which follows spreads with great rapidity. The decomposition of the gangrenous tissues leads to the evolution of gas, so that there is emphysematous crackling, and, when cut into, gas escapes. The general symptoms are those of septic poisoning with great prostration. This is rare as a puerperal disease, but the writer has known it spread from a tear in the perineum. It is to be prevented by antiseptics. When it has commenced, treatment is hopeless. Sloughing of small tags of tissue killed by the bruising and tearing to which the parts are exposed in parturition, is common, and if antiseptics are used, leads to no harm.

There may be not only the unhealthy state of the wounds of the vaginal orifice which have been described, but similar conditions higher up. The tears of the cervix may show the same appearance as those in the vulva. The inner surface of the uterus is covered by what looks like a diphtheritic false membrane. When this is stripped off, the uterine muscle is found bare, swollen, and presenting points of suppuration; and in section, venous and lymphatic channels are found filled with pus. In

some cases the inner surface of the uterus is converted into a greyish brown sloughing mass. The signs are often especially marked where the broad ligaments leave the uterus.

The inflammation may be found to have spread along the cellular tissue of the broad ligaments, which are swollen, spongy and infiltrated with sero-purulent fluid. In slight cases the poison causing the disease may be stopped by the lymphatics, and then a simple *parametritis* is the result, which may end either in resolution or in suppuration, but remains local (see *PARAMETRITIS*). In other cases there may be rapidly spreading suppuration or even sloughing inflammation, and in these cases the inflammation early extends to the peritoneum. It is to these cases that Virchow applied the term "*erysipelas malignum internum*," and it is this kind of spreading inflammation of the pelvic cellular tissue which is analogous to, and there is reason to think may be produced by, contagion from so-called "*phlegmonous erysipelas*" of skin and cellular tissue. Clinically, these cases are characterized at first by high fever, with slight physical signs, but when the peritoneum becomes affected, the symptoms of *peritonitis* become the conspicuous phenomena. It will be convenient to consider these subsequently.

The inflammation may also spread to the *ovary*, which becomes enlarged, infiltrated with serum or pus, or even converted into a pulpy mass; or, in less severe cases, just as the inflammation may end in production of a circumscribed abscess in the cellular tissue, so an *abscess*, or *abscesses in the ovary*, may be the chief features in the disease.

In slighter cases, the unhealthy condition of the interior of the uterus, may not extend beyond that organ, or lead to general infection, but remain as a *purulent endometritis*. This is especially likely to happen if a portion of the placenta or membrane be retained *in utero*. This endometritis is not itself difficult to cure. Its chief importance is that the inflammation may extend along the Fallopian tube, and cause peritonitis by direct extension; or pus may accumulate in the tube, and late in the lying-in the tube may ulcerate and burst, and the pus escape into the peritoneum. If neither of these events happen the pus may become inspissated, and partly absorbed; the tube is now liable to recurrent attacks of inflammation, by which it becomes greatly thickened, and the patient may be an invalid for months or years.

The conditions that have been described are local diseases, which induce changes in the blood, the local processes being the conspicuous and main features of the disease. There are other diseases in which blood poisoning is the main character, the local changes not being conspicuously different from what is seen in those who go through the lying-in process without grave illness. It is unfortunately the case that the names given to the diseases about to be described have been used by different writers in different ways. The words "*septicæmia*" and "*pyæmia*" have been applied to three different diseases. 1. *Septic intoxication*: also called *septic poisoning*; or, shorter, more distinctive, and therefore better, *sapræmia*. 2. *Septic infection*, or as opposed to *sapræmia*, *septicæmia*, sometimes called *lymphatic septicæmia*. The word "*septicæmia*" has been unfortunately by some writers applied without discrimination to both these diseases. 3. *Pyæmia*. This word, also, has been by some made to include *septicæmia*, that disease being called *pyæmia simplex*. *Pyæmia* has also been called *phlebotic septicæmia*.

1. **Septic Poisoning, Septic Intoxication, or Sapræmia** (σαπρός = putrid).—This disease is produced by infection of the blood, not with poisonous germs, but with poisonous matter produced by the action of organisms, in this case in the lochial discharge. The poison is here a chemical one, the effects of which are proportionate to the dose, and cease when the poison is eliminated; not a living one, which multiplies in the blood. The bacteria which produce putrefaction are not themselves a poison, for it has been shewn that they can be injected into the body without effect. They grow in dead organic fluids, not in the living body, but, by their action on dead matter, they can produce a poison capable of destroying life.

Symptoms.—The symptoms vary with the amount of the poison which has been absorbed, from mere slight fever up to a rapidly fatal illness. The symptoms may begin on the second or third day after delivery, or at any time from this up to the end of the third week. The symptoms are those of fever. The initial symptom may be a rigor, and the temperature may rapidly rise to 104° or higher. The patient feels ill, there is loss of appetite, thirst, dry furred tongue, and headache. There may be delirium, especially at night. Vomiting is common, in bad cases, and there may be diarrhoea.

There is not usually at the outset great prostration, but if the illness go on unrelieved, the symptoms become augmented, the pulse becomes rapid and feeble, the skin sallow and slightly jaundiced; sordes appear about the lips, the patient sinks into stupor, followed by coma, and death occurs. In fatal cases the disease runs a course of at least some days. The lochia may be so foetid that the smell is almost insupportable, both to patient and doctor, but in some cases there is no great alteration in the smell of the lochia. The discharge may be suppressed, or rather retained in the uterus. The decomposed matters irritate the parts with which they are in contact; hence putrid lochia in the uterus set up endometritis, which in its turn augments the amount of secretion, and thus, by furnishing fresh supplies of decomposable matter, aids the continued production of the poison.

The *post-mortem appearances* are the same as those after death from septic infection.

Treatment.—The essential point in treatment is to wash away the poisonous matter which is producing the disease. When this is done, there is rapid improvement, the symptoms sometimes disappearing in a few hours. For the removal of symptoms, it is enough to wash out the uterus with water; but as this does not destroy the germs which cause the decomposition, it is necessary for a permanent effect, to wash out the uterus with an antiseptic solution, the best being a 1 in 2000 solution of corrosive sublimate. One washing out of the uterus with this solution may be enough to cure the patient, but it may need repeating once or twice, on successive days. The best instrument for the purpose is a Neugebauer's tube, made of celluloid. This can be attached to an ordinary Higginson's syringe.

2. **Septicæmia, or Septic Infection**, is produced by the entrance of virulent micro-organisms into the blood. For the entrance of these organisms the smallest breach of surface is sufficient. Hence the liability to this disease has no necessary relation to the extent of the wounds received in parturition, or to the amount of the lochial discharge. The *symptoms* are those of high fever, with great prostration. There is usually a rigor, with rapid rise of temperature and pulse. Slight yellowness of the skin may be present. There may be mental hebetude, with delirium, deepening into stupor. The pulse, as it gets rapid, be-

comes extremely feeble. Often there is dyspnœa. The tongue becomes dry and brown, and the lips covered with sordes; there is often vomiting and diarrhœa. The temperature, high at first, may sink and become subnormal as death approaches. Death usually takes place before the end of the third day.

The *diagnosis* between sapræmia and septicæmia is very difficult, because the symptoms in the early stages are the same, and later, the two diseases are often associated. The conditions which favour the access of one class of germs, favour that of the other also. And some think that under conditions favourable to their growth, the ordinary germs of putrefaction may become, in successive generations, changed into the virulent germs of septicæmia, so that sapræmia may produce septicæmia. Septicæmia can only be distinguished from sapræmia by the greater prostration which accompanies the former disease. In any case of doubt, that is to say, in any case of severe febrile post-partum illness in which there is not present evidence of local disease sufficient to account for the pyrexia, the disease should be treated as one of sapræmia, and the uterus washed out. It must not be forgotten that such washing out may cure the patient, even though no fœtor of the discharges is reported, or can even be perceived on vaginal examination.

The *post-mortem appearances* are those of rapid decomposition with visceral congestion. The surface, a few hours after death, becomes marked with dark lines, corresponding to the superficial veins. The lungs are congested, the spleen is large and soft, the liver and kidneys are congested, the blood is fluid and imperfectly coagulated, the interior of the vessels is stained with blood, from rapid disintegration of the corpuscles. The heart is flabby, and there are ecchymoses in the serous membrane. The blood corpuscles do not run together into rouleaux, but form irregular clumps.

Treatment in septicæmia is hopeless.

3. **Pyæmia, or Phlebitic Septicæmia.**—A disease resulting from the entrance into the circulation of a specific poison developed by the action of micro-organisms in unhealthy or decomposing pus. In most cases of puerperal pyæmia a uterine phlebitis is the source of the pus. It is characterized by two series of phenomena (1) fever of a peculiar type, marked by recurrent rigors, with great and increasing depression. The rigors are sudden and severe; they recur once

in forty-eight or twenty-four hours, or even oftener. During the rigor the temperature rapidly rises to a great height, 105° F. or more, and each attack is followed by profuse and exhausting perspiration, during which the temperature falls. The breath has a sweetish odour which has been compared to that of new-mown hay. The prostration, indicated by increasing muscular weakness, small thready pulse, dry brown tongue, with sordes about the lips, and rapid wasting, increases. An icteric tint of skin (hæmatogenous jaundice) and patches of fugitive erythema are often present.

(2) The formation of secondary or metastatic abscesses. This commences from the sixth to the tenth day, and is the most characteristic feature of pyæmia. These abscesses are marked by their multiplicity, the rapidity of their formation, and the insidious way in which they come on, without being preceded by any sign of disease in the part. They are most common in the lungs and liver, but also occur in the spleen, kidneys, and other parts. Inflammation of the serous membranes is generally secondary to the formation of abscesses. Peritonitis is in puerperal women the most common of these inflammations. The effusion is usually abundant, and rapidly becomes purulent.

Suppurative inflammation of joints is frequent. The joints, often without pain or other sign of local mischief, rapidly become filled with yellowish puriform liquid. Excepting for the effusion, they are usually tolerably healthy, so that if the patient survive the disease, use of the joint is regained. There may also be diffuse abscesses in the limbs, either deep down in, or between, the muscles or superficial, under the skin. Their presence is commonly indicated by patches of cutaneous redness, and a doughy state of the overlying tissues. Suppurative panophthalmitis, dependent on the lodgment of infective emboli in the vessels of the eye, is commoner in puerperal pyæmia than in other forms. There may be retinal hæmorrhages without this destructive disease.

The *prognosis* in pyæmia is very grave. Death usually takes place about the tenth or twelfth day, although some patients linger on for six or seven weeks. Recovery occasionally occurs.

The *treatment* must be conducted on general surgical principles.

4. **Puerperal Peritonitis** is one of the commonest forms of disease included under the term puerperal fever. It may

arise in several ways: (1) as a result of direct injury, laceration, or perforation of the peritoneum; (2) by direct extension of endometritis along the Fallopian tubes; (3) by extension of phlegmonous inflammation of the womb, or of the cellular tissue, to the peritoneum covering it; (4) by the escape into the abdomen of products of inflammation from the Fallopian tube. When occurring in one of the three first mentioned ways, it quickly follows delivery, and soon becomes general. The abdomen is swollen, tympanitic, painful, and tender; respiration is thoracic, vomiting becomes incessant, the pulse hard, quick, and small, the face pinched, the patient lies on her back, with the knees drawn up, unable to move. The prostration rapidly increases, and death takes place from asthenia. After death, the intestines are found distended with gas, the peritoneum injected and covered with puriform lymph; but there is not, as a rule, a large effusion of fluid.

Treatment is, as a rule, hopeless; it consists in the free administration of opium and alcohol.

5. Late Peritonitis.—Cases of peritonitis which arise from the escape of pus from the Fallopian tube into the peritoneum are of much interest, because there is good reason to think that by prompt treatment some at least might be saved. These cases come on later, from the third or fourth day up to the end of the third week, or even later still. The symptoms of peritonitis are, as a rule, preceded by some local pain and tenderness in the region of the affected tube. The pain suddenly becomes acute, sometimes immediately following an unusual exertion, and symptoms of general peritonitis follow.

The *treatment* in such cases (cases of late onset, the general tenderness being preceded by pain in a definite spot) is to open the abdomen, search for the diseased tube, remove it and the other also if diseased, with the ovaries, and wash out and drain the peritoneum. This has not yet been done successfully in a case shortly following parturition; but there is good hope that prompt operation may yet be successful in such cases. An operation, however, could only succeed in cases in which the disease causing the peritonitis was of a purely local kind.

The same principles of treatment apply to peritonitis caused by the bursting of an ovarian abscess, but it has not yet been carried out in such a case.

The diseases which have been described all occur under like conditions—

viz., those which favour the access and growth of micro-organisms. Therefore the different morbid conditions which have been mentioned often occur together. Indeed, cases in which one form of wound disease only is seen quite pure and uncomplicated in the puerperal state are rare. All these diseases are to be prevented in the same way, which will be presently described.

TREATMENT.—The essential treatment after the mischief has occurred has been given under each heading. The treatment otherwise is simply that of fever generally. Strength must be supported by easily digested food. The tendency to asthenia must be combated by alcohol. The nervous system must be sustained with quinine, and opium, if there be pain. If the temperature be very high tepid baths are almost always grateful to the patient, although they do not seem to have much influence on the ultimate issue. If the circumstances do not admit of a bath, tepid sponging, or the wet pack may be used in its place. Antipyretic medicines are of very doubtful value.

Puerperal fever can be prevented by antiseptic precautions. These consist in perfect cleanliness of patient, doctor, nurse, and everything about the patient; that is, an aseptic condition. An aseptic condition can be attained without the use of antiseptic drugs, but without these drugs it is difficult to be *certain* of maintaining it; and therefore the patient is safer if antiseptics are used. In lying-in hospitals the difficulty of preserving everything in an aseptic condition without antiseptics is so great, and the consequences of any lapse from the aseptic condition so terrible, that the use of antiseptics ought never to be omitted.

The first thing that doctor or nurse should do when they enter the lying-in room is to well wash the hands with soap and water, using a nailbrush, and taking care that the nails are made perfectly clean. To make this easy the nails should be kept short. After washing in soap and water, and rinsing away the soap, the hands should be dipped in a 1 : 1000 solution of corrosive sublimate. The nurse should wear a dress of a light coloured material that can be washed, so that every one may see that it is clean. She should wear no rings, other than the plain wedding ring, for in the crevices of fancy rings much dirt may lurk. For lubricating hands, instruments, &c., a solution of corrosive sublimate in glycerin, 1 : 1000, is best. Before any manipu-

lation or operation, hands and instruments should be dipped in a 1 : 1000 sublimate solution. Immediately after the completion of labour the vagina should be syringed with a 1 : 2000 solution of sublimate, and this, should be repeated night and morning for the first three days; after this, until the lochia have ceased, a 1 : 4000 solution should be used. These are the precautions which have been found effective in lying-in hospitals. The objection to them in private practice is that there is some danger of mercurial poisoning. This is likely to happen if the douche be given by an unskilful nurse, in such a manner that the fluid distends the vagina and does not flow out. Therefore sublimate should be prescribed as a douche only when it is certain that it will be used by a competent person. The symptoms of mercurial poisoning, which in some susceptible patients follow the use of sublimate douches even when properly given, are slight, and quickly subside when the mercury is left off. The first symptoms are diarrhoea and slight soreness of the gums. If these occur the use of the douches must be omitted, and the diarrhoea treated by the administration of bismuth, not by opium. On account of the importance of the early recognition of poisoning, sublimate should only be used in private practice so long as the medical man is visiting the patient daily. On the whole, looking at these disadvantages, and at the slight risk of infection in private practice, it is better while using sublimate during the labour, and for the douche immediately after, to use Condyl's fluid $\frac{3}{4}$ ss ad Oj, or carbolic acid 1 : 50, for all ordinary cases during the lying-in; reserving sublimate for cases where some special circumstance, such as difficult delivery, prolonged labour, retained placenta, or exposure to risk of infection seem to indicate special danger.

(6) The old physicians grouped together cases of short and slight febrile attacks occurring in the lying-in period, under the name of *Ephemera*, or *Weed*. Such illnesses are not uncommon, and may arise from various causes. In some cases we find that with rapid elevation of temperature, and other symptoms of fever of a mild type, there is pain and tenderness over the lower abdomen. In such cases, counter-irritation to the abdomen, in the form of a linseed poultice mixed with a quarter of its bulk of mustard or sprinkled with oil of turpentine, combined with the administration

of opium, is often followed by the disappearance of the symptoms within three or four days. In such cases, the inference that there has been *slight peritonitis* best explains the symptoms and the effect of treatment.

Pyrexia of short duration in lying-in women may arise from *emotion*. This kind of fever is recognized by the rapid rise and fall of the temperature. For example, in an hour or two it may reach 104° F., and sink to normal within two or three hours. Excepting the emotional disturbance and the temperature, there are no symptoms or signs of disease.

If the bowels should become so confined that a strong aperient, possibly attended by griping, is needed, irritation from this cause is sufficient in a lying-in woman to produce slight rise of temperature.

The fact that in badly managed lying-in hospitals, febrile attacks of short duration and slight severity are more common than in those in which antiseptics are used, points to the conclusion that many slight illnesses are cases of *slight sepsis*, in which the decomposition is not enough to produce perceptible fetor, and in which the poison is small in quantity, and spontaneously eliminated.

(7) *Milk Fever*.—A febrile disease following delivery was described by the old writers under this name, and was supposed to be due to some disturbance of the system attending the establishment of mammary activity. Accurate thermometric observations made in well-managed lying-in hospitals have shown that, in a healthy lying-in, the establishment of lactation is not accompanied by fever. But if the nipples become sore and inflamed, if the breasts be not properly emptied, and become hard, painful, tender, and distended with milk, fever may arise, but it will subside when the painful condition of the mammae is removed. If not properly treated, a condition such as that described may go on to the formation of a mammary abscess.

The *treatment* for this condition is to apply glyc. boracis to the nipples, if sore: and to empty the breasts with a breast-pump if the child be unable to do it in the natural way. A soda-water bottle, filled with hot water and then emptied, forms an excellent readily procurable and easily applied breast-pump.

(8) *Erythematous Rashes* are not uncommon in lying-in women, and require mention because they sometimes cause alarm. They are not accompanied

by fever, and subside in a day or two without special symptoms.

G. E. HERMAN.

PUERPERAL INSANITY.—This is more common than insanity during pregnancy. That the puerperal state does predispose to insanity, and that the occurrence of insanity within the lying-in period is more than a mere coincidence, is shown by the fact that almost all cases occur within a month after delivery, and the majority within a fortnight. From the fifth to the tenth day is the usual time for the appearance of the symptoms.

Mania.—*Symptoms.*—This is the form of insanity most often met with, especially in the cases which occur in the first fortnight after delivery. The outbreak is often preceded by sleeplessness and refusal of food. The temperature is not raised, unless the insanity be complicated by some condition causing pyrexia, but the pulse is quick. The urine is scanty, and urea, urates, and phosphates are in excess, from the increased waste of the tissues. There is maniacal excitement, with delusions, hallucinations, sleeplessness, possibly filthy habits, obscene talk, sometimes erotic tendencies with masturbation. Patients take food badly, and are constipated.

The *prognosis* is more favourable than in almost any other form of insanity.

The *duration* of puerperal insanity of this form is seldom longer than three months.

Melancholia.—*Symptoms.*—In cases occurring after the first fortnight, this form is more common. It generally comes on more gradually, with mental depression, often with suicidal tendencies, anorexia, constipation, cold clammy hands and feet, and sleeplessness. Insanity beginning as mania may pass into this form.

The *prognosis* in this form, though still good, is not so favourable as in the maniacal cases.

Duration.—Melancholic cases last longer, but most of them are cured within six months, and the large majority within twelve months.

Ætiology.—The conditions which favour the occurrence of insanity in the puerperal state are (1) an inherited tendency to insanity; (2) anæmia, from hæmorrhage during or after labour; (3) depressing emotions, such as attend the death of the child, or illegitimate pregnancy; (4) damage to the brain from

eclamptic seizures; (5) fever in the lying-in period.

The *preventive treatment* consists in making the patient eat and sleep. The removal of pyrexia, followed by the administration of iron and quinine, and easily digestible food, favour the first indication. The sleeplessness, which in the lying-in period so often leads to insanity, is best combated by a dose of alcohol at night—e.g., 6 oz. of port wine, with hot water. Morphine and chloral are to be avoided, on account of the depression they produce. Bromide of potassium may be given if there be much reflex irritability.

The treatment of developed insanity is described under INSANITY.

The INSANITY OF LACTATION may come on at any period during the fulfilment of this function. It occurs in poor and weakly patients, and is usually of the melancholic form.

G. E. HERMAN.

PUERPERAL THROMBOSIS and EMBOLISM.—During the lying-in period the patient is especially liable to thrombosis of the veins of the pelvis and lower extremities. These veins are greatly enlarged during pregnancy; the circulation is unusually slow, the blood contains an excess of fibrin, and thus thrombosis is favoured. Phlegmasia dolens (*q.v.*) is due to thrombosis of venous and lymphatic channels. It is probable that small fragments of clot may be detached from plugged veins, carried into small branches of the pulmonary artery, and there, if not containing septic germs, be absorbed without much harm following. But a clot may be detached large enough to block the pulmonary artery, or one of its main divisions. In that case sudden death will take place. The patient is seized with sudden and intense dyspnœa, and a sense of terror; there is lividity, a rapid and feeble pulse, cold perspiring skin, and the patient may die in a few minutes, perhaps almost instantaneously. The suddenness with which death follows depends upon the extent to which the pulmonary artery is blocked. If a main trunk be not affected, the symptoms will be less severe, and the patient may linger on for some hours, days, or even weeks, dying at length from exhaustion; or it may even be that after a protracted illness slow recovery takes place. The physical signs on the chest in these cases are at first none, and later not well marked. There is some deficiency of ex-

pansion and resonance, and feebleness of the breath sounds over a greater or less area of the chest, and a murmur over the pulmonary artery. Well-observed cases of recovery from pulmonary embolism are too few to admit of generalisation as to their clinical history. In some cases the symptoms seem to be due to thrombosis beginning in the right auricle, and extending into the pulmonary artery, and some think that in the majority of cases the pathological change is of this nature.

Treatment.—The only treatment of use is to keep the patient absolutely at rest, lest any further fragment of clot should be detached, and to obviate the tendency to death by stimulants—alcohol, ether, musk, or ammonia. Warmth to the limbs, and poultices to the chest and epigastrium may give comfort.

G. E. HERMAN.

PULMONARY ARTERY, EMBOLISM and THROMBOSIS OF.

—The pulmonary artery may be blocked by an embolus, or by clotting of the blood in the vessel. Concerning the former process we have more definite evidence than the latter.

Obstruction of the pulmonary artery is apt to occur during the *puerperal state* or *after parturition*, at which times the blood in the venous system is especially liable to undergo coagulation. Post-partum hæmorrhage, placenta prævia and septic conditions of the uterus predispose to coagulation of the blood in the uterine veins; and this coagulation extends into the veins of the pelvis and legs. The femoral and saphena veins are very liable to thrombosis, a condition which gives rise to phlegmasia dolens. In such cases the clot may be detached, and by blocking the pulmonary artery, produce sudden death. Playfair collected twenty-five cases of pulmonary obstruction occasioning sudden death; seven were distinctly of embolic origin, and occurred at a remote period after delivery, in none before the nineteenth day. In fifteen cases there were no post-mortem evidences of embolism; in all these death occurred before the fourteenth day, often upon the second or third. These latter cases he attributed to *primary thrombosis*. If, however, sudden dyspnoea arise, thrombosis can scarcely be supposed to be the cause, unless it be assumed that, after the formation of a clot, the circulation is still carried on, and that the sudden accession of symptoms is due to the occurrence of further

clotting, or to the clot having shifted, so as to completely block the vessel. Pulmonary obstruction from embolism, produced by the detachment of a clot, may also occur from phlebitis in gout or Bright's disease, from thrombosis of the cerebral sinuses, or of the veins of the limbs in exhausting diseases.

Rare instances have occurred of blocking of the pulmonary artery by hydatid cysts, and by the detachment of cancerous masses which have grown through the wall of a large vein.

Cardiac Thrombosis, secondary to blocking of the pulmonary artery, is less liable to lead to sudden death than when the clot is detached from a vein; because before the clot is detached it nearly always undergoes softening and disintegration, and the débris which is discharged into the pulmonary circulation causes embolism of the middle-sized and small arterial branches, producing pulmonary infarction and its attendant symptoms; It is especially liable to occur in mitral disease, particularly mitral stenosis. In leucocythæmia a clot may be detached from the right heart of sufficient size to block the pulmonary artery, or one or more of its main branches, causing sudden death. A mere mention will suffice of the fact that in many cases in the death agony, or during the last few hours of life, a clot forms in the right ventricle which extends into the pulmonary artery and its branches.

Symptoms.—These may be divided into classes according to the size of the vessel obstructed. If the pulmonary artery itself, or one or more of its larger branches be blocked, then a train of symptoms will arise which will probably be of such short duration that death will frequently occur before the physician can be called. There will be sudden *dyspnoea*, pain in the chest with anxiety of impending death, the jugular veins may be distended, the lips blue, the skin cold and clammy, the pulse weak and thread-like, the heart's action tumultuous and irregular, or so feeble that the impulse cannot be felt. Auscultation shows that air is entering the chest freely, but the blood, being unable to reach it, the respiratory efforts are without avail. In some cases where an embolus is situated in the pulmonary artery or one of its branches, but has not completely filled it, a systolic murmur can be heard over the vessel so affected. Towards the end, which may occur within a few minutes, convulsions and unconsciousness may come on; the

patient dies, in such a case, of *asphyxia*. A number of cases, however, die of *cardiac syncope*, owing to paralysis of the heart from distension of the right cavities, the left being empty and contracted. In such cases the skin is pale, and the end sudden, often being undistinguishable from angina pectoris, rupture of an aneurysm, or of the heart itself into the pericardial cavity. The case may, however, not terminate fatally, for the clot may be driven further along the vessel and allow some portions of the pulmonary circulation to receive blood, and the patient may recover, or after hours or days another accession of symptoms may arise, terminating fatally.

Symptoms of obstruction of middle-sized branches of the pulmonary artery are dyspnoea, and blood-stained expectoration, the sputum consisting almost entirely of dark blood, or of blood mixed with more or less mucus, but there is never much air in it. This characteristic expectoration lasts for several days. A large peripheral infarction may give rise to dullness on percussion, crackling râles and harsh or bronchial respiration, and sometimes pleuritic friction. When small branches of the pulmonary artery are blocked, causing small infarctions, there may be absence of sudden dyspnoea and oppression, although on account of an attendant pleurisy the patient may complain of pain.

Diagnosis.—If one of the causes enumerated be present in association with the sudden supervention of the symptoms described, particularly if the patient be a woman who has not long been delivered, or if there be evidence of venous or cardiac thrombosis, a diagnosis may be made, but it is often attended with difficulty.

Prognosis.—When the artery or one of its large branches are blocked, the prognosis is always very grave, but if the case be not suddenly fatal, there must still be circulation going on in some part of the pulmonary system, therefore a chance of recovery exists, but it must be borne in mind that a further obstruction may occur by an addition to the clot. Some undoubtedly severe cases have, however, recovered. The occurrence in heart disease of embolism followed by hæmorrhagic infarction is, on the whole, unfavourable, since it points to weakness of the right ventricle, and hence to the formation of a thrombus in it, yet frequently the symptoms of a pulmonary infarction pass away entirely.

Treatment.—*Prophylactic.*—The acci-

dent can often be prevented by care. A patient suffering from any of the conditions which may give rise to embolism of the pulmonary artery or its branches should not be allowed to make any exertion, or to get out of bed or strain at stool, lest the clot be detached.

Therapeutic.—Very little can be done. Stimulants, such as ether, ammonia or brandy or a hypodermic injection of ether may be given in order to keep the patient alive. Leeches, dry cupping and sinapisms over the cardiac region, and perhaps bleeding from the arm might do good to relieve the distension of the right heart. If the case be not suddenly fatal, and oxygen can be obtained, its inhalation might be tried. Absolute rest should be enjoined, even after alarming symptoms have passed away, for any exertion may lead to a renewal of dyspnoea and cardiac embarrassment.

F. W. MOTT.

PULSE.—What is known as the pulse is not a distension of the artery by the blood which is being driven through it, but a change in the shape of the artery, due to a temporary increase in the tension of its walls.

Dr. Broadbent, to whose teaching on this subject the writer is greatly indebted, has shown that the pulse is felt in the normal condition only when an artery is somewhat compressed and flattened against a bone or other hard substance. With each beat of the heart the fluid pressure in the whole of the arterial system is increased, and consequently the compressed vessel tends to resume its former cylindrical form; it is this change of form which is felt as the pulse. The pulse can be felt wherever an artery lies near the surface and can be compressed against a bone beneath it, and for practical purposes the radial artery at the wrist is always chosen. The pulse may be examined by either the finger or the sphygmograph. Very rarely does the latter instrument convey more, or even as much, information as the educated finger, yet its tracings are useful as records of the pulse at various times (see SPHYGMOGRAPH). In this article, while the indications of the sphygmograph will be referred to occasionally, the descriptions of the pulse will be based upon an examination with the finger alone.

Examination of the Pulse.—The method to be pursued in examining the pulse is the following:—The first three fingers are laid lightly upon the radial

artery at the wrist and are then carried transversely to and fro across the artery. Thus, its size is appreciated and the degree of fullness between the beats of the pulse. Next, the fingers should carry the skin along the artery, using varying degrees of pressure. In this way a tortuosity of the vessel and an irregular thickening of its walls from atheroma will be detected, and when the vessel is completely emptied by pressure its walls may perchance be found uniformly thickened so as to form a cord beneath the finger. Now, pressing upon the artery with the finger, or the two fingers, nearest the heart and using moderate force, the pulse itself will be perceived. The characters of the pulse to which the observer's attention should be directed are :—

1. *The Frequency.*—This is an indication of the frequency of the heart beat, but may or may not correspond with the latter.

2. *The Size.*—That is the degree in which each heart-beat diminishes the flattening of the artery by the finger. The force of the heart-beat being the same, the size of the pulse will be greater when the arteries are relaxed and easily flattened, less when they are contracted or distended, and, therefore, not readily compressible. Moreover, in the latter condition, the size of the pulse will be found to increase as greater pressure is applied to the artery.

3. *The Uniformity.*—The beats should be regular in rhythm and equal in size.

4. In each individual beat there must be noticed the *sharpness* with which the beat strikes the finger, the *duration* of the beat and its *mode of decline*, whether gradual or sudden.

5. *The Strength.*—This cannot be estimated from the size of the pulse, since the latter will vary with the degree of relaxation or contraction of the artery; it must be judged by the amount of pressure required to obliterate the pulse. Pressure should be applied by the finger, or two fingers, nearest the heart until by the third finger the pulsation is found to have disappeared. The degree of pressure necessary will serve as a guide to the force of the heart beat.

6. *The Bilateral Similarity.*—It is desirable in certain cases to examine the pulse at each wrist, and, bearing in mind a possible abnormal distribution of the arteries, to note any differences there may exist in the characters of the two pulses, or any want of synchronism.

Recurrent Pulsation.—This phenomenon introduces a fallacy to which the

careless observer is liable. In certain conditions, even though the circulation through the radial artery towards the periphery be completely interrupted by the observer's fingers, there is still felt a slight and somewhat delayed pulsation in the artery. This is due to a transmission of pulsation through the palmar arch, and it occurs when the vessels are relaxed. It is associated with two conditions, namely, such a low tension pulse as occurs in aortic regurgitation, and the condition which is met with at the end of a case of chronic Bright's disease, when peripheral resistance to the circulation remains, but the arteries have ceased to contract upon the blood.

Abnormalities of the pulse involving all these points will now be briefly described.

Excessive Rapidity of the Pulse; Tachycardia.—The normal rate of the pulse is about 72 beats per minute, but this is easily varied by many physiological conditions, such as food, exercise, excitement, the upright position, &c. There are many pathological conditions which accelerate the pulse. Pyrexia from any cause, but especially that which accompanies scarlet fever, is perhaps the most frequent. States of anæmia and debility are notable, not only for general rapidity of the pulse, but also for the ease with which the physiological conditions mentioned above increase the average pulse rate. In Graves' disease, the symptom most constantly present is increase of the frequency of the pulse, together with a sense of palpitation of the heart. Many nervous disorders, and among these may be mentioned locomotor ataxy, are accompanied by persistent frequency of the pulse, and the same symptom is noticed as an early sign of cardiac failure from any cause.

There exists a strange group of cases in which rapidity of the pulse is almost the only symptom observed. This condition is not infrequent as a paroxysmal occurrence in gouty or mentally over-worked subjects. It comes on suddenly after slight exertion, or excitement, and is accompanied by a great sense of oppression and of impending danger. This form of so-called tachycardia, generally passes off after a period of rest in the supine position. But in another class of cases the extreme frequency of the pulse may remain for a considerable time as a constant symptom, and may reach such a degree as to cause the heart to beat more than 300 times in the minute. This tachycardia comes on suddenly, and

often without apparent cause. There is rarely any feeling of distress in the early stages, and nothing to account for the condition can be discovered by stethoscopic examination. In severe cases, the face becomes pale or cyanotic, and signs of œdema of the lungs and general failure of the circulation may be detected. The cause is doubtless some disorder of the nervous mechanism of the heart. It is not a safe condition, for sudden death has been known to occur in a number of cases. In one such case, the writer was able to detect after death nothing more than an enlargement of the heart and some degeneration of its fibres, which were more likely to be the result than the cause of its rapid action. The cardiac nerves were structurally normal. Rest, and freedom from excitement should be enjoined in such cases, and drugs which steady the heart such as digitalis, convallaria and strophanthus should be prescribed. Yet all these remedies, while useful for a time, seem powerless to effect a cure, which may, however, occur spontaneously.

Slow Pulse, or Bradycardia, may be habitual to some persons and not indicative of a departure from health. Again, it is produced by jaundice, and is found sometimes as a symptom of fatty degeneration of the heart. It must not be confused with that condition known as *dropped beat*, in which each alternate beat of the heart fails to reach the pulse. As Dr. Broadbent has shown, this is due to the second contraction of the left ventricle being too weak to raise the aortic valves, the right ventricle at the same time acting normally. An extremely slow pulse may be associated with epileptic seizures, because the slowly acting heart is incapable of supplying a sufficient amount of blood to the brain.

Intermittent and Irregular Pulse.—The pulse may vary its rhythm in relation to the heart's action or independently of this. An intermittence in the pulse may therefore be dependent on an intermission in the cardiac action, and it may be regular or irregular in its occurrence. Such a condition is habitual to some persons, is very common in gouty subjects, and is readily produced by dyspepsia, nervous excitement, and abuse of tea and tobacco. On the other hand, intermission of the pulse may be merely a form of the dropped beat just described. An irregular pulse is one in which the rhythm and possibly the force of the pulse-beats varies irregularly.

It is especially associated with cardiac failure and with mitral regurgitation. Varieties of the intermittent and irregular pulses are the so-called *pulsus bigeminus*, *pulsus trigeminus*, and *pulsus paradoxus*.

The **Pulsus Bigeminus** receives its name from the fact that the beats of the pulse occur in pairs, each pair followed by a somewhat longer interval than usual. The first beat of the pair is a normal one; the second is often much weaker than its predecessor. The heart beats correspond in rhythm, and Dr. Broadbent has observed that a mitral murmur, heard with the first beat, may be inaudible with the second, and that a tricuspid murmur may be heard only with the second beat. This pulse is common in mitral stenosis.

In the **Pulsus Trigeminus** the associated beats are three in number.

Pulsus Paradoxus is the name given to that condition in which the pulse-beat is lost or becomes much weaker, during each inspiration. It is found in association with weak heart, with adherent pericardium, and with chronic mediastinitis, where fibrous bands surround the roots of the large vessels, and also bind the pericardium to the sternum. Its ætiology in the latter case would seem to be evident, for with each inspiration the fibrous bands would be dragged upon, and thus the entry of blood into the large vessels from the ventricles would be hindered. Another mechanism, however, is possible, and may well obtain in those cases where no such adhesions are found. With each inspiration the negative pressure on the thorax is increased, and may thus offer more resistance to the emptying of the ventricles than a weak heart, or one acting under conditions otherwise unfavourable, is able to overcome.

High Tension Pulse.—The tension of the arterial walls is increased at each systole of the ventricles and causes the pulse. But the mean tension of the arteries is capable of variation under many conditions. The mean tension depends upon the force of the ventricular systole, and the amount of resistance which the blood experiences in passing through the capillaries; variations in either of these two factors will cause corresponding changes in the character of the pulse. A normal pulse is, as a rule, easily compressible, and the artery can scarcely, if at all, be felt between the beats. Increase of the peripheral resistance, together with a corresponding increase in the force of the ventricular

systole, produces the high tension pulse, the characters of which are, that it is gradual in its impulse, long in duration, slow in subsiding, with difficulty compressible and the artery is felt between the beats as a firm round cord. Usually the artery is small, and the pulsation may appear to be small and weak, until considerable pressure is applied to the artery, when the beat is found to be really very forcible. The sphygmographic tracing is characterized by a short sloping upstroke, the absence of percussion waves, a rounded or lengthened summit, and a gradual descent, in which the dicrotic wave is very slightly marked, and the dicrotic notch is high above the base line.

Virtual Tension Pulse.—If with the peripheral resistance still continuing, the heart power should fail, the pulse of high tension becomes one of, what Dr. Broadbent has named, "Virtual Tension." In this variety the artery is still full between the beats, but is generally large; the impulse is sudden, lasts but a short time, and suddenly declines. The sphygmographic tracing shows a moderately high and perpendicular upstroke, very often percussion waves, and a somewhat gradual descent, in which the dicrotic wave is well marked, but the dicrotic notch is high above the base line.

Some degree of high arterial tension is often a natural condition with individuals, and not infrequently many members of a family may show it without any symptoms of, or inclination to, disease, being detectable. As a rule, however, a high arterial tension indicates an impure state of the blood, which renders it incapable of passing easily through the capillaries, and which is induced by abuse of nitrogenous food, habitual alcoholic excesses, constipation, and deficiency of exercise. It is especially found in association with Bright's disease, gout, lead poisoning, and pregnancy. Dr. Broadbent has observed that the pulse of scarlet fever differs from that of the other eruptive fevers, in that it shows high instead of low arterial tension. Some cases of anæmia present a persistently high arterial tension, and it must be noted that neurotic subjects, under the influence of excitement or worry, will develop a great increase of the arterial tension, which sometimes comes on very suddenly and as suddenly declines; this is clearly not due to an impurity of the blood, but doubtless to contraction of the arterioles.

The pulse of virtual tension is met

with in similar conditions when the heart begins to fail. It is hence most often found in the late stages of Bright's disease.

Space will not allow of a description of the evils brought about by high arterial tension. It must suffice to say that they result on the one hand from the strain upon the heart and blood-vessels, and on the other from the failure of nutrition of all parts of the body, but especially of the nervous system, which is induced by the deficient circulation. High arterial tension is best combated by a due regulation of the habits of life and a limitation of alcohol and of nitrogenous food. Salines should be given, the bowels kept freely open, and mercurial purges occasionally administered. The pulse of virtual tension is, as has already been stated, a sign of heart failure, and calls for treatment based upon this view.

Low Tension Pulse.—The pulse of low arterial tension is sudden in its onset, short, and quickly declines. The artery is scarcely to be felt at all between the beats, and the pulse is easily obliterated by pressure. The size of the pulse will depend entirely upon the force with which the heart is acting, being large when the systole is strong and *vice versa*.

Dicrotic Pulse.—This is observed when the arterial tension is low. On applying the fingers very lightly to the artery a second impulse can be readily detected following the first. The second shock is due to the rebound of the elastic arterial walls, after the systole of the ventricle has stretched them, the closed aortic valves acting as a fulcrum. It must be carefully distinguished from the pulsus bisferiens, or pulsus triferiens observed sometimes in aortic stenosis, which are due to the reinforcement of a prolonged ventricular systole near its close, by one or two accessory spasmodic contractions. The terms hyperdicrotic and anacrotic are used to distinguish degrees of dicrotism, which are shown by the sphygmograph. They are of no practical importance. The sphygmogram of low arterial tension shows an abrupt ascent, varying in length according to the force of the heart beat, a sharp summit, and an abrupt descent, in which the dicrotic wave is well-marked and the dicrotic notch is placed near the base line.

Low arterial tension indicates a deficient power in the circulation. Its most frequent cause is pyrexia, and it is found

generally in states of debility. It calls for the administration of tonic remedies.

The Collapsing Pulse of Corrigan, found in aortic regurgitation, is a special form of the low tension pulse. It is very sudden in its impulse, large, of short duration, subsides with great abruptness, and between the beats the artery is scarcely to be felt. The size of the pulse is due to the dilatation and hypertrophy of the left ventricle, which, for the purpose of compensation, always accompanies aortic regurgitation. The non-closure of the aortic orifice during the diastole of the ventricle, allows part of the blood driven into the artery to flow out again. Thus, while the great increase of tension due to the systole of the hypertrophied ventricle is felt in its full force, yet immediately the systole is over, the artery is no longer kept distended, but "collapses." At the same time, a distinct delay can be perceived before the systole, as timed by the apex beat, produces its effect on the radial artery. In this condition, too, the blood which flowed out of the artery during the ventricular diastole is projected into the more or less emptied vessel at the next systole, and this re-filling of the artery causes the "visible pulse." The mechanism of such a pulse is thus quite different to that of the normal pulse, as felt by the fingers, which, as has been stated, is not due to progression of blood through the artery, but to increase of tension of its walls. Again, the shock of the ventricular systole, and the return of the blood to the relaxed and partially emptied arteries, causes them to move in their beds and exaggerates their curves, producing the vermicular appearance known as the "locomotive" pulse. All the features of the collapsing pulse are more marked when the arm is raised above the head. The sphygmogram shows a very high and abrupt ascent, the presence of percussion waves, a sudden descent, and a very faint and low diastolic wave.

Capillary Pulsation is a phenomenon seen in connection with very relaxed states of the arteries, and especially with aortic regurgitation. If a capillary blush be raised by scratching the forehead, its edges will be seen to pulsate distinctly with each beat of the heart. The same pulsation may be seen under similar circumstances at the edge of redness under the finger-nail, when the tip is pressed firmly.

Venous Pulse.—Dr. Broadbent has shown that in the same conditions the pulsation may be communicated even to

the veins, and can be well seen in the veins of the wrist when the hand hangs down. Pulsation also occurs in the veins of the neck, in tricuspid regurgitation, where the systolic shock of the right ventricle is communicated to the contents of the right auricle and through them to the superior vena cava and its radicles.

Aneurysmal Pulse.—An aneurysm of the thoracic aorta or of one of its large trunks may modify the radial pulse in a characteristic manner. The artery is then full between the beats, and the pulse itself is small, but becomes somewhat more evident when pressure upon the artery is increased. The impulse is not sudden, is long in duration, and subsides gradually. These points become more marked when only one radial pulse is affected by the aneurysm and comparison can be made with its normal fellow. It will then be found that the affected pulse is considerably delayed behind the healthy one.

The characteristics of the aneurysmal pulse are much more evident in the sphygmographic tracing than to the unaided finger, and can be discovered by the instrument at an earlier stage. The sphygmogram shows a low and gradual ascent, a rounded summit, a gradual descent, and almost entire obliteration of the secondary waves. Such a tracing may be imitated almost exactly by aortic stenosis, but is distinguished by this point—that considerable pressure is required with the screw of the sphygmograph to bring out the characters of the aneurysmal tracing, but is not required for that of aortic stenosis.

The cause of this modification of the pulse, when present in its typical form, is the interposition of the aneurysm as an elastic reservoir between the heart and the radial artery. The shock of the systole and also of the diastolic wave is received by the aneurysm, and only gradually distributed to the peripheral parts, while the radial artery is kept constantly full as if by the elastic reservoir of a Higginson's syringe. The position of the aneurysm will determine whether one or both radial pulses will be affected by it. If it affect the ascending arch only, both pulses may be altered, and, consequently, comparison between those of the two sides is useless. Here the sphygmograph will often be found a great help. If the aneurysm involve the innominate artery, the right radial pulse will exhibit the aneurysmal character, and not the left; and, again, the right

pulse may be behind the left in time. When the aneurysm is situated beyond the origin of the innominate artery, the right radial pulse will be normal, the left aneurysmal. If it be beyond the origin of the left subclavian artery, of course neither radial pulse will be affected. Moreover, a comparison of the radial with the carotid pulse of the same side will sometimes reveal that the aneurysm has involved the subclavian artery and left the carotid intact, and will show, too, that the aneurysm is not situated on the proximal side of the carotid.

The above remarks refer to typical cases, but the conditions are liable to be complicated. Thus the filling of an aneurysm with fibrin will, to a great extent, hinder its action as a reservoir, and so prevent its influencing the pulse. The writer thinks, too, that considerable narrowing of the neck of the aneurysm will have the same result. Again, the aneurysm may press upon the subclavian artery or cause the orifice of that artery to be greatly narrowed when it arises directly from the sac. Both these latter conditions will produce a radial pulse very like the true aneurysmal pulse, but the writer would recommend in such cases a reference to the degree of pressure required to bring out the characters of the sphygmogram. He has reason to believe that in such cases the best tracing will be obtained with a much lower pressure than is the case with the true aneurysmal tracing. In one instance he was by this means led to a correct diagnosis of embolic narrowing of the subclavian artery rather than of aneurysm of the aorta when the differences of the radial pulses suggested the latter condition. Finally, the subclavian artery may be entirely obliterated by an aneurysm, and then the pulse in the radial artery is wanting. (*See also SPHYGMOGRAPH.*)

ROBERT MAGUIRE.

PUPIL, DISORDERS OF.—The aperture in the iris, whereby rays of light are admitted to the percipient parts of the eyeball, is usually circular and situated a little to the nasal side of the middle of the cornea. The muscular portion of the iris is generally considered to consist of central circular fibres for the contraction of the pupil, and of peripheral radiating fibres having an opposing action. The centre for the regulation of the former is situated in the anterior part of the nucleus of the third nerve, behind the centre for accommodation, the connecting motor path being formed

by the second fasciculus of origin of the third nerve (probably), its trunk, the lenticular ganglion and the ciliary nerves. The centre for the dilator fibres probably lies below the corpora quadrigemina, from which the motor path extends down the cervical portion of the spinal cord, thence by the rami communicantes of the first or probably the second dorsal nerve to the sympathetic. The pupil is affected by disease implicating any part of these tracts.

Mode of Examination.—The pupils should be examined as to (1) equality, (2) size in ordinary light, (3) mobility, and (4) shape. To detect any inequality, care must be taken that the same amount of light falls in each eye. Their size may be estimated by comparison with a series of dots, ranging in size from 1–10 mm. in diameter, held alongside the eye.

Normally, on shading one eye and allowing a bright light to fall suddenly upon the other, the pupil is seen to contract (direct reflex action). The shaded pupil also contracts, coincidentally, but to a less degree (indirect reflex action). The pupils should dilate in the shade and also upon the application of some cutaneous irritation, such as the faradic wire brush applied to the neck; in some, this happens when one of the extremities is pinched.

The pupils have also an associated action with the ciliary muscle, so that during relaxation of accommodation, as in looking into distance, they dilate, but contract concurrently with increasing accommodation.

Variations from the Normal.—1. It is extremely rare for marked inequality of pupils to exist apart from disease or great difference in the refraction of the two eyes. In some cases one pupil, though at times equal to the other, is liable to undergo dilatation, and with it the accommodation is proportionally weakened. Such a condition is generally associated with neuralgia, and seems to depend upon want of tone of the corresponding part of the nucleus of the third nerve. In general paralysis of the insane inequality of pupils is usually present, but varies considerably during the course of the disease and also from day to day. In peripheral neuritis, especially of alcoholic origin, the pupils are often unequal. Irritation of the sympathetic causes a dilatation of the corresponding pupil; paralysis of the same nerve, a slight contraction, so that in a moderate light the affected pupil is rather smaller than the other.

Paralysis of the circular fibres of the pupil causes a moderate dilatation. The pupil of a blind eye soon becomes rather larger than the other.

2. The pupils are commonly large (mydriasis) after the administration of large doses of belladonna, in anæmia, syncope, aortic incompetence, bilateral paralysis of the third nerve, during great pain, and also in the convalescence from typhoid fever, in which case such dilatation sometimes occurs that the red fundus can be seen. The local application of atropine, daturine or cocaine, causes a dilatation far exceeding that which is produced by paralysis of the third nerve. Contraction of the pupil (myosis) is found in the course of typhus fever, tabes dorsalis, sleep and photophobia. It also results from the local application of eserine, and of large doses of opium internally.

3. Affections of mobility are common and of great importance. One of the earliest signs of tabes dorsalis, is the so-called Argyll-Robertson pupil, which consists of the loss of the light reflex, with the retention of the associated movement. In many of these cases, the pupils are uninfluenced by cutaneous irritation. The Argyll-Robertson pupil is also present in some cases of general paralysis and of old-standing syphilis. If both eyes be equally shaded in one-sided paralysis of the sympathetic, it will be seen that the affected pupil does not dilate, and hence appears much smaller than the normally dilated one. In those rare cases of paralysis of the circular fibres alone, the moderately dilated pupil is unaffected by the brightest light. When paralysis of both sphincter and dilator occurs (iridoplegia), the pupils are altogether uninfluenced by light, but retain their associated action, except in very old standing cases. In amaurotic eyes the direct light reflex is lost, but the indirect is increased. This is in marked contrast with what occurs in hysterical blindness, in which the light reflex, both direct and indirect, is quite normal. In some conditions these reactions to light and accommodation are mechanically prevented, as in glaucoma, by thinning of the iris and pushing forwards of the lens; serous iritis; excluded pupil, due to the gumming of the edge of the iris to the lens; and occluded pupil, in which the iris is adherent to a false membrane, occupying the area of the pupil. *Hippus* is a very rare condition in which the pupil contracts and dilates without obvious cause.

4. The most marked changes in the shape of the pupil are found in iritis, and are especially evident after the instillation of atropine, which dilates only those parts not bound down by adhesions. Sometimes shreds and filaments are seen, of the same colour as the iris and attached to the anterior surface close to its pupillary border. These are persistent remains of the pupillary membrane. In some cases of tabes dorsalis the pupils are of irregular shape, and in glaucoma they are often vertically oval. Sometimes there is a congenital cleft in the iris, usually symmetrical and always in a downward or down and inward direction.

WM. GAY.

PURGATIVES are substances which act on the bowels, causing increased evacuations. This they do either by increasing the peristaltic action, or by increasing the secretion from the intestinal glands. The former is the mode of action of the *simple aperients* or *laxatives*, the largest class, to which belong rhubarb, senna, aloes, castor oil, sulphur, magnesia, belladonna, and certain fruits such as figs, tamarinds, rhamnus frangula, cascara sagrada, &c. The other class, viz., those which cause increased glandular action or *drastics*, includes elaterium, croton oil, gamboge, and colocynth. Between these, however, are certain groups of substances which act in both ways; of such the *hydragogues* or *cathartics* act on the glandular secretion—they are mercurials, scammony, and jalap; the *salines* increase secretion whilst also promoting peristalsis—such are the sulphate of magnesia and the salts of potash and soda. One other class of purgatives remains to be mentioned, viz., *cholagogues*, so called because they promote the expulsion of bile from the body: this they do in two ways, either by stimulating the liver to an increased formation of bile—the direct cholagogues, of which the chief are sulphate of soda, nitro-hydrochloric acid, dandelion, jalap, rhubarb, aloes, colocynth, euonymin, and iridin—or they act indirectly by stimulating the intestinal glands, especially those in the duodenum, hurrying on the bile, and preventing the reabsorption which normally occurs in that part of the intestine. The mercurial preparations are the best indirect cholagogues.

Apart from constipation there are three conditions especially in which the administration of purgatives is indicated, viz., (1) at the commencement of an acute illness, when a blue pill, a dose of

calomel or colocynth may be given with benefit; (2) in general or partial dropsy, whether from heart, liver, or renal disease; in this class of cases the hydragogues are especially useful, jalap in the form of the pulvis jalapæ co. being the favourite remedy; where a more powerful action is desired a pill of elaterium may be employed; (3) in cases of cerebral hæmorrhage where a speedy reduction of the blood pressure is called for, a drastic is indicated, of which croton oil is the most efficient and speedy in its action; one or two drops may be placed on the tongue.

As a general rule, where a single purgative dose is indicated, the remedy should be given at bedtime and followed in the morning with a saline draught—*e.g.*, Carlsbad salts or seidlitz powder. In cases of dropsy where the purgative has to be administered repeatedly, it is better to give it early in the morning, before any food is taken.

PURPURA.—A comprehensive term which includes all extravasations of blood into the skin and mucous membranes, not resulting from traumatism. Thus understood, it is symptomatic of very various conditions, and may depend upon a multiplicity of causes, several of which may co-exist in a given case.

Symptomatic Purpura may be (1) mechanical, due to increased blood pressure; either permanent, as in chronic pulmonary or cardiac ailments, or temporary, as in paroxysmal affections (pertussis, epilepsy). The tendency to hæmorrhage is greatest in dependent parts owing to gravitation, and in lax tissues where the vessels are badly supported (*e.g.*, the eyelids).

(2) Dependent on changes in the blood or walls of the blood-vessels, as in anæmia, leucocythæmia, hæmophilia, Hodgkin's disease, sarcomatosis, scurvy, rickets, ague, jaundice, Bright's disease, rheumatism; or in lardaceous disease, chronic alcoholism, and old age. Purpura occurring in children immediately after birth is referred to the circulatory changes which then take place.

(3) Toxic, as in snake poisoning, and from the administration of various drugs—iodides, bromides, phosphorus, mercury, quinine, salicylic acid, chloral, ergot, belladonna, copaiva.

(4) Due to disordered innervation of the blood vessels, resulting in nutritive changes in their walls, or in their irregular contraction and consequent excessive strain at certain points. Such are the

hæmorrhages which occur in hysteria, after neuralgiæ, in tabes dorsalis, and many other diseases of the spinal cord and brain.

(5) The result of a specific infective virus—*e.g.*, in all the acute specific fevers, syphilis, tuberculosis, malignant endocarditis, and septicæmia.

(6) Cases which cannot be considered as belonging to any of the foregoing types, may be grouped together as idiopathic purpura, although recent researches tend to establish their close connection, if not absolute identity, with the last-mentioned form.

Purpura simplex represents its mildest degree. It generally occurs suddenly in persons who are apparently healthy, and especially in the young. Roundish or irregularly shaped petechiæ appear, of a deep red colour which does not disappear on pressure and soon becomes purplish, not raised above the surrounding skin, and usually remaining discrete. There are no concomitant, constitutional, or subjective symptoms. In children they are commonest about the upper part of the trunk, neck, and arms; in adults, about the inner surface of the thighs, but they may affect any part of the body, and are generally symmetrical. Fresh crops may continue to appear for weeks, each spot as it fades becoming successively blueish, greenish, yellowish and brownish.

The condition is apt to be mistaken for flea-bites.

Purpura Hæmorrhagica (*Morbus Maculosus Werlhofii; Land Scurvy*).—A greatly aggravated form of purpura simplex. Although common in weakly and anæmic persons—especially in girls about puberty—with bad hygienic surroundings, it is of comparatively frequent occurrence in the apparently robust of either sex and of any age, without appreciable cause. A severe case is usually preceded by marked general malaise, fever, headache, pains in the limbs and abdomen, and vomiting. Then hæmorrhagic points, larger than in purpura simplex, appear upon the lower limbs, soon to extend in successive crops over the whole body surface, coalescing to form irregularly shaped, extensive ecchymotic patches, or even raised bloody tumours (ecchymomata). Hæmorrhages from mucous surfaces, often alarming in amount, occur with special frequency from the nostrils, mouth, stomach, intestine and kidneys, the patient becoming greatly reduced thereby. Hæmorrhagic effusion also takes place into the

serous cavities, and sudden death may result from bleeding into the ventricles or upon the surface of the brain. Throughout the case there is generally some elevation of temperature, sometimes of marked septicæmic type, but no constant relation has hitherto been established between the severity of the pyrexia and of the general symptoms.

In considering the *differential diagnosis* from the various forms of symptomatic purpura, it is of the greatest practical importance to eliminate scurvy.

Recovery is the rule, and, in cases of average intensity, usually takes place in about four weeks. A favourable termination sometimes ensues in apparently desperate cases after several weeks' duration, but, on the other hand, death often occurs.

Pathology.—In a few recent cases, plugging of the capillaries with colonies of bacilli containing spores, or with streptococci, has been demonstrated. As the result, extravasation occurs into the corium or its papillary layer, whence it may penetrate the deeper layers of the epidermis; the serum is absorbed, and the subsequent changes in colour are due to alterations in the hæmatin, the ultimate term being hæmatoidin. In mucous membranes, breaches of continuity—hæmorrhagic erosions—rapidly form.

Treatment.—No treatment may be called for in the mildest cases. In severe cases, absolute rest in bed is imperative. The diet ought to be liberal and stimulating, generous wines, strong soups, and meat essences or jellies being useful. If scurvy be even suspected, fresh green vegetables, mealy potatoes, and lemons may be given with advantage. The bowels ought to be acted upon by mild saline laxatives, if there be any tendency to constipation. Iced drinks, iced enemata, and ice locally are often indicated. Turpentine, ergot, hamamelis, acetate of lead, perchloride of iron, the mineral acids, and chlorate of potash are the drugs usually employed, and all are occasionally of service. Arsenic has been strongly recommended by some authorities.

For Purpura Rheumatica *see* PELIOSIS.
J. J. PRINGLE.

PUSTULE, MALIGNANT.
(ANTHRAX; Woolsorter's Disease; Splenic Fever; Carbuncle; Charbon).—An acute disease, due to the absorption of a specific virus, the bacillus anthracis; sporadic among human beings, frequently epizootic and enzootic

among sheep, cattle, and some other animals.

The term Woolsorter's Disease, now in common use, is derived from the fact of the disease prevailing among the sorters of certain kinds of wool, who are numerous in Bradford. "Sorting" means dividing the wool into "sorts," according to quality. To Dr. J. H. Bell of Bradford is due the credit of having established the identity of the "Woolsorter's Disease."

MALIGNANT PUSTULE.—This term is applied specially to that form of anthrax in man, in which the virus has entered the body by a cutaneous wound, the point of inoculation becoming the site of a peculiar and characteristic sore. Nothing similar to this local sore occurs in animals, whether suffering from a spontaneous attack or from an experimental inoculation. The actual breach of surface may be very small, as observed among woolsorters in Bradford it is often not larger than a split pea, but the tumour may be as large as an apple, or larger.

Symptoms.—Sometimes the patient feels a distinct tingling or slight "pricking" pain at the time of inoculation, but it is never sufficient to attract more than momentary attention. The face, neck, hands, and arms are the most usual situations of the malignant pustule, being the most exposed parts.

In the course of some hours a pimple forms at the spot, which has itched from time to time. A few hours later a vesicle forms, the top of which is invariably rubbed off by scratching; the spot becomes redder and hard, the induration extends and the central part gradually changes to a dark grey or brown colour, and ultimately, by about the end of the second day, to a black or grey-black colour. Around this black patch a ring of vesicles forms, the individual vesicles being small, usually not larger than a canary seed. The swelling may extend and sometimes produces immense tumefaction of the neighbouring parts. When the face is attacked the features often become quickly concealed and unrecognizable, the eyes disappearing entirely in the swollen tissues. Neighbouring glands are generally enlarged, though without much tenderness, and red lines often ramify towards the nearest important collection of glands—*e.g.*, towards the axilla when the arm is the affected part. The patient may die on the fourth or fifth day, by which time the black eschar will rarely exceed a

florin in area. The surface of the tumour is sometimes red, and may be either hot and inflammatory, or cool; it is sometimes emphysematous.

The patient is perfectly conscious and clear in his mind, even when the rapid irregular feeble pulse betrays the serious nature of his disease. There is usually a good deal of local swelling before any complaint is made, but not infrequently he dies without complaining of any symptoms whatever, always answering that nothing ails him. Sometimes there is slight headache and dry tongue, but prostration and a feeling of "sinking" are the symptoms most often complained of, and also a feeling of uneasiness about the chest, hardly amounting to dyspnoea. The temperature usually rises for a brief period to 100° or 101° F. (rarely higher), but this temporary rise is soon followed by a sub-normal temperature, the thermometer standing at 96° and even 95° F. The fever is never a serious element in the disease, and the worst cases are those in which the temperature ranges lowest.

Course.—It sometimes happens that the general symptoms remain in abeyance and the ailment continues entirely local, and gradually disappears, the eschar sloughing out and the sore healing, with disfigurement proportionate to the amount of tissue destroyed. The eschar is sometimes thrown off without suppuration after the formation of a line of demarcation from the healthy tissues.

It sometimes happens that no distinct local sore is formed in the early stage, although there is extensive oedema, which has spread from a centre. Later on, if the patient survive more than three or four days, which is rare in these cases, pustules may form with eschars. If the case become one of general infection the symptoms resemble those of general anthrax (*q.v.*).

Diagnosis.—The nature of the case will generally be apparent, when the local sore has developed. Where this is not so, one most striking feature is the disproportion between the symptoms and signs, there being perhaps utter prostration without any discoverable cause. The co-existence of perfect mental lucidity, with conditions so evidently pointing to a critical state of the patient, which he does not realize, is very suggestive.

Microscopic examination of the effused fluid from the pustule or the surrounding oedema may, by the revelation of the presence of the bacillus anthracis, prove the case to be specific anthrax, but the bacilli may be entirely absent from the

inflammatory exudation, and also from the blood up to a short time before death.

Prognosis.—The gravity of the case depends mainly on the occurrence of a general infection of the organism; death, when it occurs, being due to this cause, and not to the local lesion.

Pathology.—If the disease become generalised it is essentially a case of anthrax, and differs in no way from disease acquired by internal absorption, except that it is less fatal (*vide infra*).

Structure of the Pustule.—There is usually a crust on the top of the eschar, consisting of amorphous exudation and debris of the superficial tissues, which may contain a few specific bacilli, with other microbes. It consists of the mortified papillae and upper part of the derma. Its parts are quite disorganised and it presents no structure, nor is nuclear staining possible. It is separated from the still living parts of the subjacent derma by a layer of embryonic cells, a sort of rampart between the living and the dead tissues. The subcutaneous cellular tissue beneath is infiltrated with exudation and embryonic cells. Anthrax bacilli may be present in the eschar, and if so, will be most numerous in the stratum of embryonic cells. The bacilli are scattered through the derma and subdermal tissues, sometimes in great abundance, sometimes in islets, with clear, intervening spaces, but are not found in the blood-vessels. The bacilli are also absent from the hair follicles, and from the glomeruli of the sweat glands. They do not usually extend beyond the deep cells of the rete mucosum. When they penetrate the rete mucosum they speedily cause destruction of the epidermis, and the formation of microscopic eschars. By the coalescence of several of these, larger eschars are formed. The skin and subdermic cellular tissue are frequently infiltrated with gelatinous exudation, rather resembling in consistence the vitreous humour of the eye.

Treatment.—There is no drug which can be administered with any hope of destroying the virus within the system. The administration of antiseptics internally with this view is useless, and may be injurious. The main indications are to destroy the nidus of the bacilli, so as to prevent general infection of the organism. To this end active surgical treatment is called for, and the earlier it is employed the more likely is it to be successful.

The destruction of the pustule is best

effected by the thermo-cautery or other powerful caustic, as incision may lead to the introduction of the virus into the blood through gaping wounds in the vessels. The application of roughly powdered bichloride of mercury to the raw surface is strongly recommended by some. It causes a hard, dry eschar to form. Potassa fusa, Vienna paste, carbolic acid, and chloride of zinc have also been employed for the same purpose. The local application of powerful disinfectants is especially useful, and subcutaneous injections into the œdematous tissues of such fluid is also to be recommended. For this purpose weak solutions of iodine, carbolic acid, or bichloride of mercury are the best. The injections should be made once or twice daily in several places, according to the size of the infected part. Internally, quinine, ammonia and bark, carbolic acid and iodine are especially advisable, with abundance of beef tea, eggs, and wine; in fact, any form of good nourishment which is acceptable and digestible. The bowels and skin must be attended to, and, if there be evidence that the virus entered by the intestines, active purgation and the administration of iodoform in pills, with a coating insoluble in the gastric secretions, are indicated.

INTERNAL ANTHRAX.—The virus of anthrax may be spontaneously absorbed otherwise than through a wound in the skin. In such cases it produces a disease known as internal anthrax. This form of the disease is undoubtedly due in the majority of cases to infection from the digestive tract, and probably in most cases the intestine. But infection through the lungs also occurs, and ingenious experiments have been performed (Buchner) to show that, in the case of mice, pulmonary infection is much the most frequent, and also that the bacilli are harmless when swallowed, and that the spores may pass uninjured through the stomach and intestines of those animals. But these experiments did not at all exclude the possibility, or even the probability, that some of the dust containing the virus was swallowed in the cases in which death was attributed to inhalation.

Symptoms.—In Wool-sorters' Disease the symptoms usually come on and terminate with terrible rapidity. They last as a rule three to four days, but a wool-sorter, who was well and at his work at 10 A.M., has been known to die of anthrax at 2 P.M. on the following day.

The patient usually goes to work

feeling in perfect health, and after a time complains of being dizzy, faint, or "out of sorts." Chillsiness follows within an hour or so. Sometimes there are complaints of tightness in the chest, or of dull pain in the front or back of the thorax; but pain is not a prominent feature. Usually as the case proceeds moist râles may be heard over the lungs, but there is no evidence of pneumonia. The temperature, which may rise to 100° or 101° F. for a short time, in the axilla, soon falls below normal. But this fall in the temperature of the axilla does not affect the whole body equally, and erroneous conclusions may be drawn from it. It is a regular experience to find that the rectal temperature exceeds that of the mouth and axilla much more than is normal, sometimes by as much as 1°–2° F. in the former, and 3°–4° F. in the latter.

Frequently the body is bathed in cold, clammy sweat. The patient is very weak and prostrate; he is dull and dejected, the breathing is quick and shallow, the pulse rapid and very feeble, but the mind is usually clear. Liquid nourishment is taken readily to the last. As the end approaches unconsciousness supervenes, and the breathing becomes laboured. Among the less common symptoms are delirium, diarrhœa, and severe pains in the limbs and joints.

When the local sore is extensive and foul, there may be added to the symptoms of anthrax those of wound fever, or pyæmia.

The symptoms in cases which do not run so rapid a course, generally commence with a feeling of fatigue, dull pains in the limbs and headache, singing in the ears and giddiness, with general feeling of malaise. These symptoms may be followed by pain in the stomach and bowels, with distension, vomiting and diarrhœa, the motions being sometimes bloody. As the case progresses the breathing becomes embarrassed. There is cyanosis, restlessness, or perhaps drowsiness. The pulse is generally quick and compressible. The temperature in the axilla is but slightly increased. If the case does not soon take a favourable turn, cyanosis and algidity occur with profound prostration, and the patient dies.

Morbid Anatomy.—The following are the chief changes observed. At the seat of experimental inoculation in animals there is never a tumour similar to the "malignant pustule" of man. There is, indeed, rarely pus, or other evidence of

inflammation. In animals death generally ensues so rapidly that there is little time for extensive lesions to form in the tissues. As in man the blood is not coagulated, but dark and liquid. Externally there is commonly more or less cyanosis, notably of the extreme points, nails, tips of ears, &c. There is sometimes subcutaneous emphysema, no doubt from rapid decomposition. Microscopical examination and cultivations of blood and exuded fluid may show the presence of the specific bacillus, and inoculation of mice or guinea-pigs proves the pathogenic properties of the microbe. Ecchymotic patches also occur in the lymphatics, and elsewhere. There is usually more or less exudation of serum, sometimes bloody, sometimes clear and straw-coloured, into the serous cavities. The serous surfaces of the stomach and intestines commonly present ecchymoses, varying in size from a pin's head to that of a shilling, and either light or dark red in colour. The mucous surface is generally not affected. Clear, gelatinous infiltration is often found under the sternum, and around the kidney and other parts. The spleen is enlarged and soft, or even diffuent, and very dark. The lymphatic glands, especially near the pustule, are large, dark in colour and engorged with blood. Mediastinal cellulitis with an engorged and hemorrhagic condition of the bronchial glands are also characteristic appearances.

Pathology and Aetiology.—The specific organism, the bacillus anthracis, was first observed by Delafond (1848), but Brauel (1857) first described it as pathognomonic. The researches of Pasteur, followed up and completed by those of Koch, definitely established the causal significance of the bacillus.

The bacilli are not, as a rule, to be found in the blood during life, but may be discovered in small numbers immediately before death; shortly after death the blood swarms with them. They appear then under the microscope as motionless, straight, clear, cylindrical rods in length from twice to ten times the diameter of a human red blood-corpuscle. The longer ones are found to consist of several short ones united by their extremities, the individual bacilli being about the diameter of a human red blood-corpuscle, and in breadth about a quarter to a third of their length. When stained with basic aniline colours—*e.g.*, methyl violet—a bright unstained spot appears at the junction between two bacilli, due to the ends of each being concave, and

thus leaving a space when brought together end to end (*see* Figs. 13 and 14, p. 521).

The bacilli multiply by fission within the body, but by fission and endogenous sporulation out of the body in a suitable medium, they grow readily in neutral peptone-broth-gelatine, milk, urine, on vegetables, &c., at the ordinary temperature of the air, and produce spores at temperatures between 12° and 43° C. (= 53.6° and 109.4° F.) The bacillus grows in a suitable culture-medium into long, undulating filaments, which, when stained, exhibit spores, distinguishable by not absorbing the colouring matter in the ordinary way.

The macroscopic appearance of a cultivation in or on gelatine is as highly characteristic as the microscopic appearance of the organism. Gelatine culture-medium (10 per cent.) begins to liquefy at the top from the third to the fifth day.

The bacillus is easily killed by heat, cold, desiccation, disinfectants, &c., but the spores are much more resistant: the bacillus will die in 1 per cent. solution of carbolic acid in ten seconds, but the spores will resist a 5 per cent. solution for over a month; bacilli perish in water at 55–60° C. (= 131–140° F.) in ten to fifteen minutes, but spores will resist a temperature of 100° C. (= 212° F.) for some minutes.

The process of digestion will destroy bacilli, but spores can resist it, and, by being absorbed in the intestine, may cause general infection.

At the present time it is not known that there is any material evolved by the bacillus which produces the symptoms, as has been proved by Roux to be the case with the bacillus of diphtheria.

Incidence of Anthrax.—The disease never occurs spontaneously in man. The virus in cases of internal anthrax may be derived from the consumption of meat, milk or butter from infected animals, or from dust inhaled or swallowed, as may occur during the preparation of certain mohairs and alpaca, which are usually very dry, and give off clouds of dust. The disease is practically limited to persons brought directly in contact with the virus developed in infected animals—*e.g.*, shepherds and cowherds, stable-men, slaughtermen, farmers, hide and skin dressers, and persons engaged in preparing wool, hair, bones, horns, &c. Woollsorters believe that a person may have many

slight attacks, and at last be fatally attacked; but it is proved experimentally that animals (sheep, cattle, horse, mule, ass, &c.) may be protected for some time by giving them a mild attack by inoculation of attenuated virus.

Treatment.—The indications are the same as for the local disease (*vide* MALIGNANT PUSTULE). Various methods of attenuation of the bacillus for preventive (not curative) inoculation have been practised. Pasteur uses two "vaccines." The first (weaker) has been attenuated by keeping at 42–43° C. (=107.6–109.4° F.) for twenty-four days; the second (stronger) has been similarly treated for twelve days. They are inoculated at an interval of twelve days. The attenuated bacillus may be propagated without increasing its virulence, or it may be restored to its primitive virulence by suitable cultivation. Chauveau used oxygen, Arloing utilized the action of sunlight, others have used certain disinfectants (carbolic acid, &c.) to effect attenuation. After "vaccination" with attenuated virus, animals enjoy immunity for about a year.

T. W. HIME.

PYELITIS, (including **Pyelonephritis** and **Pyonephrosis**).—Inflammation of the pelvis of the kidney. If combined, as is often the case, with inflammation of the kidney substance itself, the term "pyelonephritis" is given to the disorder; while if the purulent results of the inflammation are pent up in the pelvis of the kidney the resulting cyst, filled with pus, is called a "pyonephrosis."

Pyelitis is produced by the mechanical irritation of calculi or blood-clot lodged in the pelvis of the kidney, or by the presence of parasites, tubercle, or tumours in its mucous membrane. Pyelitis may also arise in the course of various specific fevers, of diabetes, and of chronic Bright's disease. It may be the result of cold or of the action of turpentine, cantharides and other irritant diuretics given internally. Stagnation of urine in the pelvis of the kidney and ureters, especially if the urine be decomposed, is prone to set up severe pyelitis. Such stagnation may be due to obstruction in the ureter or to pressure upon the tube from the outside, as by a tumour or the pregnant uterus. Inflammation may extend to the pelvis from the lower urinary passages, from the kidney itself, or from neighbour-

ing tissues. When secondary to bladder or urethral disease, pyelitis is a variety of so-called SURGICAL KIDNEY (*q.v.*).

Symptoms.—The early symptoms are pain and tenderness in one or both lumbar regions. A slight amount of pyrexia may be caused by the pyelitis alone, independently of the original disease. The urine is generally faintly acid, contains a large quantity of mucus, and deposits copiously the characteristically irregular epithelial cells of the pelvis of the kidney. A small quantity of blood also may be present in the urine. Somewhat later, the irregular cells become fewer in number and pus corpuscles take their place. The urine contains albumen, but in quantity only proportionate to the amount of blood and pus which are found in it, provided that the inflammation be confined solely to the pelvis of the kidney. When the disease has extended to the kidney substance proper, constituting a pyelonephritis, albumen appears in larger amount, and with it various forms of casts and cells from the renal tubes may be found in the urinary deposit. The urine is commonly passed more frequently than is normal. There may be rigors, becoming more pronounced and frequent as pus formation is more definitely established. Accompanying the rigors, the temperature shows variations resembling those of hectic fever. The bowels act irregularly. Usually there is obstinate diarrhoea, but when the pelvis of the kidney becomes so distended as to press upon the colon constipation is observed.

The condition of the urine as described above is subject to variations, for ropy mucus and viscid pus, coagulated blood, epithelial debris, or portions of calculus and hydatids, according to the nature of the original cause of the inflammation, tend to obstruct the lumen of the ureter, and so lead to the accumulation in the pelvis of the kidney of the inflammatory products which no longer reach the bladder. If the disease be unilateral the urine now becomes normal, since it comes from the normal kidney; if bilateral the abnormal deposit in the urine is diminished in amount; such obstruction is usually temporary. When at last it is overcome, there is a sudden rush of the pent-up secretions and the urine is again loaded with pus, mucus and epithelium.

The accumulation of inflammatory products distends the pelvis of the kidney,

and in the later stages causes a swelling to appear in the lumbar region. This swelling has the ordinary character of a tumour of the kidney, it is crossed by the colon, it can usually be separated from the liver and spleen respectively, and it often causes distinct bulging, not only in front but behind, in the loins. It is dull on percussion, presents obscure fluctuation, is tender on pressure, and is the seat of dull, aching pain. The swelling may attain a considerable size, but is in this respect subject to variations according to the relatively closed or open state of the ureter as mentioned above.

When a swelling has formed in the flank, the urine may still possess the characters already described. By this time, however, it has in most cases decomposed and become alkaline and ammoniacal. In certain cases the distended pelvis is completely shut off from the lower urinary passages, and then, provided that the opposite kidney be sound, the appearance of the urine is normal.

The symptoms described above are those which are due to the pyelitis itself. In addition, the primary disease, whether stone, hydatids, or tumour of the kidney, will cause its own characteristic symptoms, which may even entirely overshadow those of the secondary pyelitis.

Results.—When free communication is maintained between the kidneys and the bladder, the discharge may gradually disappear, or it may continue profuse and the patient be exhausted by the drain. The sac of a pyonephrosis may undergo spontaneous cure. This occurs in several ways. The pus may become inspissated; if so the sac contracts, its walls thicken, and at last nothing may be left but a mass of fibrous tissue in the place of the kidney. Again, the contents of the sac may become caseous, especially if the exciting cause be tubercle. Lime salts may be deposited in the inspissated pus in such amounts as to cause absolute obliteration of the sac and its transformation into a calcareous mass. Lastly, the sac may burst, and the liberated pus may make its way along various channels; these are mentioned under the headings SUPPURATIVE NEPHRITIS and PERINEPHRITIS.

Diagnosis.—Without tumour in the flank, the symptoms of pyelitis are likely to be mistaken for those of cystitis, and it must be remembered that the two conditions may be combined. With

pyelitis there is pain and tenderness in the region of the kidneys, the urine is more frequently acid than in cystitis, and there may have been a history of renal colic or renal hæmaturia, pointing to a stone in the pelvis of the kidney. The character of the cells found in the urine will not help in the diagnosis. The tumour of pyonephrosis must be diagnosed according to the rules for other renal tumours. Its fluctuation, deeper than that of perinephritic abscess, its regular form, the preceding pyrexia, and the constitutional symptoms of suppuration will serve to distinguish the pyonephrosis from other tumours of the kidney. The fluctuations in size of the tumour, corresponding with variations in the state of the urine, constitute an important diagnostic feature.

Prognosis.—This depends on the cause of the disease. If it be due to cold or to one of the general diseases mentioned, it is commonly of little importance. If caused by obstruction to the lower urinary passages, it adds materially to the gravity of the prognosis, whatever may be the nature of the obstruction. The rupture of a pyonephrosis is a very serious matter. The recent advance in renal surgery has rendered the treatment of cases of pyonephrosis more successful than formerly, and though the condition is grave, favourable results may be obtained by the adoption of proper measures.

Pathological Anatomy.—In the early stages the mucous membrane of the pelvis of the kidney is congested, and may even show ecchymoses. Microscopic examination reveals proliferation of the epithelial layer. Sometimes, in severe cases, portions of false membrane may be seen to cover the surface of the pelvis. In the later stages, the mucous membrane is thickened and of a greyish colour. It is often ulcerated in patches, while on microscopic examination the tissue is seen to be infiltrated with leucocytes, and the normal coating of irregular and dove-tailed cells is exchanged for layers of leucocytes. The pelvis is now more or less dilated, and the infundibula become merged into the general cavity.

In pyelo-nephritis, in addition to the changes mentioned above, the kidney shows the appearance of parenchymatous nephritis, or even of acute interstitial suppuration.

When pyonephrosis has formed, the appearances vary according to the stage which has been reached. A sac of pus

is invariably found, to which may be attached an almost normal kidney. As the distension of the pelvis increases the kidney-substance atrophies, so that finally nothing is found but a loculated sac, constituted by dense fibrous tissue, filled with more or less inspissated pus and degenerated epithelial cells, with possibly a calculus or other matter which has been the exciting cause of the inflammation. If the urine has remained acid, a deposit of uric acid or urates may be found. When, however, the urine has become ammoniacal, phosphates are deposited. Adhesions are commonly observed between the sac and surrounding parts.

Treatment.—The cause of the pyelitis must be treated by the measures appropriate to each condition. The pyelitis itself may be treated in the early stages by rest, warm fomentations and poultices, and leeches or cupping applied to the loins. The diet should be light and easily digestible, diluent drinks should be administered freely. Pain, if severe, may be alleviated by the use of opium. When the disease has become chronic and a pyonephrosis has developed, the object of treatment should be to diminish the secretion of pus and promote the obsolescence of the suppurating sac. To this end, the internal use of the mineral acids, the perchloride of iron, alum, and other astringents may be tried. In very chronic cases turpentine, best given in capsules, and tincture of cantharides, have been found of value in checking the inflammation. The patient's strength must be maintained by nourishing food, quinine, cod-liver oil and change of air. If, however, there are signs of hectic and the patient is becoming emaciated and worn out by continuous discharge, palliative treatment is no longer to be pursued, and surgical interference is urgently called for. Nephrotomy must be performed according to the recognized rules of surgery. Further, when the kidney has been transformed into a cheesy mass, and also when, after incision, the abscess cavity refuses to close, the more serious operation of removing the whole kidney (nephrectomy) may be required.

ROBERT MAGUIRE.

PYLORUS, OBSTRUCTION OF.

—The pylorus may become obstructed from the cicatrization of a neighbouring ulcer, or from fibroid thickening, but most commonly it results from cancer. It may also be due to the pressure of neighbouring tumours and to spasm

arising from the presence of an ulcer in the neighbourhood.

Symptoms.—Pyloric obstruction is evidenced by pain and vomiting. The pain steadily increases as digestion proceeds, and extends from the epigastrium round the waist. If the obstruction be severe it is only relieved when vomiting occurs. Vomiting is delayed till four hours or more after food, or may occur only once a day, or at still longer intervals, and is profuse in amount on account of the dilated state of the stomach. The vomited matters may contain sarcinæ and torulæ (see figs. 7 and 12, p. 521), but no bile, the regurgitation of which is barred by the obstructed pylorus. As obstruction increases, the stomach becomes dilated and its muscular coat hypertrophied.

On examination of the abdomen, while the symptoms are at their height, and before vomiting has taken place, a depression of the epigastrium and a fulness of neighbouring regions of the abdomen, especially of the *left* hypochondrium, will probably be detected, and peristalsis may be observed. The area of stomach dullness or the stomach percussion-note will be extended downwards. A succussion splash may be felt, or heard with the stethoscope. The heart will probably be found displaced upwards. The range of the stomach downwards may be plumbed with a probang.

Diagnosis.—The differential diagnosis between obstruction due to malignant and non-malignant disease is often a matter of considerable difficulty. It turns mainly on the presence or absence of a defined tumour, but also upon the age of the patient and the history of the case. The degree of emaciation is rarely of much service as a guide, as it is usually considerable in either case, owing to the small quantity of food absorbed. Obstruction of the duodenum from the cicatrization of an ulcer and subsequent dilatation of the pylorus is a condition practically indistinguishable from pyloric obstruction (see ABDOMINAL TUMOURS).

Prognosis.—If the obstruction be of cancerous origin, the condition is necessarily fatal; if it be due to cicatrices or fibrous thickening and is partial only, careful feeding combined with washing out of the stomach may enable the patient to live in comfort; but if it be complete, operative means can alone give permanent relief.

Treatment.—An attempt must be made to utilize the stomach to the extent of its power without overloading it. To

this end, some fluid food, as plain soup, milk, arrowroot or gruel, should be given in quantities not exceeding $\frac{1}{2}$ pint, at three-hour intervals. If this be tolerated the quantity may be cautiously increased, and a little bland, solid food, such as bread soaked in milk or finely minced meat, may be experimentally added, until the limit of the digestive power of the stomach has been ascertained.

To remove, as far as possible, the risk of distension by gas, fermentation should at the same time be checked by the administration of 1 grain of carbofic acid or 1 minim of creasote, or $\frac{1}{2}$ grain of thymol, in pill, or a drachm of sulphurous acid in 3 ounces of water, or a teaspoonful of charcoal stirred up in water, once or twice a day.

Pain should also be relieved, and irritability of the gastric wall reduced, by morphine, belladonna, or hyoscyamus. Hydrocyanic acid is sometimes useful.

If tolerance of ordinary food cannot be established by the above means, artificially digested aliments may be substituted, but in the majority of cases it is necessary sooner or later to prepare the stomach for the reception of food by a systematic process of "washing out," and as a rule the earlier in the case this mode of treatment is adopted the better for the patient. The operation should be conducted at first half an hour before each meal.

The instrument used (Tosswill's siphon) is a long soft india-rubber tube, fitted with a ball pump. The patient being seated the tube is slowly passed into the stomach with a gentle rotary movement. The patient will very soon be able to do this for himself. Water is first injected into the stomach, the organ is then completely emptied of its contents and subsequently washed out with tepid water containing dilute sulphurous acid (a drachm in 2 to 3 ounces of water). The meal taken half an hour later should be as "dry" and of as small a bulk as possible. After a week or so the washing may be done less frequently, once a day being soon sufficient, but care must be taken not to allow the stomach to become distended. Under this treatment vomiting ceases and nutrition markedly improves; in fact it offers to the subject of pyloric obstruction immunity from some of the worst consequences of the condition.

Rectal feeding may, of course, be resorted to as an aid to other measures.

The operation of digital stretching of the pylorus (Loreta's operation) has

been performed with success in a few cases, and is worth a trial if other means fail.

Another surgical procedure, known as "short-circuiting the duodenum," in which the stomach is united to the upper part of the jejunum has been resorted to in a few cases. ISAMBARD OWEN.

PYOMETRA.—Pus within the uterus. The condition is rare, and occurs almost exclusively in old women who have ceased to menstruate. The pus is the result of endometritis, and its escape may be prevented either by atresia of the cervix from cicatrization, by blocking of the cervix by fibroid or cancerous growth, by fixation of the uterus in a bent shape by adhesions, or by "kinking" of the thin-walled uterine canal by flexion.

Symptoms.—Pyometra *per se* causes few symptoms, and those of a vague kind. It is usually discovered owing to advice being sought for the disease of which pyometra is an effect; and it has often been unexpectedly found post mortem.

The treatment is to open up the cervical canal and let out the pus.

G. E. HERMAN.

PYROSIS (Water-brash).—Strictly speaking, pyrosis means heartburn, but it is always used to indicate the ejection of a clear watery fluid from the mouth in certain forms of gastric disorder. An attack commences with severe spasmodic pain and a sense of constriction at the epigastrium, which is not relieved until this clear, tasteless fluid is ejected. The quantity is generally small, about two or three ounces, but may be a great deal more; it is non-albuminous, and has been found by some observers to contain sulphocyanide of potassium, a fact which would point to its consisting in part at least of saliva; others believe that it is produced in the stomach, chiefly near the pylorus. Pyrosis is a symptom of dyspepsia rather than of organic disease of the stomach, and is commoner in women than in men; it is met with much more frequently in some districts than in others, and is believed to be largely due to the coarse character of the diet adopted by those who suffer. The astringent vegetable infusions (gentian, orange, cinnamon, or any containing tannic acid) in ounce doses, combined, if need be, with small doses (5 to 10 minims) of laudanum, give the most satisfactory results in treatment.

PYURIA.—The presence of pus in the urine. This condition may depend upon disease of any portion of the urinary or genito-urinary tract. Increased frequency of micturition is the only symptom common to all the different forms, and even this is not constant.

Characters.—The urine is generally slightly albuminous. Its appearance varies with its reaction when passed. If *neutral* or *acid*, it is turbid, and gradually separates into an ivory-tinted sediment and clear supernatant urine. Urates may impart a pinkish tinge to the deposit, but more often they occur as an upper stratum. The addition of an equal bulk of liquor potassæ to a portion of the sediment dissolves the pus cells and renders the resulting mixture clear, and at the same time so tenacious that, when poured from the test-tube, it falls *en masse* like imperfectly set jelly. A deposit of triple phosphates (NH_4MgPO_4) may be distinguished from that of pus by the fact that it is whiter and more flocculent, is soluble in acetic acid, and occurs but rarely in acid urine. When the urine is *alkaline*, as for example in cystitis, the sediment is less defined, but forms more rapidly. It is tenacious andropy, while the supernatant fluid remains cloudy. The urine is often fœtid and generally contains a deposit of triple phosphates. The addition of liquor potassæ to the deposit may slightly increase its tenacity; the less ropy and tenacious the sediment, the more marked will be the effect of the liquor potassæ. If necessary, pus may be distinguished from mucus by the addition of corrosive sublimate, which precipitates pyin but not mucin (Ralfe). Under the microscope, pus cells will, in any case, be seen as globular bodies somewhat larger than red blood discs and granular; the addition of acetic acid clears up the granular contents and brings the nuclei into view.

These are small, two or three to each cell, partly superimposed or closely aggregated, and often take the form of a bent chain with three links.

Causation.—(1) In renal abscess the pus is in small quantity, and some of the cells may be found imbedded in casts from the renal tubules. The urine generally contains blood and is of acid reaction. (2) In the so-called surgical kidney (acute consecutive nephritis) the characters of the pus are much the same; cystitis often coexists, and the urine will vary accordingly, but the presence of pus casts would be conclusive evidence that the kidney was affected. (3) In pyelitis, owing to occasional temporary blocking of the ureter, the urine varies greatly; at one time there may be a copious deposit of pus, at another none at all. In the early stages red corpuscles may be found as well as swollen epithelial cells—spindle-shaped, caudate or spheroidal—from the pelvis of the kidney. (4) In cystitis the urine is alkaline and presents the characters already described. (5) In urethritis or inflamed prostate the pus is small in amount and imperfectly mixed with the urine, forming small shreds. A drop or two can generally be squeezed from the orifice of the urethra. (6) In leucorrhœa or vaginitis, the quantity is small, and vaginal pavement epithelium abounds in the deposit. (7) If an abscess burst into any portion of the urinary tract, the pus is at first passed in large quantities, and then either disappears altogether or a small quantity is passed daily. In gouty subjects or those who have suffered from previous attacks, a very slight cause, such as a trifling error of diet or a chill may produce a transient pyuria.

The pathology and treatment are considered in the descriptions of the diseases which give rise to this condition.

H. MONTAGUE MURRAY.

R

RAYNAUD'S DISEASE (Symmetrical Gangrene).—This affection, named after Maurice Raynaud, who first accurately described it, includes at least three fairly well defined disease states, which probably correspond to different stages of the same morbid process.

These are, in order of increasing severity, **Local Syncope**, **Local Asphyxia**,

and **Local Gangrene** (*Symmetrical Gangrene*).

The essential factor in the disease appears to be a narrowing (vaso-motor spasm) of the small arteries and capillaries in certain parts of the body, notably the extremities, attended by great retardation or even arrest of the capillary circulation; whilst the general character and symptoms of individual

cases are chiefly dependent on the situation, extent, and nature of the effects of the vascular disturbance on the nutrition of the affected areas. The symmetrical arrangement of the lesions is often very striking, and constitutes a diagnostic point of some importance, but it is not constant, as was formerly believed, and unfortunately led to the adoption of the somewhat inappropriate term symmetrical gangrene.

Local Syncope.—The phenomenon familiarly known as “dead finger” is essentially local and compatible with perfect health. Females suffer more than males. The commonest determining cause is cold, but a degree of cold which would produce no effect on individuals not predisposed. This statement applies equally to the other forms of the disease. Sudden emotion and mental shock are mentioned as causes, and the coldness of the hands which accompanies nervousness is suggestive in this connection. The condition is also sometimes observed after meals. The affected fingers or toes become cold, dead-white, and bloodless; cutaneous sensibility is blunted or abolished; and motor power may be temporarily lessened. The attack is transient, and is succeeded by a period of reaction which is often painful.

Local Asphyxia.—In this form of the disease the affected parts become cold and cyanotic. The skin assumes a bluish-white, violet, slate-coloured, or blue-black tint not unlike an ink-stain. The lesions are symmetrical in the large majority of cases, and most often affect the extremities. In some cases they are limited to one or more fingers or toes, whilst in others a segment or even an entire limb may be involved. The severity of any given case does not necessarily stand in any definite relation to the surface extent of the lesions. Next to the limbs the ears are most frequently involved, and less commonly the tip of the nose also suffers. Much more rarely the appearance of symmetrical livid patches on the backs of the hands or some other part of the arms, legs or trunk, constitutes the only deviation from health. There is often slight œdema of the affected parts, and livid venous marblings above the level of the discoloured areas are common. The capillary circulation in the livid patches is always much retarded, so that the dead-white mark caused by pressure with the finger-tip is always slow to disappear. Pain is a very frequent, but not invariable, symptom. It

may be localized in the livid extremity or radiate through the affected limbs. It is at times of an excruciating character, and may precede the appearance of the lividity. There is generally more or less complete cutaneous anæsthesia, which interferes considerably with the performance of fine movements, and there is nearly always some loss of motor power. The period of reaction is usually attended by irritating, tingling sensations.

The *progress* of local asphyxia is mostly paroxysmal, periodicity being often well marked and frequently of quotidian type. In such cases each attack commences in the same region and follows the same order of development, the blueness lasting from a few minutes to several hours.

As the attack passes off, less livid patches make their appearance in the affected region, and gradually coalesce; at the same time, a zone of vermilion colour invades the blue skin from the proximal side, eventually giving place to the normal pink colour of the skin. When the asphyxia is limited to the fingers or toes, there is no appreciable disturbance of the arterial circulation; but when it occupies the whole of a limb, the pulse may become small and feeble at the commencement of the attack, the beats recovering their usual strength and volume as the asphyxia subsides.

In course of time a sort of flabby false œdema of the affected digits may become established, but is by no means common. This has been attributed to an overgrowth of the subcutaneous cellulose-adipose tissue. More often the fingers gradually acquire tapering extremities. The general health, as a rule, is good. Not a few of the subjects of this disorder, however, are chlorotic and hysterical.

The differential *diagnosis* from cyanosis due to other causes is easy. The absence of organic heart or lung disease, the occurrence of local pain or tingling, the intermittent character of the affection, and the absence of clubbing of the fingers are some of the more important diagnostic signs of the disease.

The ultimate *prognosis* is usually favourable; but it must be borne in mind that local asphyxia may eventuate in local gangrene, although the symptoms of this condition do not invariably precede those of the graver disease.

Local or Symmetrical Gangrene.—In this form of the affection the extremities become first exsanguine and then blue, or from the first assume a purple or reddish livid hue. At the onset the

affected areas are often the seat of itching or tingling sensations, and the patients commonly believe they have chilblains. These early pains are often relieved temporarily by the application of cold, but in the course of a few days increase greatly in severity, whilst the deepening violet colour and icy coldness of the parts, leaves little doubt as to the nature of the affection. At this period livid marblings usually make their appearance in the neighbourhood of the affected part, extending for a varying distance up the limb. Beyond this stage the progress of events varies in different cases. In some, one or more digits become entirely black and insensitive; small blisters form on the tips of the fingers, break, and eventually heal up in the course of a few days, as the vitality of the part becomes restored. Such a recovery is often but temporary, being followed at intervals by a series of similar attacks affecting the same or other digits. In such cases, at an advanced stage of the disease, a number of small, hard, white, depressed scars may be seen on the pulp of all the fingers. The affected digits tend to become conical, shrivelled and tough, resembling parchment. The digits, however, may become mummified without the previous occurrence of blisters.

In other cases the gangrene develops more rapidly. The extremity of a digit or an entire phalanx rapidly becomes black and icy cold. Blisters do not form, but the affected part is sometimes covered with beads of sweat. In the course of a few days a line of demarcation forms at the proximal side of the necrosed tissues, which are then gradually thrown off by suppuration. The slough is often not more than one or two millimetres in thickness, although the aspect of the part before its separation might lead one to expect much deeper destruction. Sometimes, however, the process results in the loss of part or the whole of the ungual phalanx, or of the whole digit, and in cases of exceptional severity whole segments of limbs may separate. The remaining stump is covered with granulations, which generally heal rapidly. Not rarely the several stages of the process occur simultaneously in the same patient.

Although the gangrene commonly affects the extremities, a good many cases are recorded in which other parts of the body were attacked. Thus, in several instances, gangrenous patches have appeared on the heels, malleoli,

calves, tibiae, &c., parts be it observed which have a counterpart on the other side of the body. More rarely mortification attacks the nose, and has been known to destroy it almost entirely, whilst considerable damage may result to the helix of both ears from repeated attacks of the disease.

When the extremities are the seat of the disease the growth of the nails is always arrested during an attack. Sometimes the nails are shed; at others, when they have grown again, a transverse depression indicates the period of arrest.

Pain is the dominating symptom of the disease. The numbness which accompanies local syncope is here replaced by darting or burning pains, either limited to the affected parts or radiating through the limbs. These pains may be prolonged for weeks, and are often excruciating. The affected parts are insensitive and their motility is always more or less impaired. A true motor paralysis may become established from the association of peripheral neuritis. As regards the circulation, there may be an initial rise in the pulse-rate without elevation of temperature. Livid venous marblings are often present, and the capillary circulation is always slowed. The arterial pulse in the affected limb may diminish temporarily in volume, but never becomes altogether obliterated. The general health of the patient is usually good.

The *progress* of local gangrene may be continuous or intermittent, but the continuous type is relatively rare. Speaking generally, the most profound gangrenes present most regularity in their development. Raynaud describes three stages:—(1) The period of invasion, during which symptoms of local asphyxia predominate; (2) the stage of painful crises, during which the gangrene becomes limited and complete; and (3) the period of elimination, which is of varying duration, generally from three to four months, sometimes longer.

Diagnosis.—This should not present any difficulties; still, in the earliest stages there may be some difficulty in distinguishing from chilblains. Gangrene once established, the diagnosis from senile gangrene rests mainly on the age of the patient (the average age of over 120 cases was about 27 years), the symmetrical or multiple character of the lesions, their incomplete and limited nature, their non-progressive character, and the previous state of the vessels leading to the affected areas. From gangrenous

ergotism, the chief diagnostic sign is supplied by the history.

The *prognosis* is grave, but not unfavourable. Patients seldom die of the uncomplicated disease, and experience uniformly shows that the actual amount of destruction is nearly always very far short of what the earlier stages of the process (asphyxia, coldness, &c.), seem to foreshadow. In very young children, however, the disease may assume a very acute and destructive type. There are on record several such acute cases, in which symptoms of asphyxia and gangrene have progressed uniformly and uninterruptedly to a fatal issue in from two to four days. If gangrenous patches make their appearance within fourteen days of the date of invasion, there is a reasonable hope of recovery in four or five months. The immediate prognosis is, however, less good in the milder cases of intermittent type with recurring blisters and cyanosis. Although not dangerous to life, this form of the disease often exposes the patient to long-continued and intolerable pain.

Pathology and Ætiology.—This somewhat rare disease is relatively frequent amongst children, and a considerable portion of the cases occur between fifteen and thirty, but after that age the liability to the affection diminishes. The oldest well-authenticated case was fifty-nine, whilst a child of eight months under the writer's care presented a well-marked local asphyxia of paroxysmal type. Women appear to be more liable to the disease than men, and it shows a decided preference for persons of a nervous or excitable disposition.

Exciting Causes.—The effect of lowering of the external temperature has been already alluded to. Whether suppression of the menses should find a place here appears doubtful, although Raynaud himself attached considerable importance to this accident.

Attacks of local asphyxia may be ushered in by a fit of passion or follow close upon some sudden mental shock. A considerable number of cases have occurred in lunatics, and it may be observed in this connection that symptoms of hysteria of every grade may accompany the attacks of Raynaud's disease. In one recorded case there was acute mania. A condition of unstable nervous equilibrium thus appears to be an important predisposing factor. Raynaud mentions a case in which a blow on the outer part of the arm in a man was followed by a profound local syncope of

that extremity, lasting continuously for ten days. In a boy of nine, recently under the writer's care, a series of well-marked paroxysms of local asphyxia affecting the left hand was determined by a dog-bite in that situation. This patient was at the time suffering from syphilitic ulceration of the pharynx.

Associated Diseases.—*Intermittent hæmoglobinuria* is often associated with local asphyxia and symmetrical gangrene. The clinical features presented by such cases, as might be expected, vary considerably. In some, dark urine is passed during or shortly after attacks of local asphyxia; or a typical attack of hæmoglobinuria may take the place of a typical paroxysm of local asphyxia.

Or again, a patient suffering from symmetrical gangrene will pass smoky or dark urine at intervals, or suffer from attacks of temporary albuminuria or oxaluria. In other cases patients suffering from paroxysmal hæmoglobinuria spontaneously develop symmetrical or asymmetrical gangrene of the extremities or of the nose or ears.

A study of the recorded cases shows that the alliance is a very close one, and a consideration of the two diseases reveals a marked parallelism between them. Both are essentially paroxysmal in nature, and stand in the same relation to changes of temperature. In the large majority of cases both diseases occur primarily in cold weather, and tend to diminish in warm weather. In both the attacks may be accompanied by some abdominal pain, and be followed by drowsiness and some sallowness of the complexion and conjunctivæ. The alterations present in the blood obtained from the finger of a patient during an attack of hæmoglobinuria—crenation, disinclination to form rouleaux, presence of granular masses in serum, &c.—have also been observed in the blood drawn from an extremity affected with local asphyxia. It has been truly observed that "the two conditions seem so to approach each other and mingle as to make it impossible to draw a distinct demarcation between them." Indeed, the view has been put forward that the two diseases are one and the same, *i.e.*, that hæmoglobinuria is a symptom of the more general affection. On the other hand, it should be pointed out that whereas Raynaud's disease is more common among females, hæmoglobinuria appears to affect a decided preference for the male sex. Malaria, which is an ætiological factor of considerable im-

portance in hæmoglobinuria, has hitherto been comparatively rarely found in association with the allied condition. Lastly, abdominal symptoms, such as epigastric pain, hiccough, colicky pains, nausea and vomiting are usually more prominent symptoms of hæmoglobinuria than of Raynaud's disease. The points of difference are admittedly of degree only, and cannot be held in any sense to impair the close analogy between the two conditions.

Affections of the Skin.—True chilblains are rare, but there are cases of localized subcutaneous purple mottlings, permanent for a time and then gradually fading, with or without pigmentation, which are closely related to local asphyxia. Urticaria—sometimes painful—has been known to occur during the paroxysms of Raynaud's disease. The parchment-like condition of the fingers has already been alluded to. A case is on record in which scleroderma of the chest walls developed in the wake of Raynaud's disease. Two patients suffering from scleroderma of the hands and feet had long been subject to dead hands and feet, and in one of them mild attacks of local asphyxia continued after the onset of the scleroderma. A man who suffered from extensive scleroderma of the trunk and extremities ultimately developed gangrene of the fingers and toes for which no gross lesion could be discovered post-mortem.

Joint Affections.—Effusions into joints—knee, elbow, shoulder, and wrist—have been observed. Fibrous ankylosis of the terminal phalangeal joints and thickenings of the palmar fascia may also occur.

Ague.—In several instances the disease has developed during or shortly after recovery from ague.

Syphilis, congenital or acquired, has been observed in several cases. Its precise bearing, if any, is as yet undetermined, but the well-known vascular and nervous lesions of this disease suggest the possibility of a causal relationship in some instances.

The relation to *peripheral neuritis*—one of considerable interest—is still undetermined. A few cases of symmetrical gangrene are recorded in which unmistakable post-mortem evidence of inflammation of the nerves of the affected extremities was obtained, and in one or two others clinical signs suggestive of neuritis, such as wrist-drop, diminished faradic irritability, &c., have been observed. These cases have been mostly of a chronic kind, and their progress does not

appear to have been much modified by the presence of neuritis. On the whole it appears doubtful whether peripheral neuritis should be regarded as an essential factor in this variety of spontaneous gangrene, and at all events it may safely be asserted that alone it is altogether inadequate to explain the early and paroxysmal stages of the affection (local asphyxia).

As regards the changes in the vessels, the view propounded by Raynaud has been generally accepted, viz., spasm of the capillary vessels, dependent on a reflex exaggeration of the excitomotor energy of the grey matter of the cord which controls vaso-motor innervation (spinal vaso-motor centres). There is some difference of opinion respecting the part of the vascular system which is affected, whether the arterioles alone or the capillaries as well become contracted. It appears probable that during profound local syncope arteries, capillaries and minute venules are all in a state of spasm, and it has been suggested that the supervention of asphyxia may be due to a dilatation of the venules. It is generally admitted that simple spasm is sufficient to account for the phenomena of local syncope and some cases of local asphyxia, but some authorities seem disposed to invoke the aid of another factor to explain the more inveterate cases of asphyxia and the production of gangrene, viz., a degradation of the vitality of the tissues involved, over and above that which must necessarily result from the slowing or temporary arrest of the circulation in the affected area.

The *retinal changes* described by Raynaud and other observers may fittingly be referred to in this place. In one of Raynaud's patients "the sight at times became troubled and confused. When the eyes were examined on these occasions, the central artery of the retina and the arteries which proceeded from it presented very clear contours, and it was established very definitely that they were narrower in their commencement near the papilla than at the periphery; here and there was observed a sort of partial strangulation." Another of his patients complained of dimness of vision at the commencement of some of his attacks of asphyxia. The correctness of these observations has since frequently received confirmation.

Some rare epiphenomena of the disease have been attributed to similar disturbances of the cerebral circulation. Such are mental hebetude on awaking from

sleep, accompanied by a loss of the notion of time and of position in space, temporary aphasia, temporary loss of consciousness and epileptiform seizures.

Treatment.—The affected parts should be protected from the external air by wrapping them in cotton-wool. The local application of warmth often relieves the painful crises, but in some cases cold applications have proved more efficacious. Galvanism of the affected limbs has often been attended with good results. This is most conveniently done by immersing the hand or foot in a basin of hot water containing the negative electrode whilst the other electrode of the constant-current battery is applied over the upper part of the limb or over the spine, due care being taken to thoroughly moisten the skin and the electrode before the latter is applied. The current employed should be of such strength as the patient can comfortably endure, and it should be frequently interrupted so as to cause moderate contractions of the limb. This mode of stimulation is usually better borne by the patient than is friction with the hand. The current may also be applied by simply "painting" with two sponge electrodes applied to the limb at a short distance from each other. It will often diminish pain to such an extent as to enable the patient to bear shampooing afterwards. In chronic cases the good effects of galvanism are less obvious, but even here it is of value in maintaining nutrition and averting gangrene. Shampooing is of especial value in these cases, particularly where atrophy of the extremity with contraction and fibrous ankylosis are taking place. Quinine has been used with good results in cases associated with malaria. In the case of the boy before referred to, the paroxysms ceased with the cure of the syphilitic ulceration from which he was suffering. Nitrite of amyl has been recommended on theoretical grounds, but has not, so far, achieved success. Among sedatives, opium and morphine are the best to combat pain. Careful attention to the general health and the exhibition of plenty of nutritious food are of importance. Among internal remedies, iron in some form is very often indicated. In cases of gangrene of the limited form, the expectant method recommended by Raynaud has been repeatedly justified; but, with deeper involvement of tissues, amputation has been performed with advantage.

W. PASTEUR.

RECTOCELE.—Prolapse of the posterior vaginal wall with the rectum.

The posterior vaginal wall may become inverted and protrude at the vulva, without the rectum. But often it drags the anterior wall of the rectum with it, so that a pouch is formed in the front of this viscus, in which fæces may lodge, and thus the emptying of the rectum becomes difficult or impossible until the prolapsed vaginal wall has been pushed up. Rectocele is usually associated with uterine prolapse, but it may occur by itself.

Treatment.—When associated with uterine prolapse, the treatment is to keep the uterus well supported by a proper pessary. If rectocele exist by itself, or if support of the uterus fail to give relief, the best means of cure is a plastic operation to contract the posterior vaginal wall. In the case of a woman young enough for subsequent child-bearing to be likely, treatment by mechanical support is preferable to an operation on the vagina, for the latter, if extensive enough to be effective, will either much obstruct delivery, or will render delivery only possible by considerable tearing of the parts.

G. E. HERMAN.

REFLEX DISORDERS.—In different parts of this work many affections are described which occasionally own a reflex origin, and others which perhaps are always dependent upon it. It is not intended here to consider each individual instance, but rather to inquire into the nature and origin of the group as a whole by reviewing certain illustrative cases.

—The mechanism by which reflex disorders are produced is the same as that which is required for the performance of reflex actions; indeed, the former often consist of nothing more than reflex action carried to an inordinate and pathological degree. Each case requires the integrity of the reflex arc—*i.e.*, the afferent sensory fibres, the ganglionic centre, and the efferent motor or secretory fibres. This is all that is necessary for the production of reflex action, and in some cases (such as renal colic, caused by a calculus in the ureter) is probably the whole of the mechanism required to induce a reflex disorder. Usually, however, the brain plays an important part, for it undoubtedly exercises a controlling power over reflex action, but opinions differ as to whether this is the result of diffusion of the afferent impulse into other areas or the restraining influence

of a special centre or centres. However this may be, various emotional states have a great effect upon reflex action, and may themselves take the place of, and produce the same result as, peripheral afferent impulses. Such cases are not purely reflex in origin, but they present such strong analogies that they will be considered here. A good example of these modes of action is afforded by laryngismus stridulus, which is essentially a respiratory spasm. This may be excited by peripheral irritation, *e.g.*, laryngitis or exposure to wind, and also by certain emotional states, such as sobbing and passion.

Varieties.—Efferent fibres are distributed to glands, voluntary and involuntary muscular fibres, and hence any of these may be modified under abnormal reflex conditions; and as the secretory functions of the glands may be by these means excited or suspended, so there may be over-action (spasm) or suspension (paralysis) of the muscular functions.

1. **Modified Secretions.**—These may be the result of emotional states or of reflex irritation. The most striking examples of the latter are found in the disturbances of the functions of the kidney under certain conditions. Complete suppression of urine is a common result of severe injuries to the abdominal viscera, and sometimes occurs after such slight irritation as attends the passage of a catheter or after the performance of Holt's operation. Psychical states may profoundly influence secretion, as is shown by the occasional suppression of saliva as a result of fear and of the urine in hysteria, but more often they are attended by increased secretion, and give rise to an increased flow of pale urine of very low specific gravity, and sometimes even to diarrhoea.

2. **Spasm of Involuntary Muscle.**—This forms a large group of cases, far more purely reflex than those just considered, because in most of them cerebral influence may be neglected. Renal, biliary and intestinal colic belong to this class, and result from the irritation of mucous membrane by some abnormal substance. Vaginismus and œsophagismus sometimes arise in the same manner, and asthmatic attacks (due probably to spasm of the bronchial muscles) may result from the pressure of an aneurysm on the trachea, or from some abnormal condition of the nasal mucous membrane. Micturition has been known to be invariably excited by pressure over the bladder, and a fluid stool to be evacuated

after dressing a bed-sore. The occurrence of premature labour from some great nervous shock, and the constriction and dilatation of arterioles from emotion, afford illustrations of the influence of the brain upon unstriated muscular fibre.

3. Disorders of Voluntary Muscles.

—It is well known that epilepsy and the convulsions of infancy are occasionally due to peripheral irritation, such as the presence of ascarides in the intestine. The removal of the exciting cause in time may be sufficient to prevent the recurrence of any more attacks; but not infrequently the affected centres develop a habit of discharging, and convulsions afterwards appear to occur spontaneously. The reflex character of the fit is very clear in those rare cases in which there is an undoubted epilepto-genetic zone. The writer had under his care a boy of very nervous temperament; he patted him on the head to give him confidence, and there immediately ensued an epileptic attack, which inevitably followed irritation of that area of the scalp. Tremor of the hand and arm, closely simulating that of paralysis agitans, is sometimes caused by some constant irritation of the upper extremity, such, for instance, as the presence of a piece of glass in the palm of the hand. The removal of the source of irritation is soon followed by the relief and ultimate cure of the symptoms. It was formerly believed that reflex paralysis was comparatively frequent, but it is very probable that most of the cases described were really of organic origin. Nevertheless, it is impossible to doubt that instances of it sometimes occur, for how otherwise are such cases to be explained as sudden cure of a paraplegia following expulsion of ascarides, inability to pass water for some days after an operation on the anus, and the almost immediate return of power to a paretic arm after the extraction of a decayed wisdom tooth? Such cases are probably due to reflex inhibition of the spinal centres by some peripheral irritation; but another view refers them to the agency of the vasomotor nerves, which are reflexly irritated, and contract to such an extent in certain regions of the cord as to suspend its functions in those areas.

Closely allied to ordinary reflex action is the reflexion of pain from the source of irritation to some more distant region, as in cases of renal calculus, in which pain is referred to the testicle. In the same manner a carious tooth may excite neuralgia in some distant branch of the fifth nerve, and, it is said, even in the

cervico-brachial region. Irritation in the course of the fifth nerve sometimes induces an impairment of vision, consisting of a concentric contraction of the field of vision on the same side, and in some cases a slighter contraction of the opposite field. The removal of the exciting cause, which is often a decayed tooth, is generally followed by an improvement in the symptoms.

WM. GAY.

REFLEXES, SPINAL.—There are two varieties of spinal reflexes: (1) The superficial or skin reflexes; (2) the deep or so-called tendon reflexes.

Superficial Reflexes.—The following are the most important superficial reflexes, with the method of exciting them, the character of the movement induced, and the level of the cord on which the reaction depends.

The *plantar* reflex is obtained by tickling the sole of the foot, the result being usually a slight movement of the toes, and sometimes of the foot and leg. This reflex depends on the spinal centre corresponding to the first, second, and third sacral nerves.

The *gluteal* reflex is obtained by stimulating the skin of the buttock, the result being a contraction of the glutei muscles. This reflex takes place through the fourth and fifth lumbar nerves.

The *cremasteric* reflex is obtained by stimulating the skin of the upper and inner part of the thigh, the result being retraction of the testicle. This reflex takes place through the first and second lumbar nerves.

The *abdominal* reflex is obtained by stimulating the skin on the side of the abdomen from the ribs downwards, the result being a contraction of the abdominal muscles. This reflex takes place through the eighth, ninth, tenth, eleventh, and twelfth dorsal nerves.

The *epigastric* reflex is obtained by stimulating the skin of the chest over the fifth and sixth intercostal spaces, the result being a dimpling of the epigastrium on the side stimulated, from contraction of the upper part of the rectus abdominis. This reflex takes place through the fourth, fifth, sixth, and sometimes the seventh dorsal nerves.

The *scapular* reflex is obtained by stimulating the skin in the inter-scapular region, the result being contraction of the scapular muscles and of the posterior axillary fold. This reflex takes place through the lower two or three cervical and the upper two or three dorsal nerves.

These reflexes are liable to considerable

variations in health, sometimes being easily elicited, sometimes sluggish or absent. The reactions are obtained more readily in children than in adults, and variations may also be ascribed to other causes, such as obesity and temperament.

The condition of these skin reflexes is sometimes of service in determining the localization of spinal lesions or their vertical extent. Considerable caution, however, should be exercised in drawing inferences from the state of the cutaneous reflexes, and it is especially important to bear in mind that some or all may be absent even in health. The plantar reflex is probably less often wanting than the others, and on this account is of more importance.

The plantar reflex and the knee-jerk are not always similarly affected in disease. In hemiplegia, the former is usually diminished or absent on the paralysed side, whereas the latter is exaggerated. Again, in locomotor ataxia, the plantar reflex is often present, the knee-jerk being absent. The superficial reflexes are increased in those cases of paraplegia in which there is rigidity with exalted tendon reflexes; diminished or absent in most destructive affections of the grey matter of the cord, such as acute myelitis.

Deep or Tendon Reflexes.—Of the deep or so-called tendon reflexes, the *knee-jerk* or *patellar tendon reflex* requires special consideration. The knee-jerk depends on the integrity of the cord at the level of the second and third lumbar nerves, as well as on that of the motor and sensory nerves of the reflex arc. Into the arguments for and against the reflex nature of the knee-jerk it is unnecessary here to enter, but it is indisputable that a reflex action is concerned in its production, and that conditions which heighten or depress the reflex function of the spinal cord exert an identical influence upon the deep reflexes.

The knee-jerk, though liable to considerable variations, is probably always present in health. It is a moot point whether the reaction may be wanting in the normal individual.

It is well to bear in mind that absence of the knee-jerk may be the sole indication of structural changes in the nervous centres. It is sometimes important, therefore, to take special precautions to overcome involuntary effort before assuming that the reaction is really absent. By the ordinary method the patient is made to cross one leg over the other, and

then the tendon is percussed with the ulnar border of the right hand. Care should be taken that the leg hangs loosely. In a doubtful case, the patient should be seated on a high chair or table with the lower limbs bare, hanging freely, and off the ground. The tendon is then struck smartly just below the lower border of the patella, the patient at the same time being directed to interlock the semi-flexed digits of the hand into those of the other and to pull strongly. The knee-jerk is often difficult to obtain in very fat people, in highly muscular individuals, and in children. In the last named the reaction may often be obtained with more facility if the knee be semi-flexed and the sole allowed to rest on the observer's palm.

In children, in whom the tendon is short, it is often difficult to percuss smartly with the ulnar border of the right hand in the usual way, and hence a percussion hammer is useful. In adults, however, a specially constructed instrument is not essential. The knee-jerk varies much in health, sometimes being very feeble and obtained with difficulty, at other times brisk and elicited with great ease. However slight the knee-jerk may be, provided the reactions are equal on each side, it is not justifiable to infer the existence of an abnormal condition of the nervous centres; on the other hand it should be borne in mind that when the briskness in the knee-jerk is abnormal there is often inequality in the reactions and ankle- or knee-clonus is commonly present on one or both sides.

Loss of the Knee-jerk may occur in the following conditions:—(1) local injuries, such as fractured patella and rupture of the quadriceps femoris; (2) disease of the quadriceps, as in pseudo-hypertrophic paralysis; (3) disease of the anterior crural nerve, as in peripheral neuritis, such as commonly results from alcohol; (4) in lesions involving the anterior or posterior nerve-roots, such as meningitis or tumours, and more commonly in locomotor ataxia, in which the posterior root zones are involved; (5) in destructive affections of the grey matter of the cord involving the centre which presides over the knee-jerk, such as infantile paralysis and acute myelitis; (6) the reaction is often wanting in diphtheritic paralysis, the morbid anatomy of which is still uncertain, and sometimes absence of the knee-jerk occurs in diabetes, in disease of the cerebellum and immediately after an epileptic seizure.

Exaggeration of the Knee-jerk is pre-

sent in the following states:—(1) in the early stage of hemiplegia, from the withdrawal of the controlling cerebral influence; (2) in the later stages of hemiplegia when rigidity is present, from descending degeneration of the pyramidal tract; (3) in all diseases in which the lateral columns of the cord are affected, whether primarily or secondarily. Among such affections are primary lateral sclerosis, amyotrophic lateral sclerosis, disseminated sclerosis, and paraplegia from pressure; (4) occasionally in hysterical paraplegia, in typhoid fever, phthisis, and other debilitating conditions; sometimes immediately after an epileptic seizure, and frequently in persons under the influence of anæsthetics. Exaggeration of the knee-jerk is often, but not necessarily, associated with clonus.

Ankle- or foot-clonus is obtained by suddenly pointing the foot upwards so as to stretch the calf muscles, and then keeping up the pressure against the sole. The knee should be slightly flexed. The resulting clonic contractions are rhythmic and vary from six to nine per second. The level of the cord on which ankle clonus depends corresponds to the first three sacral nerves. A knee clonus may sometimes be obtained by forcibly pushing down the patella and then keeping up the pressure, the knee being extended. Another method is by pressing the left middle finger firmly against the upper edge of the patella, and percussing downwards with the fingers of the right hand. Clonus may occasionally be obtained in other muscles, such as the flexors and extensors of the wrist and sometimes in the lower jaw. Ankle-clonus never occurs in health; it is associated with an exaggerated degree of knee-jerk, and usually indicates structural changes in the lateral column of the cord. The phenomenon, however, may be obtained together with exaggerated knee-jerks, in such debilitating conditions as typhoid fever and phthisis, in persons under the influence of anæsthetics, after an epileptic seizure, in chronic rheumatoid arthritis, and probably in hysterical paraplegia. It is important to bear in mind, therefore, that ankle-clonus does not invariably indicate organic change in the cord.

Front Tap Contraction.—This name has been given by Dr. Gowers to a phenomenon often obtained when the knee-jerk is exaggerated, and which is a delicate test of increased irritability. The foot is placed at a right angle to the leg, and the muscles in the front of the

leg are tapped, the result being extension of the foot from contraction of the gastrocnemius. The front tap contraction does not always point to actual structural change in the cord, but its presence on one side only is of diagnostic significance. Muscular contractions are sometimes to be obtained in the upper limbs, on percussion of the tendons of the flexors and extensors of the wrist and of the tendons of the triceps. Percussion of the lower end of the radius (radial tap) may be followed by contraction of the biceps and supinator longus; and percussion of the lower end of the ulna by contraction of the triceps. These phenomena are usually well marked in hemiplegia with rigidity, but in health they are commonly feeble or wanting, and hence their diagnostic importance is limited.

W. B. HADDEN.

RELAPSING FEVER.—An acute specific disease characterised by a short febrile paroxysm ending in crisis, followed by a well-marked remission, and that by a relapse on or about the fourteenth day.

Symptoms.—After an interval of about five days following exposure to infection, the patient is suddenly seized with chilliness or a rigor accompanied by headache, pain in the back and limbs, and, especially in children, by nausea and vomiting. The temperature rises rapidly, reaching 103° or 105° F. or higher in the first twenty-four hours; the pulse also becomes rapid, thirst is extreme, and there is complete anorexia. The patient is restless rather than prostrate, and may not apply for treatment until the second or third day of his illness.

The symptoms of a fully developed attack are very pronounced. The face is flushed and the eyes suffused; the patient complains of severe headache, generally frontal, of pains, often described as rheumatics in the muscles and joints, and very commonly of giddiness, which may be so extreme that relief is only obtained when lying absolutely still in the recumbent posture. The mind is, as a rule, quite clear, though noisy delirium is occasionally observed towards the end of the paroxysm. Insomnia is frequently very persistent and distressing. There is no characteristic eruption; but in a small proportion of cases there may be a slight roseolar rash with subcuticular mottling. Petechiæ are very easily produced. Profuse perspiration is a marked symptom, and sudamina are of common occurrence. A peculiar musty odour often present is described as resembling

burning straw. The temperature is high, generally over 104° F., but is not uncommonly much higher, even 108° F.; these high temperatures, however, are not attended by grave nervous symptoms, and are not necessarily of bad prognosis; a slight remission occurs daily, generally in the morning. The pulse is full, bounding and rapid from 100 to 140; the degree of acceleration presenting, as a rule, a general correspondence with the height of the temperature. A hæmic murmur may be heard at the base of the heart. Respiration also is hurried, but the pulse-respiration ratio is generally maintained. The tongue is moist, large, indented by the teeth, and covered by a white fur, which, after the second day, tends to clear from the tip and edges, leaving a clean red surface. Appetite is completely destroyed, but thirst is constant and intense. Nausea is almost always present, and vomiting may be severe, the vomited matter being bile stained, or consisting only of glairy mucus tinged with bile; occasionally there is hæmatemesis. The spleen and liver are enlarged: the bowels tend to be loose. Jaundice has been frequently observed in some epidemics. Epistaxis is not uncommon, and may be profuse. The quantity of urine passed during the paroxysm varies in different cases, but it may not be diminished; the urea is increased, and bile pigments may be present if jaundice exists; in some cases albumen, with or without casts, is found.

The symptoms continue to increase in severity for from four to eleven days, when the crisis occurs and terminates the first paroxysm. This crisis, which in a large proportion of cases occurs on the seventh day, is characterised by a fall in the temperature more rapid and extensive than is observed in any other disease; the decline may be at first at the rate of 1.5° F. to 2° F. an hour, and may amount to as much as 12° , 13° , or even more in the course of twelve hours, so that the body-temperature becomes subnormal, the reading of 95° F. being frequently observed. Coincidentally the frequency of pulse also in most cases rapidly diminishes, decreasing from 140 or 150 to 80, 70, or even 60 or 50. The character of the pulse also alters, becoming compressible and dicrotic. This rapid defervescence is nearly always attended by some critical discharge, usually sweating, though metrorrhæia, epistaxis, diarrhœa, and vomiting may take its place. The critical urine is pale, and of low specific gravity; and the total urea is

at this period rather below than above the normal quality.

The patient now begins to improve, the temperature falls, the pulse regains tone, the urine after remaining pale and copious for two or three days again becomes natural; the appetite returns, the enlargement of the liver and spleen disappear, and the patient seems to be recovering from his disorder, whereas he is in reality passing through the period of *intermission*. The *relapse* occurs after seven days, or a day or two earlier or later; all the symptoms of the primary attack return with the suddenness which characterised its onset. The temperature again rises to 104° or 105° F., but seldom attains the highest point touched during the last day or two of the primary paroxysm. The duration of the relapse varies from a few hours to seven days or even longer, the average being three or four days; it usually terminates by crisis, which may be as well marked as that which ends the first paroxysm. There may be three, four, or even more relapses, but each tends to be shorter and slighter than its predecessor. During convalescence desquamation may occur, generally in small flakes.

An abortive form of relapsing fever has been described in which no relapse occurs. It should, however, be borne in mind that the relapse may be of very short duration, and thus escape observation unless carefully looked for. In the so-called bilious typhoid or congestive form of relapsing fever the symptoms assume the adynamic type—there is jaundice, marked enlargement of liver and spleen, epistaxis or metrostaxis, dry brown tongue, hiccough, diminished or suppressed secretion of urine, low delirium, and an imperfect crisis, which is not followed by a complete intermission, but by a fluctuating temperature.

Complications.—In the congestive form pneumonia is frequently present, but it may also occur in typical cases of relapsing fever and materially modify the course of the pyrexia. Among other respiratory complications may be mentioned laryngitis, bronchitis, and pleurisy; whilst phthisis is a not uncommon sequela. The enlargement of the spleen may be so extreme as to end in rupture, and is frequently accompanied by peritonitis; copious hæmatemesis may be observed. Diarrhœa occurs with varying frequency in different epidemics, but is only rarely so severe as to be a determining cause of death. The stools do not present any characteristic appear-

ances; they are not infrequently dark or black from altered blood. Albumen occurs in the urine more frequently in some epidemics than in others, and, when present in small quantity only, does not appear to have any specially unfavourable significance. The passage of highly concentrated albuminous urine, with perhaps tube casts, is a serious symptom, though recovery may occur after even total suppression. Hæmaturia is also a serious complication. The pains in the joints are occasionally accompanied by swelling. A frequent cause of death is sudden collapse, which may occur at the crisis, may be secondary to copious hæmorrhage, or associated with the hyperpyrexia, or be due to cardiac thrombosis. Purulent otorrhœa and parotitis are frequent complications. Paralysis of certain muscles, of the forearm, or of one upper or lower limb is sometimes observed, and in some epidemics post-febrile ophthalmia is frequent. Pregnant women attacked by this fever almost invariably abort; the child, if viable, is either stillborn or dies after a few hours, but in the majority of cases the mother recovers.

Diagnosis.—Relapsing fever is not always easy to distinguish until the fact of its epidemic prevalence has been recognized. It is to be diagnosed from typhus fever mainly by the sudden onset of the initial symptoms, the very rapid rise of temperature, the severity of the gastric symptoms, the absence of delirium, the presence of vertigo, of pains in the joints, of jaundice, and the absence of rash; later by the occurrence of the characteristic crisis, intermission, and relapse. The specific spirillum may be discovered by microscopical examination of the blood. Its mode of onset presents a striking contrast to that ordinarily observed in enteric fever, the temperature curve is throughout different, and the abdominal distension and pea-soup diarrhœa of enteric are not observed in relapsing fever. The congestive form of the latter disease, however, more nearly resembles the former, and has probably often been confounded with it. The same form of the disease, when complicated by marked jaundice, has been mistaken for yellow fever; the presence of enlargement of the spleen, the infrequency of albuminuria, and the great rapidity with which the temperature rises, taken together with the general circumstances of the locality as to epidemics, generally enable a diagnosis to be made. Relapsing

fever may be confounded with grave forms of remittent fever, but the character of the pyrexia and the course of the diseases are not the same; remittent fever only occurs in malarial regions, while relapsing fever is contracted from a previous case, and quinine, while exercising a notable controlling effect over the former, has little or no influence over the latter. Examination of the blood may reveal the characteristic pigment bodies or spirillum respectively. Cases of relapsing fever, where perspiration and pain and tenderness of the joints are marked symptoms, may be confounded with acute rheumatism, the discovery of a cardiac murmur may make the resemblance more exact, and the very high temperature may excite a fear of hyperpyrexia. In relapsing fever, however, nausea and vomiting are generally present, with enlargement of the spleen and liver; there is insomnia, but no delirium; and there is a decided tendency to hæmorrhage. The invasion of small-pox somewhat resembles that of relapsing fever, and, if both diseases are epidemic, it may be necessary to reserve a diagnosis until the fourth day. In every case, in fact, the general circumstances of the locality as to prevalence of epidemic disease within it must have great weight in forming a diagnosis in the early stage of the disease. Typhus and relapsing fevers, however, are liable to be epidemic contemporaneously.

Prognosis.—The mortality from relapsing fever is low, about 5 or 7 per cent., so that the prognosis is generally favourable. Unfavourable symptoms have already been mentioned; special reference need only here be made to the occurrence of convulsions or prostration and low delirium, of deep jaundice or suppression of urine, and of collapse. Pneumonia, which is, perhaps, the most frequent, is also the most fatal complication. A previous history of alcoholism is a most serious element in prognosis.

Morbid Anatomy.—The morbid appearances after death from relapsing fever are not characteristic; the spleen is very notably enlarged; there may be some surrounding peritonitis, and the capsule of the spleen may be perforated; the Malpighian bodies are enlarged, and the parenchyma presents numerous infarcts due to venous thrombosis. These at a later stage break down and form abscesses. The liver is enlarged from congestion; its epithelium is in the condition of cloudy swelling, and there may be small infarcts, which later give place

to minute abscesses. The kidneys are enlarged from congestion, the capsules may present ecchymoses, and the cortex infarcts; the epithelium is in the condition of cloudy swelling. The medulla ossium is softened, almost puriform, owing to proliferation and subsequent degeneration of the lymphoid cells. The number of white corpuscles in the blood also is increased. Cloudy swelling of the cardiac and voluntary muscles is followed by granular degeneration.

Etiology and Pathology.—Relapsing fever has been generally regarded, on very insufficient grounds, as standing in some intimate causal relation with famine. It is, however, a specific disorder, due to a specific contagium, and becomes epidemic under circumstances of the same nature as those which favour the epidemic prevalence of typhus fever—the accumulation of decomposing filth, and overcrowding of ill-ventilated rooms. It is independent of climate, is little influenced by weather, and has no relation to the soil. It is believed to be endemic in Ireland and in Hindustan, and it has occurred epidemically in England, Scotland, Russia, Scandinavia, Germany, Austria, Belgium, the Levantine littoral, and the islands of the Mediterranean, North Africa, and North America. It can be carried by travellers, and apparently by fomites, and can be transmitted by inoculation of the blood from man to man, and from man to monkeys.

A spirillum is found in the blood from a little before the first paroxysm, or at the least, shortly after its commencement, until shortly before the crisis, when it disappears; it is not discoverable during the remission until very shortly before the relapse commences, when it again appears in large numbers. From five to ten may be visible in a field (500 diam.), or they may be very much more numerous, and the number may vary from day to day. The spirillum is a homogeneous spiral filament, very thin, but in length it equals from one and a half to six times the breadth of a red blood-corpuscle. In fresh blood it is in constant motion of rotation, flexion and progression. The organism cannot survive for more than an hour at blood-heat; it has been found in certain cases at periodic dates, when, nevertheless, no pyrexia ensued, and it has not been found in certain cases during short febrile attacks lasting one day. For these and other reasons some prefer to believe that the spirillum is an epiphenomenon, and not the specific contagium

of the disease as is confidently affirmed by others.

Treatment.—Relapsing fever is very little influenced by treatment. The pyrexia is not even modified by the free administration of quinine, arsenic, salicylates or aconite, nor is the relapse postponed or rendered less severe. To relieve pain and procure sleep opium may be administered by the mouth, or preferably, morphine subcutaneously ($\frac{1}{4}$ grain every six hours). Light fluid food should be given from the beginning in small quantities at short intervals. Stimulants are well borne. The abdominal pain at the outset may be relieved by an emetic, and at a later stage persistent nausea may be treated by small doses of calomel (gr. $\frac{1}{4}$ — $\frac{1}{2}$ every two hours) or by subnitrate of bismuth. Strong aperients should be avoided. Diuretics have been recommended. Dr. Murchison's prescription was:—Pot. nitratis, \mathfrak{zj} — \mathfrak{zj} , acid. nitrici dil., \mathfrak{zj} , tinct. digitalis, \mathfrak{zss} , aq. ad $\mathfrak{z}\mathfrak{v}$, in divided doses during the twenty-four hours. Relief may be obtained by sponging the surface with tepid or cold water, or by cold affusions to the head.

DAWSON WILLIAMS.

RENAL CALCULUS AND GRAVEL.

—The solid constituents of the urine are liable to be deposited in the urinary passages under the following conditions:—

(1) When the solids are present in too large a quantity to be dissolved by the fluid of the urine. This may be due to an increase in the amount of the solids, or a decrease in the amount of the fluid. Under this heading, too, may be mentioned the condition in which an abnormal substance of sparing solubility, such as xanthine or cystine, is present in the urine.

(2) When the reaction of the urine necessary to maintain the solids in solution is altered, or when certain substances whose presence determines the solubility of other constituents of the urine, are decreased in quantity. There are certain constituents of the urine, the phosphates, which are insoluble in alkaline solutions, and are therefore precipitated, should the urine assume an alkaline reaction. Again, a hyper-acidity of the urine favours the precipitation of uric acid. But it is probable that slight changes of reaction determine the solution or precipitation of several constituents of the urine. Even the composition of such bodies may be readily altered so as to

produce from a soluble substance a comparatively insoluble one. Sir William Roberts has shown that this quadrurate of soda, a normal constituent of the urine, is readily changed into the bi-urate and uric acid by contact with water. Such a reaction goes on gradually in normal urine after its removal from the body, the uric acid being thrown down as a red precipitate. The bi-urate of soda, as soon as it is formed, is changed once more into quadrurate by the superphosphates contained in the urine, and is subjected again to decomposition by the water. These reactions go on until all the uric acid of the urine is at last deposited in the insoluble form. But although these reactions take place when the urine stands for some time, in ordinary conditions they are hindered or delayed. Sir William Roberts has observed that this hindrance is chiefly due to the presence of the saline matters and the pigments of the urine. The conditions, then, which accelerate the precipitation of uric acid, and lead to its concretion within the body, are, as summarised by Sir William Roberts—(a) high acidity, (b) poverty in salines, (c) low pigmentation, and (d) high percentage of uric acid.

There is also reason to believe that oxalic acid may be derived from uric acid in the body (*see* OXALURIA), and may then be deposited in the urinary passages as oxalate of lime.

(3) When substances of a colloidal nature are present which determine the precipitation around them of normal urinary ingredients. Dr. Vandyke Carter found that the nucleus of urinary calculi was composed of crystals of uric acid or of oxalate of lime, which had a globular shape, and which were not formed when these substances crystallized in ordinary conditions. Further, in such a nucleus a colloidal matrix could be detected. Mr. Rainey and Dr. Ord have shown, too, that the globular forms of crystals arise only when a colloid substance is present in the crystallizing solution. Thus, it appears that the presence in the urine of colloid matter, such as albumen or mucus, the result of catarrhal inflammation of the urinary passages, will determine the crystallization of uric acid or oxalate of lime in the spheroidal form, and thus lay the foundation for a calculus.

(4) When the pouching of the pelvis of the kidney is abnormally great. Sir William Roberts has suggested that such a condition, by favouring stagnation of

the urine, may be a cause of calculus formation in the kidney. This is very probable, but as yet lacks anatomical proof.

A renal calculus may consist of only one ingredient, such as uric acid, oxalate of lime, cystine, &c., or it may be composed of several primary deposits arranged in concentric layers, and representing different phases of calculous formation. Even when composed of only one ingredient, the arrangement in concentric layers may still be seen on section; or, on the other hand, the deposited matter may be arranged in lines radiating from the centre. But this primary calculous deposit is subject to the formation upon it of a secondary crust of phosphate matter, due to ammoniacal decomposition of the urine after the stone has been first formed. Thus, a stone may consist of a nucleus, a body and a crust. The nucleus may consist of globular crystals of the primary formation mixed with a colloidal matrix or of a mass of mucus alone, or again, of a small blood-clot or the eggs of *Bilharzia hæmatobia*. Renal calculus is more common in males, and slightly more frequent on the right than the left side. Probably, too, it is usually formed before middle age.

Small concretions which may be passed by the urethra are usually styled "gravel," while larger masses are known as "stones" or "calculi" proper.

VARIETIES OF RENAL CALCULI.—(1)

Uric Acid.—This is the most frequent constituent of renal calculi. It forms stones which vary in size from small pisiform bodies, which may be passed as gravel, to large masses which may completely fill the pelvis of the kidney. The larger stones are of variable shape, but have the general outline of a wedge in which the apex fits into an infundibulum of the kidney, and the base projects into the pelvis. Several of such wedges may, however, be joined together so as to form an irregular mass, which is embedded in the pouches of the renal pelvis. The uric-acid stone is reddish in colour, of moderate hardness, and it is prone to be formed in both kidneys. The immediate causes of its formation have been discussed above. The constitutional conditions in which it arises will be found described in the article upon URIC ACID DIATHESIS. The urine of a patient who is suffering from a renal calculus composed of uric acid is acid, and deposits urates and uric acid crystals on standing.

(2) **Urates.**—Stones composed entirely

of urates are rare, and are nearly always confined to children. They are usually small and soft. Deposits of urates are common in the straight tubes of the kidneys of newly born children. But urates are frequently found mixed with some other ingredient of a urinary calculus. The urine from kidneys containing urate calculi resembles that which is associated with concretions of uric acid.

(3) **Oxalate of Lime.**—Oxalate of lime may be passed in the form of gravel under conditions already described in the section on OXALURIA. It may also form a calculus, which may reach a very large size. Such a calculus is usually single. It is very hard, of a dark grey colour, and its surface is studded with numerous spiny projections, which render it extremely irritating to the tissues in contact with which it lies. The urine from which it is deposited is acid.

(4) **Phosphates.**—It is very rarely that calculi are found composed entirely of phosphates, although, as has already been stated, the secondary deposit on other stones is composed entirely of such salts. Calculi have been found, however, constituted entirely of calcic phosphate, and of this salt combined with ammonio-magnesian phosphate.

(5) **Carbonate of Lime.**—Calculi composed of this substance are very rare in man, but common in the horse. They may be voided in considerable numbers as gravel, but may attain a considerable size and be retained in the kidney.

(6) **Cystine.**—Cystine may also be passed as gravel, or may be retained in the pelvis of the kidney, forming a calculus. It forms a soft stone, yellowish in colour, changing to a greenish tint on exposure to the air. Its chemical characters will be found described in the article on URINE, EXAMINATION OF.

(7) **Xanthine.**

(8) **Fibrine or Blood.**

(9) **Indigo.**—Dr. Ord has described a specimen of renal calculus composed of indigo, derived, doubtless from indol, absorbed from the small intestine.

SYMPTOMS.—If a stone be so lodged in the pelvis of the kidney as to retain its position during the ordinary movements of the body, it may remain for years without causing any symptoms from which its presence may be suspected. This, however, is comparatively uncommon, and definite symptoms are produced, either by the movements of the stone or by the irritation which it sets up in the surrounding parts. Of these symptoms those due to the pas-

sage of the stone down the ureter on its way to the bladder, constituting an attack of renal colic or the gravel, will be first considered; and, secondly, those which arise when the stone remains in the pelvis of the kidney.

Renal Colic.—The symptoms produced by the attempt on the part of the stone to pass down the ureter, occur at an early stage, before the stone has attained any great size. After some strain, or exertion, or a sudden twist, or even in the midst of apparently perfect health, the patient is seized with sudden pain in one or other renal region, shooting in various directions, but mainly downwards in the course of the ureter, and along the inside of the thigh. The pain is most acute and well-nigh unbearable. During its continuance the patient is extremely restless, rolling from side to side in agony, no posture giving relief. He is faint, a cold sweat breaks out over the body. There are rigors and often severe vomiting and retching. The testicle on the side of the pain is retracted, and in some cases is congested, tender and swollen. There are frequent calls to micturate, but only small quantities of high-coloured, and often bloody urine are passed at a time, and the act of micturition is painful. The bowels may become distressingly distended. The nervous system, too, may be so disturbed as to give rise to delirium and even epileptic convulsions. After a little time a febrile movement is prone to set in, and may reach a high degree. These symptoms last for a variable time, sometimes for only an hour or two, sometimes for several days. In the most fortunate case, when the stone has finally passed from the ureter in the bladder, the patient is suddenly relieved of all his symptoms, and in a short time the stone which had caused his trouble is passed by the urethra.

Calculus in the Ureter.—Less fortunately, however, the stone may remain impacted in the ureter, usually at the narrowest part, where the ureter enters the bladder, and then, although the symptoms gradually subside, they do so very slowly. It may happen, too, that the opposite ureter has at some previous time been blocked by a stone and its kidney disabled; then impaction of a stone in the second ureter will give rise to obstructive suppression of urine, which, if not overcome, will kill the patient.

Calculus in the Renal Pelvis.—Of the symptoms which arise when the

stone remains in the pelvis of the kidney, *pain* is the most constant. This may vary in its character, but is usually a dull aching in the lumbar region, extending to the front of the abdomen and downwards along the course of the ureter to the testicle and the inside of the thigh. The pain is not always limited to one side, even though only one kidney be the seat of stone. The opposite kidney is frequently the seat of pain, and the pain has been known to be localized only in the healthy organ. Again, the pain may be reflected to far distant parts of the body, such as, in recorded cases, to the knee and sole of the foot. The pain is, it is said, the most severe when the stone is composed of oxalate of lime or covered by phosphates. The pain is increased by exercise, most of all by riding, least by walking. In certain postures, too, which the patient learns for himself, and which are usually those in which the kidney is relieved from pressure by the surrounding parts, the pain is lessened. Sometimes, but rarely, the pain instead of being a mere aching, is extremely severe, and neuralgic in character. As a rule there is tenderness on pressure over the seat of the stone, and in some cases a slight fullness can be detected in the region of the kidney. Yet, on the other hand, instances have been known in which the pain was relieved by pressure. Where more than one stone is present in the pelvis of a kidney, a sensation of grating may be perceived by the patient, and may even be obvious to the physician on palpation.

Hæmaturia is an important symptom of stone in the kidney. It is very frequently present, and though seldom profuse, is prone to be constant. Its conditions of origin are important. It is often induced by movement, and generally by those conditions which increase or provoke pain in the kidney, and it subsides or diminishes when the patient remains at rest. Hence the urine passed in the early morning is free from it, whereas, as Dr. Dickinson has remarked, in the case of malignant growths, the night's rest in the supine position favours the accumulation of blood, and causes the hæmaturia to be well marked in the morning.

The testicle is not infrequently persistently retracted and swollen, on the same side as the renal calculus, and may be the seat of neuralgic pain. Bladder symptoms, especially irritation and frequent micturition, may be so pronounced

as to call off the attention from the kidney, which is the real seat of the trouble.

Digestive disturbances of all kinds are common accompaniments of renal calculus. Flatulence and acid dyspepsia are the most common, but severe vomiting and retching and gastrodynia may also be met with.

A frequent result of the irritation of the calculus is pyelitis, with, as its consequence, the discharge of pus and tailed epithelium with the urine. Its symptoms have already been detailed in the article on PYELITIS.

Dr. Dickinson has shown that there is some reason to believe that mental derangements are to be counted amongst the other conditions produced by renal calculus.

RESULTS.—The stone may, as has already been noted, remain quiescent from the earliest period of its formation. The symptoms which have been described, may, after a time, subside, and never again, or only after a considerable interval, trouble the patient. On the other hand, the constant or frequently recurring pain may wear him out. The irritation of the stone may produce not only pyelitis and pyonephrosis, but may cause constant congestion of the kidney, shown by the presence of albumen and casts in the urine, and as the result of this there may arise overgrowth of the interstitial tissue of the kidney with, finally, fibroid contraction and atrophy. Similar atrophy occurs when the ureter has been permanently blocked by a calculus. It is obvious that thus the kidney is disabled, and if a similar accident should befall the opposite organ, death must result from obstructive suppression of urine. But the irritation may spread beyond the limits of the kidney and cause perinephritis. Then by a process of ulceration, as detailed in the article on PERINEPHRITIS, the stone may get outside the confines of the kidney, and be discharged externally, with the pus from a perinephritic abscess. An abscess of the kidney may, by perforating the intestine or the peritoneum, be the means of conveying the stone into the intestine or the peritoneal cavity. If into the latter situation, the result is almost invariably fatal.

DIAGNOSIS.—The direction of the pain, the frequency of micturition, and the non-supervention of jaundice, will suffice to easily distinguish an attack of renal from one of hepatic colic. It is only necessary to mention the possibility of

the intestinal distension causing a mistake to arise between intestinal and renal colic.

Symptoms similar to those of renal colic may be produced in patients who are the subjects of the uric acid diathesis, by the passage of urine which is highly acid, or which already contains crystals of uric acid or oxalate of lime. But in such a case, the pain is not so acute as in the true renal colic, is not so paroxysmal, and is not accompanied by retching or vomiting, and is easily relieved by a few doses of alkalies.

The hæmaturia of malignant disease may cause it to be mistaken for renal calculus. But the hæmorrhage in calculus, as stated above, is always lessened by rest, and is not so copious, and there is no appreciable tumour to be felt. Moreover, while the urine from a case of calculus may contain crystals of the same nature as the stone, it would never contain portions of cancerous tumour, such as may appear in cases of malignant disease.

The diagnosis of stone in the kidney from tubercle of the kidney is sometimes difficult. In both there may be pain, tenderness, slight fulness in the loins, frequent and painful micturition, and a discharge of pus in the urine. But in tubercle the pain is never so great as it can be at times in cases of stone, and hæmaturia, too, is somewhat rare in tubercle, but common in stone. The urine in cases of tubercle often contains more granular debris than is the case in calculous pyelitis, and it may contain the tubercle bacillus, though this is difficult of detection in the urine. In tubercle, also, there may be signs of the same disease elsewhere in the body, and the evening temperature may be persistently high, which would be a very rare phenomenon in calculous pyelitis.

TREATMENT.—When suffering from an attack of renal colic, the patient should first be placed in a warm bath for a time and then removed to bed. He should have copious warm drinks containing bicarbonate of potash, and warm fomentations or poultices should be applied to the loins and the front of the abdomen. A large warm enema often assists in relieving the pain, but morphine should always be given (subcutaneously) in somewhat large doses, since such patients commonly bear it well during their paroxysm. Belladonna and hyoscyamus given internally are also of use. It occasionally happens that change of posture, even, in

one instance, the inversion of the patient, suffices to displace the stone and cause it to fall back into the pelvis of the kidney. The course of the stone along the ureter may also be assisted by massage of the abdomen in the direction of the ureter.

During the intervals of renal colic, care should be taken to avoid all sudden shocks, or violent exercise, such as have been found to bring on paroxysms of pain or hæmaturia. The nature of the stone having possibly been determined by an examination of the urine, a due arrangement of diet and habits, and the washing out of the kidney by copious libations of Salutaris or other pure water, and the administration of alkaline remedies, such as the citrate of potash, acetate of potash or citrate of lithia, will prevent further increase in the size of the stone and so assist in obtaining its quiescence in the renal pelvis. Symptoms must be relieved as they arise, pain by rest, morphine and warm applications; hæmorrhage and pyelitis, by the remedies detailed in the articles upon those affections. Attention must be paid to the general health of the patient and this sustained by tonics, change of air, &c. A visit to the Spas of Vichy, Carlsbad or Ems, with a course of the waters at those places, is often beneficial. Attempts have been made to dissolve the calculi as they lie in the kidney, by altering the reaction of the urine by means of drugs. In the case of phosphatic renal calculi this is impossible. For the solvent treatment of uric acid calculi, Sir William Roberts recommends the use of the citrate of potash in large doses every three hours. The drug should be pure, and is best given in a mixture having the following formula:—Pot. bicarb. $\mathfrak{z}\text{xij}$, acid. citric. $\mathfrak{z}\text{viij}$, gr. xxiv, aquam ad $\mathfrak{z}\text{xij}$. Of this one ounce, which contains one drachm of the citrate, should be given as a dose, mixed with 3 or 4 ounces of water. If, however, the urine become ammoniacal, the treatment should at once be suspended.

If the symptoms persist and the patient's health is being undermined by constant pain, and discharge of pus, or he is prevented from following his occupation by the distress thereby induced, surgical means must be employed to relieve him of his trouble. The progress of modern surgery has removed many of the risks attendant upon operations upon the kidneys. The operation most generally called for is nephro-lithotomy, by

which the stone is removed through a lumbar incision. Nephrotomy, or mere incision of the kidney, may be called for to drain a pyonephrosis or inflamed renal pelvis, without removal of the stone, when the latter is firmly fixed or the kidney is greatly disorganized. Nephrectomy, or the removal of the whole kidney, for stone, is a dangerous operation, and one which can only be advised when the patient's life is in danger and all other methods of relieving pain have failed.

ROBERT MAGUIRE.

RETROPHARYNGEAL ABSCESS—Inflammation terminating in suppuration in the connective tissue between the spinal column and the pharynx.

Symptoms.—In idiopathic cases the symptoms come on rapidly, dysphagia being the first to be noticed; there is acute pain, rapid pulse and fever. As the abscess enlarges, difficulty in breathing occurs and the respiration is stertorous, and there is usually a croupy cough. When secondary to disease of the cervical vertebræ, the affection is preceded by stiffness of the neck and deformity of the cervical vertebræ, the symptoms come on more gradually, and there may be an entire absence of fever. On examination, a projection of the posterior wall of the pharynx may be found, and on palpation this may be felt to be elastic and fluctuating. Externally, a swelling may be seen and felt at the angle of the lower jaw. If it can be used, the laryngoscope is the best means of ascertaining the size and situation of the abscess.

Diagnosis.—The disease may be confounded with diphtheria, but the result of an objective examination should suffice to clear up any doubt.

Prognosis.—This must in all cases be guarded, as death may occur from complete closure of the glottis by pressure, or from the occurrence of œdema, or the abscess may burst during sleep and the contents enter the larynx and suffocate the patient. In secondary abscesses the prognosis is very grave on account of the nature of the diseases which cause them.

Pathology.—Lymphadenitis as a result of extension of inflammation from the mucous membrane seems to be the cause of the abscess, two lymphatic glands at the level of the second and third cervical vertebræ being the starting-point of the suppuration.

Ætiology.—This is especially a disease

of infancy and childhood. It may be idiopathic, being met with in connection with oral and pharyngeal catarrh, or it may be caused by caries of the spine, or occur as a result of measles, scarlet fever and septicæmic conditions.

Treatment.—The abscess should be opened as soon as possible, and the head held forward to prevent the pus entering the larynx. The after-treatment should be of a supporting nature.

F. DE HAVILLAND HALL.

RHEUMATIC ARTHRITIS (Chronic Rheumatoid Arthritis; Osteo-arthritis; Rheumatic Gout; Nodular Rheumatism; Arthritis Deformans).—A joint disease of chronic course, characterized by inflammatory overgrowth of the articular cartilages and synovial membrane, with destruction of those parts of the cartilages subject to intra-articular pressure, and progressive deformity.

Symptoms and Progress.—The disease begins—often not long after the subsidence of an attack of ordinary rheumatism—with painful swelling, redness and stiffness of one or more of the smaller joints, usually of the hands. The acute symptoms subside after a while, but generally recur in the same joints before these have quite recovered their normal size and shape; at the same time other joints are apt to be affected in the same way. Thus the articular pain and swelling tend to recur, at progressively shorter intervals, in all the joints previously attacked, and, upon each recurrence, to invade other articulations which had previously escaped. While the exacerbations become somewhat less acute in character, the intervals between them become so shortened as to be practically absent, and ultimately every joint in the body exhibits, more or less, the effects of the disease. The joints are swollen, nodulated, laterally expanded, stiffened, and distorted; and some are never wholly free from pain. On movement, creaking may be heard and felt. In proportion as they become fixed, the muscles in connection with them waste, functional activity of all kinds is increasingly impaired, and, though the mind may be unaffected, bodily suffering increases. In extreme cases, the patient presents the appearance of a pallid, helpless, pain-worn, deformed and bed-ridden cripple, always sensitive to cold and painfully appreciative of changeable and inclement weather.

The disease may possibly be arrested in its early stages by appropriate and energetic treatment, but later on it is practically incurable; and, though very rarely fatal *per se*, it necessarily predisposes the subject to risks of serious complications, especially to those of a pulmonary nature.

Pathology.—Anatomically examined, the affected joints in the early stage of the malady exhibit enlargement and general distension by an excessive effusion of serum. The synovial membrane is thickened and hyperæmic, its fringes becoming hypertrophied and developing lumpy and pyriform excrescences, at first fibrous and later cartilaginous in texture. The articular cartilages likewise increase by cell-enlargement and proliferation. In their central portions, where the intra-articular pressure is severe and constant, the cavities which contain the proliferating cells break into one another, so as to form vertical linear tubules, opening on to the free surface and discharging their cell-contents within the synovial cavity. Hence the articular cartilages, owing to this vertical striation, appear velvety and pitted. By an extension of the same process they become partially eroded, until the osseous surfaces are exposed, and these finally become, by mutual attrition, worn to an ivory-like smoothness. Coincidentally, at the periphery of the joint, and where freed from pressure, this hypertrophy of the cartilages and synovial fringes leads to a lateral expansion of the joint surfaces. The effusion is absorbed, and the joint becomes dry and creaking; the irregular ecchondroses become more or less separated from their original site of growth, form new attachments, and ossify. Thus are gradually produced the lateral expansion, the irregular distortion and nodulation, the rigidity, the dislocations, and the (usually false) ankyloses which are so characteristic of marked rheumatic arthritis. The sterno-clavicular joints usually appear to be only simply enlarged; the temporo-maxillary exhibit enlargement in front of the ear, often with some distortion of the jaw and chin. The chief symptom in connection with the vertebral column is rigidity. In the hip-joint the disease may simulate simple dislocation, Charcot's disease, and intra-capsular fracture.

Considerable bilateral symmetry is often observable in the distribution of the joint affections of rheumatic arthritis.

Etiology.—The tendency to rheumatic arthritis is frequently hereditary. The

disease is common in those who have at some time previously suffered from other forms of rheumatism—with which it clearly has an intimate pathological connection. All depressing and debilitating influences predispose to it, and women at the climacteric age are frequent sufferers. Although mainly a disease of the declining period of life, young persons are not exempt from it, and cases of its occurrence in infancy have been recorded.

Treatment.—The general treatment of rheumatic arthritis is essentially that proper to other forms of rheumatism. Cod-liver oil, iron and arsenic are always useful, together with warm woollen clothing, careful attention to the general health and to the hygiene of the skin, free exposure to direct sunshine, and residence in a warm, dry, bracing climate whenever this is possible. Tincture of iodine, in doses of 5 to 10 minims thrice daily, occasionally proves of service (*see also* RHEUMATISM, CHRONIC).

Local treatment is important, and may be of great service in arresting the disease in its early stages. The most useful measures are repeated hot fomentations of the affected joints, followed by painting with equal parts of the liniment and tincture of iodine, continued to the verge of blistering; the frequent inunction of iodine or of mercurial preparations, of plain oil, or of lanoline and of sulphur; burying the joint thrice daily for two or three hours at a time in a sand bath at 140° to 150° F., friction, massage and galvanism.

Courses of anti-rheumatic thermal baths in England or on the Continent, and prolonged tropical or sub-tropical sea-voyages, are of service. Whatever be the measures adopted, they must be followed out with continuous perseverance.

In the advanced forms of the disease treatment can be little more than palliative; yet much can often be done to allay pain and discomfort, to improve the general health, and to prevent the further progress of the malady by such means as are indicated above, and under RHEUMATISM, CHRONIC.

C. E. SHELLY.

RHEUMATISM.—A general disease affecting chiefly the joints, the fibrous structures and the muscles of the body, the acute form being marked by fever, profuse sour-smelling sweats, and shifting inflammation of the joints and fibrous textures.

RHEUMATISM, ACUTE (Rheumatic Fever).—**SYMPTOMS AND COURSE.**—The disease may arise suddenly, but usually a few days of malaise, with stiffness and intermittent aching in the joints and limbs, a sense of chilliness, and some sore throat or tonsillitis precede the onset of marked pyrexia. By this time one or more of the larger joints (ankles, wrists, knees or elbows) are found to be swollen, hot, extremely tender, more or less painful and somewhat reddened. The patient is prostrate and the cheeks are flushed; the tongue is foul, furred and moist; the pulse frequent, weak and soft. There is anorexia, with great thirst, and some irregularity of the bowels, the motions being commonly offensive; the urine is febrile and excessively acid; and the skin is bathed in an abundant, sour-smelling sweat, frequently attended with a development of sudamina and miliaria. While the general febrile condition persists with only slight and occasional diminutions of its intensity, in the course of a day or two, or even within a few hours, the inflammation commonly rapidly subsides in the joints first attacked, leaving them merely weak, feeble and slightly swollen: but coincidentally with this local improvement other joints become similarly affected with the characteristic pain and swelling, which, again, subside as yet other articulations are attacked in their turn, the joint symptoms thus irregularly shifting hither and thither, and, not rarely, again affecting joints which had apparently recovered. This state of things usually lasts for about a fortnight, but may continue indefinitely, until, with a gradual subsidence of the local and general inflammatory symptoms, the patient, much weakened and emaciated, begins a somewhat tedious convalescence, or the disease declines into a chronic form. In either case a *relapse*, in which all the more acute symptoms may again appear, is very apt to interrupt the course of what promised to be a satisfactory recovery.

COMPLICATIONS.—Simple acute rheumatism, as such, is never fatal, but the malady is apt to be attended by complications, of which those involving the heart and the respiratory organs respectively and an excessive degree of fever are especially dangerous. Inflammation of the sclerotic and of the conjunctiva—"rheumatic ophthalmia"—sometimes occurs during, or subsequently to, the acute articular form of the disease.

Cardiac Disease.—This, in the form

of either pericarditis or endocarditis, occurs in about one-half of all rheumatic cases. The affections commonly develop quite early in the course of an acute attack, but may do so at any time. Youth, and childhood especially, is prone to these complications, which are comparatively rare in persons over thirty. The liability to endocarditis increases directly in proportion to the severity of the attack, and women suffer more frequently than men. Changes in the myocardium are probably present in all severe cases, and are possibly the cause of the functional derangements, such as palpitation and distress, which may arise in the course of, or as a sequence of, acute rheumatism.

Diseases of the *Respiratory Organs*—pleuro-pneumonia, pleuritis, pneumonia, bronchitis, pulmonary congestion—not rarely complicate the primary disease and add greatly to its fatality; they usually arise during the later period of the malady.

Hyperpyrexia is a rare, but very fatal, complication, and may occur at any period. Its onset is indicated by a flushed face and excited manner, passing into delirium, subsidence of the articular pain and swelling, cessation of the perspiration, and a body temperature of over 103°F ., which continues rapidly to rise, in fatal cases reaching 108° or even 112° . The condition is generally accompanied by symptoms of acute cerebral excitement.

Rheumatic Nodules.—Attention has of late years been directed to the frequent occurrence as a complication of rheumatism, of small subcutaneous nodules in connection with fibrous structures, such as tendons, the deep fasciæ and the pericranium.

The most common situations of the nodules are on the limbs, the fingers, the backs of the hands, wrists and elbows, the trochanters, the margins of the patellæ, and the malleoli. They may also occur on the pericranium, pinna of the ear, spines of the vertebræ and scapular spines, the crista illi, and the ischial tuberosities. The skin over them is usually normal, but may be a little reddened. They vary in size from that of a pin's head to an almond, are movable on the underlying structures, and are not, as a rule, either painful or tender, but in some cases both pain and tenderness have been noted, the latter more often than the former. The nodules are arranged either singly or in groups, their distribution being often absolutely symmetrical; they can generally be more

easily felt than seen. They may appear in a crop or singly, and may, after their discovery, increase in size or remain unaltered; after attaining their maximum they may continue unchanged for a few days only, or for months (fourteen months in one case), but, as a rule, they ultimately either diminish in size or disappear completely, though after diminishing in size they may again enlarge.

The nodules have been observed much more frequently in children than in adults, and, as regards sex, girls are observed to be affected far oftener than boys.

They are not necessarily associated with pyrexia, but whenever present in a child they constitute an undoubted evidence of rheumatism, but similar nodules have been observed in adults in whom no rheumatic history could be obtained.

In children the nodules have, in nearly all cases, been present in association with endocarditis, often of a serious and progressive character; pericarditis and pericardial adhesion have also been noted, whilst chorea and other rheumatic manifestations have naturally been present in a large number of recorded cases.

Microscopically, the growths are found to consist of wavy strands of fibrous tissue, with cells of various shapes, caudate, spindle-shaped and nucleated, and numerous blood-vessels.

The nodules require no treatment, but their presence adds somewhat to the gravity of the prognosis in rheumatism in children, owing to their frequent association with endocardial changes.

The more acute *nervous symptoms* observed in some cases are usually attendant on hyperpyrexia. But *chorea*, a not uncommon sequel, may also arise during an attack of rheumatism. Rheumatism is frequently associated with *erythema* and *erythema nodosum*, and occasionally with remarkable purpuric eruptions—*purpura vel peliosis rheumatica*. The disease also occurs in the course of, or as a sequel of, *scarlatina*. *Glycosuria* is sometimes developed during an attack of acute rheumatism.

Cases of *Sub-acute Rheumatism* present symptoms differing from those of the acute disease mainly in their greater mildness and their more varied grouping, but they often display a persistent tendency to the recurrence of the joint affection in a sub-acute form.

PATHOLOGY.—The precise cause and origin of rheumatism is unknown. Various theories exist which explain the disease as being due to an excessive pro-

duction or accumulation of *lactic acid* within the system; the influence of *chill*, either causing retention of lactic acid or evoking trophic and vaso-motor neuroses and arthropathies; the action of *micrococci*, producing an endocarditis to which the joint symptoms are secondary; the presence of a specific vegetable microbe, *zymotosis translucens*; and a miasmatic, malarial poison. The blood in acute rheumatism contains an excess of fibrin, but no abnormal principle has been discovered in it.

The chief tissue changes observable in fatal cases are, in the affected joints, swelling and hyperemia of the synovial membrane and of the neighbouring tendons, ligaments, &c., with patches of swelling, softening, and even of erosion (due to rapid cell-proliferation and consequent vertical striation) in the articular cartilages. The joint cavity is occupied by an alkaline, albuminous fluid, occasionally turbid with flakes of lymph, and but rarely purulent. The various complications previously noted would be responsible for further pathological changes, including the granular degeneration, fluid blood, and liability to rapid decomposition which are noted in cases of hyperpyrexia.

ÆTIOLOGY.—The disease is commonest in young persons from sixteen to twenty-five years of age, as a first attack, but a liability to the disease is increased by a previous attack and by the influence of heredity, which is traceable in over 25 per cent of all cases. Social position and occupation, as influencing exposure, poverty and exhaustion, may act as potent predisposing causes. The influence of sex, as such, is not marked.

DIAGNOSIS in completely developed cases of acute rheumatism is easy; it may be for some time uncertain during the stage of invasion. The acute disease for which it is perhaps most often mistaken is *Pyæmia*, secondary to acute osteo-myelitis; but in pyæmia the joint affection is persistent and may proceed to suppuration, the fever is notably remittent, the sweating is neither continuous nor sour-smelling, and the subsequent history of the case will still more distinctly declare its nature (*see SEPTIC DISEASES*).

Gout is distinguished by its more sudden invasion, by its preference for the smaller joints, by the special characteristics of the joint symptoms, by the previous history, and by the presence of uric acid in the blood.

Simple *Synovitis*, whether traumatic or constitutional in origin, is persistent,

rarely multiple, never migratory, and owns a definite cause.

Rheumatoid Arthritis exhibits the characteristic deformity, with a different ætiology and method of progress.

In *Gonorrhæal Rheumatism* the joint trouble is more persistent, especially in the knees, and is associated with the specific urethral discharge or with a history of recent gonorrhœa.

Glanders may resemble rheumatism in its early stage, but the disease soon displays marked differential characteristics.

It must not be forgotten that either the pyrexia or the joint symptoms, or both, may be very slightly marked, and even completely absent, in some cases of rheumatism, especially those occurring in young children, and yet such cases are not the less liable to develop cardiac complications.

TREATMENT is directed to securing general and local rest, the avoidance of any check to the cutaneous secretion, the relief of acute symptoms, the prevention of complications and the correction of their effects.

The patient must be placed on a firm, narrow bed, protected from draughts, in a warm, well-ventilated room, and should lie between the blankets, clothed in a long flannel bedgown opening all down the front, the sleeves being slit open along the outer seam and re-fastened by tapes fixed at suitable intervals. This gown and the blankets should be changed as frequently as the patient's condition will admit. It is well to wrap *all* the larger joints, whether inflamed or not, in a thick layer of cotton-wool, kept in place by the firm and even application of a many-tailed bandage of soft and porous texture, and this cotton-wool should be renewed occasionally, until its employment is gradually relinquished during the progress of convalescence. The joints should be lightly sponged with warm soap and water before the cotton-wool is applied. When pain is severe, the affected joints may be encased in a single thickness of lint, saturated with a weak alkaline lotion containing tinct. opii \mathfrak{zss} , extr. belladon. gr. xx, chloral hydrat. gr. ij, or lin. aconiti \mathfrak{zss} , to the fluid ounce, covered with oiled silk and enclosed in cotton-wool as above. The whole surface may be sponged piecemeal with tepid soap and water, and immediately dried by another warm sponge or soft cloth, night and morning.

The *Diet* must be fluid, sustaining and unstimulating. Milk, diluted if necessary with an alkaline mineral water, may

be given freely; toast and water, barley-water, and water—plain or aerated—may be taken (like the milk, by sips) to quench thirst; small quantities of weak chicken-broth are allowable, and “egg lemonade” (the whites of two eggs, the juice of half a lemon, and a little glycerin, mixed with half a tumbler of water, but not beaten to a froth) is both refreshing and nourishing; but beef-tea and strong soups are undesirable, except when their stimulating qualities are specially required. All food must be given at short and regular intervals, and stimulants may be indicated by great prostration and in the event of serious cardiac or respiratory complications. As convalescence becomes established, small quantities of fish, custard, fowl and the like may be gradually added to the dietary, but butchers’ meat, if taken within a week after the complete subsidence of all rheumatic pain, is almost certain to provoke a recrudescence of the more acute symptoms. Ale, stout and the stronger wines should be forbidden for a considerably longer period.

If seen at the outset, and before the disease has definitely declared itself, the administration of a calomel purge, and tr. aconiti mj in a little aq. camph. every hour for the first twenty-four hours, may do much to lessen discomfort and even to abate the severity of later symptoms. The most generally successful treatment of acute rheumatism consists in the administration of sodium salicylate (gr. xx for an adult) with pot. bicarb. (gr. xv) or of salicin (gr. xv in wafer-paper) or of salicylic acid (gr. xx in milk, or with liq. ammon. acet.) every two or three hours until the pain is subdued and the temperature becomes normal, after which the remedy must be continued in diminished doses or at longer intervals for several days—otherwise the acute symptoms recur. Or a rather smaller dose of the salicylate may usefully be combined with 10, 15 or 20 grains of citrate of potash, especially if the urine be excessively acid. If each dose be guarded by about 5 minims of tinct. nucis vom. the effects known as “salicysm” (deafness, ringing in the ears, sickness, cardiac depression and delirium) are less frequently observed. These symptoms, however, now that salicylic acid can be obtained free from impurities, are rarely met with. When the salicylates disagree, full doses of the alkaline citrates, bicarbonates or tartrates may be given at short intervals until the urine becomes distinctly alkaline, after

which the same medicine is to be given in such doses and so often as will just serve to maintain the alkalinity of this secretion. Or quinine may be given, alone or with alkalis, in doses of 3 to 5 grains every four hours. Calomel occasionally and in moderate doses may be given with advantage during the administration of the salicylates.

Opium, in the form of pulv. ipecac. co., is often useful as an anodyne hypnotic—when not contra-indicated by respiratory or renal complications.

Antipyrine, in doses of 15 or 20 grains every few hours, will sometimes relieve acute symptoms when other measures have failed.

The salicylates and the alkalis usually need to be given well on into convalescence, and only gradually withdrawn as a more tonic medication is adopted. But as rheumatic pain gives place to mere aching, quinine becomes of marked value, and—especially if the urine be found of low specific gravity—iron is also indicated; in this stage also the tincture of bryonia dioica, in 3 to 5 minim doses, is often serviceable. A regular and sufficient action of the bowels must be maintained throughout the illness. If rheumatic joints continue stiff, swollen and weak, they may be lightly blistered, or painted with iodine, and shampooed, while guaiacum and potassic iodide are given internally. Change of air, especially to a warm, dry climate, does much towards completing the cure, but the convalescent must be careful in respect of clothing and of exposure. His underclothing, from throat to wrists and ankles, and his socks, must be woollen, and changed at least once a week, and he should be warned how greatly one attack of rheumatism predisposes to a second.

The prevention, detection and treatment of *Complications* is most important. The heart must be carefully examined at the onset, and its condition observed daily throughout the course of the disease, while care is taken to avoid all needless and too frequent exposure of the chest wall. Should signs of inflammation of the heart or pericardium be detected, the treatment proper to these conditions, including a succession of flying blisters, must be promptly adopted. The greatest caution should be observed in allowing such patients to leave their beds; and, indeed, there can be little doubt that, if all cases of acute rheumatism, however slight, were kept in bed for at least four to six weeks, the later

cardiac symptoms would be much more rarely developed, or would at least be much mitigated in severity, as they would also be more certainly detected in their initial stages.

The various respiratory complications demand their appropriate treatment, and, like those referable to the heart, often call for free stimulation.

Hyperpyrexia when slight, may be treated by frequent sponging of the whole surface with cold water; in its more acute form it is best combated by placing the patient in a bath at a temperature of about 98° F., and cooling this down by the addition of cold water to about 60° or 70°. When the patient's rectal temperature is reduced to 99°, or should he begin to shiver, he must be at once dried, removed from the bath, replaced in bed and kept lightly covered. The cold bath, or the cold pack in milder cases, may be repeated if the temperature again rise rapidly or to an abnormal height. The glycosuria commonly yields to the administration of salicylates.

Rheumatism occurring in gouty subjects must be treated with due regard to the dominant diathesis. Potassic iodide in combination with ammoniac chloride and salicylate of potash is often useful; and colchicum may be of service in relieving pain.

C. E. SHELLY.

RHEUMATISM, CHRONIC.—

This affection is intimately associated with the acute form of the disease, being sometimes developed either subsequently to it, or as its final stage, and commonly appearing amongst those who inherit the rheumatic diathesis.

Chronic rheumatism is, however, a disease more of middle than of early life, but it is apt to be provoked by the same causes—hardship, exposure, damp, cold, &c.—as those which predispose to the acute form; and its progress is marked by anatomical appearances and pathological changes which do not differ from those observable in ordinary sub-acute articular rheumatism, save in those extreme examples of the chronic form which merge into, and are practically indistinguishable from, rheumatoid or chronic osteo-arthritis.

Symptoms.—The salient features of chronic rheumatism are associated with the joints, and comprise essentially two symptoms, viz., *stiffness*—accompanied with a sense of dryness and with audible creaking on movement—and *pain*; the latter is mostly severe, heavy and wearing in character, and often involves the

contiguous muscular and bony structures of the limb. Both symptoms are generally relieved by local friction and by free and persevering movement within moderate limits; are aggravated by over-exertion, as well as in cold, damp and sunless weather; and are very apt to be excited by local strain or injury. Although prone to shift from joint to joint, and in time to implicate a gradually increasing number of articulations, the symptoms are more persistent, and more often recur in the joints first attacked than is the case in acute rheumatism.

Beyond the effects of pain and of the impediment to exercise and locomotion, the general health is not appreciably impaired in the milder class of cases. But in those of a more severe type, the frequent recurrence of pain and swelling in certain joints—particularly in those of the hands—becomes associated with a gradually increasing enlargement and deformity of those structures. As the disease progresses, other joints, great and small, become successively invaded; the exacerbations of local pain and swelling recur at still shorter intervals, until at last they are practically continuous, though then often less acute. The general health suffers in proportion and the several joints may become irregularly swollen, dislocated, ankylosed and variously distorted to an extreme degree. It is in these, the more severe cases, that cardiac complications are most usually met with; they are commonly the sequel of an endocarditis due to an attack of acute rheumatism which has preceded, or occurred in the course of, the chronic malady.

In all its forms the disease is very persistent, except under the most favourable conditions, difficult to arrest, and extremely prone to recur on very slight provocation.

Diagnosis.—The aching and swelling associated with varicose veins of the leg and thigh, the reflected pains of early hip disease, and the pains sometimes complained of in commencing popliteal aneurysm, may simulate mild chronic rheumatism; the differential diagnosis is easily made by physical examination. The non-affection of such articulations as the temporo-maxillary, the sterno-clavicular and the inter-vertebral is considered to distinguish severe chronic articular rheumatism from advanced rheumatoid arthritis; but such distinction must be regarded as little more than arbitrary. The pains of syphilitic periostitis are mostly experi-

enced in the shin, the parietal and the frontal bones, are greatly aggravated by pressure, almost invariably more severe during the night, and are apt to be associated with local bosses—syphilitic nodes.

Treatment.—Change of residence to a drier, more sunny and less variable climate—for the colder part of each year at all events—is a most valuable measure whenever it can be adopted. A temporary submission to the local regimen of Bath, Buxton, Droitwich; or of Aix-les-Bains, Baden and other similar continental health-resorts is also useful. The Turkish and the ordinary vapour bath give good results in suitable cases. Warm woollen underclothing, frequently changed; sufficient regular exercise, short of fatigue; early hours; warmth and efficient ventilation of living and sleeping rooms are all useful measures. The diet should be rich in fats and poor in sugar, the food being eaten slowly, and at regular intervals. The stronger wines and ale should be avoided. Freedom from all mental and physical excess and from worry, are important points in the general hygiene of rheumatic subjects. Medicinal treatment includes the administration of cod-liver oil; of a long-continued course of potassic iodide and arsenic, in fairly large doses, in infusion of broom; together with alkalies, bark, iron and strychnine, as indicated by the condition of the general health; and careful attention to the hygiene of the skin, teeth, bowels and kidneys. The ammoniated tincture of guaiacum, with bromide of ammonium and a hepatic stimulant, such as podophyllin or euonymin, is sometimes serviceable. Sulphur in lozenge or pill, or in the old-fashioned prescription of an abundance of freshly prepared mustard taken at each meal, is undoubtedly of value. And some cases, otherwise intractable, have markedly improved during the administration of a strong infusion of common horse-radish (a large stem scraped into a pint of sound whisky or gin or old ale; 1 or 2 ounces of the infusion, after standing for twenty-four hours, to be taken night and morning for a month), and of extract. conii, gr. iij in pill, night and morning, with a diuretic alkaline mixture. Chronic rheumatism occurring in the syphilitic and in the gouty is favourably influenced by the iodides and by colchicum respectively.

Local treatment is always called for, and often affords great relief. It includes counter-irritation by iodine or blisters; friction with stimulating and anodyne liniments, especially after hot bathing or

fomentation; the continued application of a hot saturated solution of common salt in vinegar, friction with flowers of sulphur; local steaming of the affected joints; passive motion; and massage.

C. E. SHELLY.

RHEUMATISM, GONORRHEAL (Gonorrhœal Synovitis; Urethral Rheumatism).—Persons suffering from a discharge from the genito-urinary mucous membranes are apt to develop an inflammatory affection of the joints, with their associated muscles and fibrous structures, which presents points of resemblance on the one hand to articular rheumatism and on the other to pyæmia.

The disease is usually observed in the course of a gonorrhœa, sometimes appearing during the early and acute stage of that malady, but often not until after it has subsided into a simple gleet, or even not until after all discharge has ceased. It is far more common in men than in women; its subjects often possess a marked tendency to gout or to rheumatism; it is apt to be excited by local injury or chill. A previous attack begets a decided predisposition to a recurrence of the disease on every re-excitation of urethral inflammation, whether this be simple or specific.

Symptoms.—The knee is the joint most commonly and chiefly affected, probably because it is that most liable to strain and injury: but the patient may first complain of pain in the lumbar and plantar regions with swelling of the feet, then the ankles, knees, or wrists become suddenly hot, tender, and extensively swollen. The pain and tenderness may extend to the fasciæ, especially of the loins, the palms, and the soles; to the tendons (as the tendo-Achillis); to the muscular aponeuroses, as of the thigh, arm, and shoulder; and to the nerve-sheaths, as of the sciatic. At the same time a well-marked catarrhal conjunctivitis is frequently developed in one or in both eyes.

The amount of pain, and both the degree and the extension of the joint symptoms, vary much in different cases, but there is always more or less malaise and anorexia, with furred tongue, restlessness, and depression. In the mildest cases the arthritic symptoms may be limited to only one or two joints and may speedily decline; or while the pain disappears, the affected joints may remain weak and distended by a chronic synovitis, but free from tenderness. In

the most severe instances the disease progressively invades one joint after another, those previously attacked recovering but slowly or even scarcely improving at all; so that in the course of several weeks or months all the joints may become affected, including the sterno-clavicular, the maxillary, and the inter-vertebral, as in the worst cases of chronic rheumatic arthritis. In the more chronic cases, the general symptoms grow gradually less acute, there is little, if any, fever, and the appetite is retained; but the patient becomes debilitated, depressed, and generally impaired in health in proportion to his persistent and increasing helplessness.

The disease is of very variable duration, but is not directly fatal.

Diagnosis.—This hinges mainly on the association of joint-inflammation with an existing, or recent, discharge from the urethra; it is strongly suggested by the occurrence of the articular symptoms in a young male, which should always prompt to a careful examination of the patient's urethra, and by the co-existence of conjunctivitis; it may also be assisted by a previous history of similar illness in connection with gonorrhœa, or by the history of a liability to urethral discharge or irritation, and by the absence of cardiac complications.

Pathology.—The affected joints are in the early stage acutely inflamed, hyperæmic, and distended with serous effusion; the surrounding structures are also swollen or cedematous. In a more advanced stage of the disease the intra-articular effusion becomes flaky or even purulent, the cartilages may become eroded, and the joints ankylosed or utterly disorganized. It is noteworthy that the heart and pericardial structures are never involved in the morbid process.

Ætiology.—The causation of gonorrheal rheumatism is obscure; very often it is not "gonorrheal" at all, being developed in connection with a merely simple, gouty, or traumatic urethritis. The disease has been variously regarded as acute or sub-acute articular rheumatism accidentally associated with a gonorrheal or similar urethritis; as a form of pyæmia originating in infection from the inflamed urethral surface; and as a reflex tropho-neurosis excited by an abnormal state of the genito-urinary system. It may be observed that the pyæmic and the tropho-neurotic theory might each equally well explain those cases of articular disease which have been observed in connection with chronic in-

flammatory discharges from other mucous surfaces—e.g., in chronic endometritis, in chronic bronchitis, and in dysentery; while a reflex tropho-neurotic irritation would also explain the recurrent swelling, pain, and tenderness of the joints, which are, in some women, regularly associated with pre-menstrual pyrexia, and would better account for the absence of all those cardiac complications which are so frequent in true rheumatism.

Treatment.—The proper treatment of an existing gonorrhœa, including an appropriate dietetic regimen, must be persevered with. A sharp purge, followed by full doses of alkaline salines, with quinine or the salicylates, should be given in the acute stage; in the later stage, and in more chronic cases, potassic iodide with alkalies, iron, and nux vomica or bark, are useful; and mercury may be given with good effect if syphilis be present. Rest—which must be absolute in severe cases—should be afforded to the inflamed joints, while pain is relieved by the application of hot fomentations with anodyne liniments of opium or belladonna, or by light blistering; and in sthenic cases by local leeching. Sub-acute cases are benefited by firm strapping of the affected joints; and in the chronic forms friction, massage, galvanism, and moderate exercise are useful. The more intractable cases, and especially those in which ankylosis is threatened, should betake themselves to a warm dry climate—and preferably to some health-resort at which they can be subjected to a complete course of thorough and persevering treatment.

In every instance, the patient should be impressed with the double fact that, while the danger of a recurrence of the joint-inflammation increases with each fresh exposure to infection, prognosis increases in gravity with each repetition of the attack.

C. E. SHELLY.

RHEUMATISM, MUSCULAR.

—This form of the disease affects single muscles or groups of muscles, with their associated tendinous expansions, in various parts of the body.

Symptoms.—It is marked by local pain, severe and often lancinating in character, aggravated by movement and by slight or irregular pressure, but relieved by firm support and by complete relaxation of the affected muscle. It is usually accompanied with more or less general febrile disturbance, which may closely resemble that noted in the milder cases of acute rheumatism, and sometimes

with a catarrhal (rheumatic) conjunctivitis, but pain is often the only symptom of any note. Even in mild cases of muscular rheumatism, the more acute symptoms may last for many days, or even weeks; they decline gradually in severity, are liable to sudden and severe exacerbations if the affected part be again exposed to any exciting cause, and are, for a long time after their apparent cure, prone to recur upon slight provocation. In its most chronic form the disease never entirely leaves the patient, who suffers from an increase of his habitual pain in the affected muscles or tendons with every recurrence of cold or damp or snow, and especially with the onset of east and north-east winds.

Local varieties of the malady have been distinguished by special titles. Thus, a rheumatic condition of the muscles of the neck, notably of the sterno-mastoid and trapezius, constitutes muscular *torticollis*, *wry-neck* or *stiff-neck*; of a part of the intercostal, pectoral or serratus muscles, *pleurodynia*—this is frequently excited by coughing, sneezing, &c., it is not accompanied by the auscultatory and other physical signs indicating disease of the lungs, pleura or heart, or by the three *points douloureux* which are pathognomonic of intercostal neuralgia. *Lumbago* affects the muscles of the loins and their fibrous attachments, on one or both sides; it compels a more or less stooping posture, and is much aggravated by any attempt to bend, twist or straighten the back. The symptoms are usually very characteristic, but care must always be taken to exclude other possible causes of lumbar pain, especially disease of the kidney, bladder, uterus and rectum, perinephritis and perityphlitis, abdominal aneurysm, caries of the spine and lumbar abscess, spinal meningitis, hip disease (rheumatic or other), sciatica, &c. *Lumbago* sometimes co-exists with a similar rheumatic affection of the abdominal muscles; and this, again, may be observed without any associated pain in the loins. *Dorsodynia*, *omodynia*, or *scapulodynia* signifies rheumatism of the muscles of the shoulders and upper back; and *cephalodynia* affects the occipito-frontalis muscle, the pain being chiefly experienced in the forehead or occiput and sometimes involving the eyeballs.

Muscular rheumatism, in any form, may appear suddenly, or the muscular pains may be preceded by a day or two of moderate febrile malaise, sometimes accompanied with sore throat.

Pathology.—No special pathological

changes—beyond those which necessarily result from impaired motion of the structures involved—have been recognized in this disease.

Etiology.—The disease is most frequent in persons of the rheumatic diathesis, and its development is favoured by causes identical with those which predispose to the acute disease; the directly exciting cause is frequently the exposure of a muscular surface to local cold or draught immediately after active exertion and during free perspiration; or, again, the sudden or awkward execution of some unusual or excessive muscular effort. It is not limited to any special period of life, but torticollis is common in childhood, pleurodynia in adolescence, and lumbago is more usually met with in the adult and aged.

Treatment, prophylactic and general, is essentially that of the rheumatic diathesis (see RHEUMATISM, ACUTE, and CHRONIC). An effective purge at the outset should be followed by alkalies and salines; the iodides, with arsenic and guaiacum, are serviceable when the symptoms are protracted or obstinately recurrent, and debilitated subjects require iron, quinine and a more generous dietary, often with a fair proportion of bland, sound stimulants.

Local treatment is important, and includes especially local rest and support, as by strapping, and counter-irritant applications, *e.g.*, turpentine stupes, mustard plasters, hot fomentations and stimulating liniments; and anodynes, such as belladonna liniment and plaster, morphine *sub cute*, &c. Immediate recourse to a vapour bath sometimes cuts short an attack; as also will a hypodermic injection of atropine (gr. $\frac{1}{100}$ to gr. $\frac{1}{50}$), this latter often proving effective in lumbago. Local warmth and protection from cold and damp are highly necessary. Cases otherwise intractable are benefited by a change of climate, and by the use of such thermal and mineral waters as are recommended in the articles RHEUMATISM, ACUTE, and CHRONIC. C. E. SHELLY.

RHINITIS, ACUTE (Acute Nasal Catarrh; Coryza).—Acute catarrhal inflammation of the mucous membrane of the nose, *i.e.*, an ordinary cold in the head.

Symptoms.—The chilliness, headache and feeling of stuffiness in the nose, followed by sneezing and discharge of a watery, irritating fluid from the nostrils, are such a common experience that it

will be unnecessary to do more than mention them. After a time the watery fluid becomes muco-purulent, and finally ceases. Accompanying the local manifestation there are usually evidences of constitutional disturbance, as shown by slight pyrexia, loss of appetite, furred tongue, constipation and high-coloured urine.

Pathology.—There is hyperæmia of the mucous membrane of the nose, with increased cell-proliferation.

Ætiology.—There seems to be an hereditary tendency to coryza, and there is also some evidence in favour of its contagiousness. Exposure to cold and damp, especially when the system is below par, is the chief exciting cause.

Treatment.—This, to be of any avail, must be undertaken at the very commencement of the attack. The most successful plan is the administration of 10 minims of tincture of opium, $\frac{1}{2}$ drachm of the spiritus ætheris nitrosi, $\frac{1}{2}$ ounce of the liquor ammonii acetatis made up to an ounce with camphor water, every six hours for four doses, the patient meanwhile being kept in a well-warmed room, and on a light diet. When the acute symptoms are over, quinine may be given with advantage. The writer can speak from personal experience of the utility of carbolized smelling salts in warding off a threatened attack of coryza. The following formula can be recommended:—R Acid. carbolicæ ꝑviii. ammon. carb. ʒij, pulv. carbonis ligni ʒij, ol. lavandulæ ꝑvj, tinct. benzoini co. ʒj, liq. ammon. fort. q.s.; misce bene

F. DE HAVILLAND HALL.

RHINITIS, CHRONIC ATROPHIC (Ozæna).—Chronic inflammation and subsequent atrophy of the mucous membrane of the nose, accompanied by the formation of dry crusts and by a most offensive odour. The term *ozæna* was applied to the disease on account of this odour.

Symptoms.—Patients generally complain of some feeling of discomfort or irritation in the nose, and this may lead them to pick or scratch the interior, producing excoriation of the mucous membrane and slight hæmorrhage. The prominent symptom, however, is the odour which proceeds from the nose; this is something quite indescribable and *sui generis*, but once experienced it is readily recognized. The patient, fortunately for himself, loses the sense of smell. There is a puriform secretion which rapidly dries up, forming hard,

greenish-brown crusts, sometimes the size of the last phalanx of the patient's little finger. Owing to the dilated and altered condition of the nasal passages air reaches the larynx and lungs without being filtered, warmed and moistened, so that a dry and atrophic condition of the pharynx, and chronic laryngeal and bronchial catarrh frequently complicate the rhinitis. It also gives rise to many reflex symptoms, such as paræsthesiæ in the throat and larynx, headache, neuralgia, giddiness, &c. Ear trouble is met with in some cases; e.g., acute and chronic catarrh of the middle ear.

On making a rhinoscopic examination, it will be found that the nasal passages are so capacious that the posterior wall of the pharynx can often be distinctly seen; the mucous membrane is usually covered with greyish crusts of inspissated mucus, which stink abominably, and on the removal of these it is found excoriated or abraded in places, and may bleed a little, but the occurrence of well-marked ulceration is unusual; the middle turbinated body is more often excoriated than other parts of the nose. The colour of the mucous membrane may be normal or pale; sometimes it is slightly reddened.

By posterior rhinoscopy a similar condition of atrophy can be recognized in the posterior nares. Almost invariably the pharynx will be found dry and glistening or covered with adherent mucus, which in towns is usually black from soot and other impurities in the air, the capacious nostrils having failed to arrest them. A dry glazed state of the pharynx or the presence of adherent mucus should suggest the idea of atrophic rhinitis.

Diagnosis.—This is seldom a matter of any difficulty; the characteristic stench emitted by the patient and the dilated nasal passages with dry crusts of mucus are not present in other diseases. Suppuration in the antrum might possibly be mistaken for atrophic rhinitis, but in this condition the discharge is one-sided, and, as Christopher Heath points out, "the offensive smell is perceived only by the patient, and not by his friends, the reverse being the case in *ozæna*; and, again, the discharge is only occasional, is determined by the position of the head, and is simply purulent, whereas in *ozæna* the discharge is constant, and mixed with offensive crusts from the nasal cavities."

Prognosis.—Atrophic rhinitis does not in any way threaten life; it is, however, a most obstinate disease to treat, and

some of the best authorities aver that, though relief may be obtained, a cure is unknown.

Morbid Anatomy.—Much discussion has taken place in regard to two points connected with the pathology of atrophic rhinitis: first, as to whether it is always preceded by an hypertrophic stage? Second, whether a specific micro-organism is at the root of the mischief? The first question must be answered in the affirmative, as there is no evidence of a primary atrophic rhinitis; everything points to the atrophic being a sequel of pre-existing catarrhal inflammation. The atrophy affects all the structures of the nose, the bones shrinking as well as the mucous membrane. Some writers attribute the characteristic smell to change taking place in the gland cells, with fatty degeneration and liberation of the fatty acids. Whether this be so or not, there is no doubt that the increased size of the nasal cavities plays an important rôle in the production of the disease, as it allows the dried secretion to be retained, and this still further irritates the mucous membrane. On the other hand, there are authorities who maintain that atrophic rhinitis is predisposed to by defective development of the turbinated bodies and osseous structure of the nose generally. As regards the existence of a specific micro-organism, this must remain an open question; but the absence of bacteria in the mucous membrane renders it unlikely that the disease is of parasitic origin. The bacteria found in the secretions are probably concerned in the production of the factor, but are not the cause of the disease.

Ætiology.—It is possible that certain diatheses, especially inherited syphilis, may exercise considerable influence upon the formation of the atrophic stage of rhinitis, but under what conditions is unknown. The only factor as to the existence of which the writer has been able to satisfy himself is anæmia, the disease being most frequently met with in anæmic young women. Bearing in mind the frequency of gastric ulcer in the same kind of patients, it would seem that there is a special vulnerability of the mucous membrane in anæmia. The great majority of the cases commence in early life, and only very seldom are they seen to begin after twenty-five. The disease is much more frequently met with in women than in men—in about the proportion of seven to two.

Treatment.—If any underlying general condition of ill-health can be discovered,

this should be treated. In anæmia the combination of 3 minims of arsenical solution with 10 grains of ammonio-citrate of iron given thrice daily generally exercises a beneficial effect. The writer has not seen any good resulting from the administration of iodide of potassium in ozæna due to atrophic rhinitis. It is, however, on local treatment that the chief reliance is to be placed. Thorough and systematic cleansing of the affected parts must be insisted on. This can most satisfactorily be done by the use of the hand-ball spray apparatus. Ten grains of a mixture of equal parts of common salt, borax and bicarbonate of sodium and 5 grains of white sugar in 2 ounces of warm water will be found very useful. In some cases the addition of 10 or 15 minims of the glycerin of carbolic acid to the above solution will be found advantageous; or the sugar may be omitted, and 10 to 15 minims of the solution of the permanganate of potassium substituted. At first it may be necessary to spray out the nostrils two or three times daily, but as improvement takes place it will be possible to lessen the frequency. After the nostrils have been thoroughly cleansed, various astringent and antiseptic remedies may be tried. The writer has had good results from the insufflation of equal parts of iodol and boric acid. Weak solutions (5 to 10 grains to the ounce) of sulphate of zinc or alum may be tried. A spray of thymol gr. $\frac{1}{2}$, glycerin and alcohol āā 3ss, in water ℥j , used two or three times a week, and followed by fluid cosmoline in an atomizer, has been highly praised. In some obstinate cases using a tampon of cotton-wool, either medicated or plain, as recommended by Gottstein, has given relief when other measures have failed. Anointing the interior of the nose at night with vaseline after previous spraying is sometimes successful in preventing the formation of crusts, or an oily solution of menthol (20 per cent.) may be poured into the nostril and allowed to run into the throat. F. DE HAVILLAND HALL.

RHINITIS, CHRONIC HYPERTROPHIC (Chronic Nasal Catarrh).—A chronic inflammatory condition of the mucous membrane of the nose.

Symptoms.—The chief complaint made is of the excessive flow from the nostrils, which may be watery or muco-purulent in nature. There is generally also a feeling of stuffiness in the nose, a nasal twang to the voice, and deafness, due to

catarrhal swelling of the Eustachian tubes. On a rhinoscopic examination, the mucous membrane of the nose is found to be thickened, and this is usually most marked over the inferior turbinated bodies. The application of cocaine will cause constriction of the mucous membrane, but not to the same extent as when there is simply swelling of the erectile tissue without any hyperplasia.

Pathology.—There is an increase in the thickness of the mucous membrane of the nose, due to the increased afflux of blood and consequent increased cell-proliferation and tissue formation.

Ætiology.—The condition is the sequel of repeated attacks of acute coryza.

Treatment.—The general health of the individual must be improved by attention to the points indicated in the article on CHRONIC PHARYNGEAL CATARRH (*q.v.*). Locally, relief may be effected by the use of the chloride of ammonium inhaler, or of the alkaline spray, and after thorough cleansing of the mucous membrane mild astringents, such as acid. tannic. gr. v-x ad 3j, zinc. sulph. gr. v-x ad 3j, or potass. chlor. gr. x, may be ordered in the form of spray; but in the majority of cases the galvano-cautery, as advised under HAY FEVER, must be employed to cause contraction of the thickened membrane, before much improvement can be expected. The writer has found speedy and marked improvement follow free cauterization of the turbinated bodies; in some cases even a single application will suffice to give great relief.

F. DE HAVILLAND HALL.

RHINOSCLEROMA.—An extremely rare form of granulation tumour which arises from the anterior nares or adjacent parts.

Only very few cases have been observed in England, and all in foreigners. The majority of reported cases have occurred in Austria and Italy, but the disease is said not to be very rare in Brazil.

Symptoms.—It first shews itself in the form of raised tubercles of bony hardness, isolated or conglomerate, arising from the septum or alæ of the nose, the upper lip, or palate. The colour of the skin may be unaltered or deep brown. Soon the surface cracks, viscid fluid oozes forth and dries up to form scabs. The nose becomes flattened out, finally the nostrils are occluded. Pain is complained of only when the growth is pressed upon. No secondary growths occur, but rapid return of the disease has always followed its extirpation.

Pathology.—The growth consists of a dense small-celled infiltration with very little stroma. As in the closely related granulomata—lupus and lepra—characteristic bacilli have been conclusively demonstrated.

Diagnosis.—Differential diagnosis must be established from syphilis, keloid and epithelioma.

Treatment.—Injections of a 2 per cent. solution of salicylic acid of soda, combined with douches, snuffs, and ointments of salicylic acid, are said to have brought about some improvement.

J. J. PRINGLE.

RHINOSCOPY.—The examination of the nose. That of the anterior nares is termed anterior rhinoscopy; that of the posterior nares, posterior rhinoscopy; for both kinds the reflector and light used for making a laryngoscopic examination are employed.

In order to appreciate what is seen, the observer must habituate himself to the examination of noses both in health and disease, for it is only by comparison that it is possible to distinguish the normal from the abnormal, as the arrangement of the turbinated bodies, the direction of the meatuses, and the position of the septum, vary very much.

For Anterior Rhinoscopy the specula usually employed are Thudichum's, Fraenkel's fenestrated instrument, and Duplay's bivalve speculum. The spring of Thudichum's speculum is so stiff that patients complain of the pain caused by its introduction; the mucous membrane prolapses through the fenestræ of Fraenkel's, and thereby obscures the view. Duplay's speculum is most suitable for general use, the others being only necessary in exceptional cases.

By anterior rhinoscopy the inferior turbinated, and most of the middle turbinated, can be seen, and occasionally a glimpse is obtained of the upper turbinated bodies. The condition of the passages between them and the state of the septum can also be inspected.

Posterior Rhinoscopy.—Posterior rhinoscopy is a much more difficult task than making a laryngoscopic examination, as there are a certain number of persons in whom on account of the conformation of the naso-pharynx it is impossible to obtain a satisfactory view of the posterior nares, or in some cases any view at all. The best mirror for posterior rhinoscopy is Fraenkel's; the mirror is attached to the shank by a hinge, and is so arranged that by pressing

a trigger the mirror may be placed at any angle with the shank. Before commencing the examination the patient is told to hold the breath, or else to breathe quietly through the nose, and to say "hang" if requested. The object of this advice is to arrange that the soft palate may hang down in a relaxed condition, and not be drawn up tightly against the pharynx. The tongue is then gently depressed by a suitable spatula held in the left hand, and the rhinoscopic mirror, well warmed, is introduced behind the soft palate, on one side or the other of the uvula. When it is in position the trigger is pressed so as to elevate the mirror, and by this means a view of the posterior nares may be obtained. Should the soft palate be very irritable, both it and the pharynx and tongue may be sprayed with a 20 per cent. solution of cocaine, or the solution may be applied by means of a brush. This will facilitate the view of the posterior nares, both by causing contraction of the mucous membrane, and thereby increasing the size of the passage, and also by abolishing the sensibility of the palate, and thus permitting the speculum to be opened wider than could otherwise have been the case.

Various hooks and snares have been recommended for pulling the soft palate forward, but men of great experience in this method of examination, such as Schech, do not employ them, and say that more is to be done by patience than by instrumental assistance. Beyond stating the bare facts that on a rhinoscopic examination (or rather, on repeated examinations, because on account of the smallness of the mirror and the anatomical arrangement of the parts, they cannot all be brought into view at the same time) the septum nasi, the posterior extremities of the superior, middle and inferior turbinated bodies, with the superior, middle and inferior meatuses, and the orifice of the Eustachian tube should be seen, it is useless, without the aid of a diagram, to describe the appearances met with in such an examination.

F. DE HAVILLAND HALL.

RICKETS.—A disease of the whole of the tissues of the body, having its most characteristic manifestations in the bones.

Symptoms and Course.—The earliest symptoms are referable to the nervous system: restlessness—chiefly nocturnal, the bed-clothes being kicked off, and

sweating, also chiefly nocturnal, and occurring most abundantly about the head. Tenderness is another symptom; but this is often absent, and has probably been confounded with the "touchiness" or irritable weakness of the nervous system. Beading of the ribs and enlargement of the wrists are the earliest bony signs of rickets. The bony changes may be of the slightest kind, or of the most marked degree. The cranium presents different changes in different cases. It may be brachycephalic or dolichocephalic or asymmetrical; there may be "bossing" of the parietals and frontals and craniotabes (*q.v.*) may be found. A square, broad forehead, and overhanging brow, is regarded as of rachitic origin, but such protuberance below the frontal eminences, and sometimes of those parts, may certainly be due to syphilis, and may accompany brain defects without syphilis or evident rickets. The anterior fontanelle is often larger than natural, and may not be closed till long after the usual period—eighteen months of age. The face and jaws are small by comparison. The teeth are often cut late; there may be but one tooth in the jaws at the age of eighteen months. The growth of the skeleton generally is usually much retarded, and the long bones become curved, but not always in the same direction. The forearms become convex backwards, the humerus convex outwards about the deltoid insertion; the femur convex outwards and forwards; the tibia convex forwards, or else bent at a right angle (sabre-shaped tibia) at the junction of the middle and lower thirds. The ligaments become weakened and elongated, so that deformities of the joints may appear. The thorax may show lateral grooves passing downwards and outwards, usually external to the beadings, at the junction of the cartilages with the ribs; the sternum is convex forwards— anterior convexity. The outline of a transverse section is fiddle-shaped, and so also is the shape of the trunk, as made up of the thorax and abdomen; the latter being large and globular, corresponds to the wide part of the belly of the violin. Rickety children are very prone to catarrh of the respiratory and alimentary tracts; also to convulsions, tetany and laryngismus (*q.v.*)

Diagnosis.—This is easy if the beading of the ribs be perceptible to the touch; but in slight cases the failure of the child's health may not be attended by any recognizable bone change. It is very common in feeble infants a few weeks

or months old to note the sign of craniotabes. When the wrists are enlarged and the bones curved, the merest tyro may diagnose rickets with ease. Excessive irritability of the muscles and nerves and chronic catarrh are seldom due to anything else than rickets during the first months of life. The knee jerks are always exaggerated; ankle clonus may very rarely be obtained.

Prognosis.—As a rule this is good; but a few cases may persist or pass on to the stage of late rickets, but not, the writer thinks, if suitable treatment be carefully carried out. The dangers to life come rather from the nervous and pulmonary complications or accompaniments of rickets. The prognosis, therefore, varies with the prominence of such symptoms, and with the general state of health. Bronchitis and diarrhoea do not usually fail to yield to judicious treatment.

Pathology.—Rickets affects all the tissues, but especially those which are growing most rapidly—the nervous system and the bones. Infants are prone to catarrh of the mucous membranes and have very excitable nervous organs. Rickets promotes both these tendencies by debilitating and irritating these tissues. The bone changes and osteal neoplasia, though often most evident, are far less important as regards the life of the child than the catarrhal complications, the muscular debility, and the neurosal liabilities. A rickety infant is liable to universal convulsions; to tetany, especially of the extremities; and to tonic spasm of the larynx (eclampsia, tetany, laryngismus stridulus). It is prone to naso-bronchial, gastric, and enteric catarrh, rickety bronchitis, and diarrhoea. Rickets is credited with the power of causing splenic, hepatic and lymphatic enlargement; but some hold that in these cases congenital syphilis is co-operative and chiefly causative. Bossing of the frontal bones more than the parietal bones is probably of rachitic origin. The author has seen many cases which support this view, which may be restated thus:—if the parietals are more thickened than the frontals, the chief cause of the bone change is syphilis. Craniotabes, localized atrophy of bone, producing the so-called “parchment crackling,” is believed to be due to rickets as well as syphilis. It is doubtful whether rickets causes true tenderness of the muscles; there is in bad cases a general hyperæsthesia and “touchiness”—a rachitic neurasthenia; and there are

some grounds for believing that rickets may induce peripheral neuritis. But true tenderness should suggest the co-existence of scurvy, with hæmorrhages in the periosteum of bones, or of syphilis with inflammatory new growths about the periosteum and the area where the shaft and epiphysis join.

The beaded ribs (rickety rosary) are common effects of rickets, the thickening being most evident at the junction of the ribs with their cartilages; the fifth, sixth, and seventh are most affected, and the visceral aspect much more than the subcutaneous. Situate about the angles of the ribs behind, there may be found, especially at necropsies, posterior beadings or nodosities, which perhaps commence as spontaneous fractures; or the great strain on these parts may excite a new formation of bone.

An infiltration of the frontal lobes of the brain with an albuminoid-looking material, as described by Sir William Jenner, is, in the opinion of the writer, due to simple œdema and anæmia. The edges of the frontal and other flat bones of the skull are said to be thickened at the cranial sutures, the sutures appearing as furrows, but close observation shows that the furrows are not precisely at the sutures and are really grooves in the bone, in which dilated veins run.

The relationship of rickets to osteomalacia is obscure. In some cases of rickets there is bone softening, resulting from a sort of rarefying osteitis, and there may be a growth of new limeless bone having but little consistence. Billroth has called osteomalacia a fungous, fatty osteomyelitis, the hard mineral bone disappearing before the advance of fungoid granulations, some of which have become fattily infiltrated. But Rindfleisch asserts that in osteomalacia the salts of the compact bone are first dissolved out, whilst the organic matrix remains longer, and the dentate or crenate outline of the bone around the fungating material is not found in that disease, there being a gradual thinning of the bone with retention of its smooth surface (halisterischer bone atrophy of Volkmann).

Microscopical Appearances.—The most characteristic histological change in rickets consists in the irregular overgrowth of the layer of proliferating cartilage at the area of junction of the shaft and epiphysis. This lamina is like a disc in healthy ossification, whereas in rickets it is very uneven, and sends roots or peninsulæ into the vascular shaft;

sometimes islets of proliferating cartilage wholly detached from the parent growth are seen there. Around the bone at the junction of the shaft and epiphysis, and beneath the periosteum, a spongy soft vascular overgrowth takes place (spongoid tissue). Instead of there being a regular neat conversion of cartilage into bone, there is irregular overproduction of cartilage and of a soft granulation tissue which fails to grow into Haversian systems of lamellar bone. In microscopic section of the excessively overgrown red medulla a network composed of irregular fibrillated tissue, containing angular corpuscles, may be seen; the perverted representatives of what would have been true bone corpuscles. In the meshes of the network there appears a small round-celled highly vascular growth; this is like the new formation beneath or in the periosteum.

The changes at the epiphysial lines curtail the growth of the bone in length, but the wealth of medullary tissue entails an excessive production of compact tissue, hence the stunted dense bones of completed rickets. During the active period of rickets it is obvious that there must be a great defect of mineral matters; in Kassowitz's view, the new formation of blood-vessels and the hyperæmia are the real causes which melt away the bone and prevent deposition of lime.

The blood changes in rickets are like those found in anæmia; it is possible that this impoverishment and poor formation of the blood is the agency which determines the rachitic changes in the nervous system, bones, and other tissues. Altered blood may also conceivably cause fibroid growth in the spleen, liver, and lymphatic glands, such as may be found in some cases in which true rachitic changes occur.

Ætiology.—The combination of bad air, bad feeding, bad light, and want of cleanliness and sleep, is the one most likely to produce rickets. Excessive feeding with starchy compounds is a more effective factor during the early months of life than the giving of fats and proteids; but any method of feeding which throws upon the digestive and assimilative organs work of an unnatural kind tends to produce rickets.

It may certainly date from foetal life, but the so-called foetal rickets is frequently not identical in essential changes with ordinary rickets.

It chiefly affects infants during the

first two years of life, and is in some form or other the commonest infantile disease of populous towns.

Treatment.—This requires minute attention to details, but two broad principles have to be kept in view: rectification of the hygiene, especially of the dietary, and the use of tonic measures. Not only may the food given be of the wrong description, but it is often also indigestible; hence the necessity for careful consideration of the diet. The fact that the gastric juice does its work best when the surface on which it has to act is most extensive is the reason for ensuring a fine division of the curd of milk and of any other food. Minced meat, pounded chicken and fish, cream and milk, may be safely recommended. A little wine just before or with the chief meal may prove of great service. As a rule, sugary and starchy foods are given in excess. Food should be taken at regular intervals.

The castor-oil mixture is very serviceable in cases of slimy diarrhoea of rachitic origin: \mathcal{R} Olei ricini $\mathfrak{m}\mathfrak{v}$, mucilag. tragacanth $\mathfrak{m}\mathfrak{xv}$, syrapi $\mathfrak{z}\mathfrak{ss}$, aq. menth. pip. $\mathfrak{z}\mathfrak{j}$; to be taken three times a day.

The diarrhoea, and its congener bronchitis, require protection of the chest and abdomen by means of woollen garments, which should envelop the whole of the body except the head and hands.

Correction of excessive acidity of the food and of the contents of the stomach and intestines is important. If fats agree, cod-liver oil, bacon fat, and cream may be given. Most children take well a mixture of cod-liver oil and vinum ferri. Other tonics may be tried, such as hypophosphites, lactophosphate, acid phosphate, or pyrophosphate. Phosphorus in doses of $\frac{1}{100}$ grain dissolved in sweet almond oil, a minim of the phosphate of oil, three times a day; phosphate of lime in 2-grain doses; syrup of the phosphate of iron, or of the hypophosphites or of the iodide of iron, are valuable preparations. Letting the child sleep in a hammock is a suggested mode of preventing chills due to perspirations, which for some reason are most copious during sleep and about the forehead. Frequent exposure to the fresh air is a most valuable tonic. "Send the child out six times a day for ten minutes at the time" is a good prescription, and this may be done in almost any weather if due precautions are adopted against cold.

Late Rickets would appear to be fairly

well named, since in these cases occurring in children after the period of infancy (after two years) there is over-production of cartilage at the epiphysal line. But the disease may possibly be only a recrudescence of infantile rickets. It may follow acute illnesses, especially measles and scarlatina. Whether it be really identical with rickets is a speculative pathological problem; and, with regard to congenital and foetal rickets, the same may be said.

Foetal Rickets is often foetal cretinism. Its main features are:—Large head, large belly, thick stunted limbs, depressed nose root, and abundant overgrowth of subcutaneous tissue. The thyroid gland may be normal or enlarged, but the "cartilaginous digitation" of rickets is absent; in its place a fibrous lamina intervenes between the shaft and epiphysis. A premature ankylosis of the basi-sphenoid and basi-occipital bones is found as in cretins; the membrane bones are well grown or overgrown. The brain may be deformed owing to the shortening of the basis cranii and the over-development of the cranial vault, and sometimes dropsy of the ventricles is present. The heart may be malformed, but such cases usually succumb at birth.

Infantile Osteomalacia may be associated with rickets or occur separately. Cases have been described in which the whole skeleton, but especially the long bones, was softened, friable and thinned; fractures occurred easily, and craniotabes was present. Occasionally rachitic digitation of the growing cartilage was noted, and other alleged rachitic signs—*e.g.*, sweating without fever, splenic enlargement, anæmia, emaciation, restlessness, and sleeplessness. The bones exhibited in some cases buttresses of massive spongy osteoid tissue beneath the periosteum, as may occur in rickets, especially where greenstick fractures exist. The children were under two years of age; the cases frequently ended favourably after lasting a few months. The treatment of such cases is that of rickets. Congenital debility may be assumed to exist.

ANGEL MONEY.

RIGIDITY.—The term is applied to parts, which should be freely movable or distensible, but have become stiff and fixed.

It is used to designate the immovability of joints, the result of ankylosis, also the condition of the cervix uteri,

when it does not dilate coincidentally with the increase of uterine contractions. The arteries are said to be rigid, when they are no longer fully dilatable, on account of fibrotic changes in their coats, and the valves of the heart, when as the result of atheroma and other conditions they cease to be freely movable.

Muscular spasm is a frequent cause of rigidity, which often occurs in the course of paralysis, either of cerebral or spinal origin. It is not necessarily, however, due to an organic lesion, nor is it always associated with paralysis. Rigidity frequently supervenes in the course of *hysterical or functional paralysis*. It is then usually hemiplegic or paraplegic in its distribution, but in some cases all four limbs are affected and in others only one. Various positions are assumed by the parts attacked, but commonly the elbow is semiflexed, the thighs are adducted, the knees extended, the heels drawn up and the feet turned inwards in the position of talipes equino-varus. This condition is maintained during sleep, and remains constant during the day. It generally ends in more or less sudden recovery, but it may persist for years. In the latter case the muscles undergo a certain amount of wasting. It is believed that secondary sclerotic changes may occur in the cord, and so render the condition permanent.

The rigidity, which ensues *after hemiplegia*, is called "early" or "late," according as it occurs a few days after the attack, or in the course of a few weeks. The early variety is much the slighter, and consists usually of a flexion of the fingers and elbow on the paralysed side, intermitting throughout the day, and usually disappearing during sleep. It is supposed to be due to irritation of the fibres in the neighbourhood of the effused blood. Late rigidity in the upper extremity generally consists of a state of flexion of the various joints. The elbow is bent at a right angle, the wrist pronated and flexed, and the fingers curved in towards the palm of the hand. This condition is sometimes associated, especially in cases of incomplete paralysis dating from early life, with an irregular spasm, which has been termed *hemiplegia chorea* when it affects the whole limb, and *athetosis* when the thumb and fingers particularly suffer. Sometimes, though rarely, the elbow is straightened, the wrist extended, and the hand and fingers assume the position of the griffin's claw. The leg is much less frequently affected with rigidity than the

arm, but sometimes there occurs a certain amount of flexion of the hip, knee, and ankle. Mobile spasm is also much more uncommon in the leg. The muscular excitability is nearly always increased on the affected side, the various jerks (knee, wrist, and triceps) are exaggerated, and ankle clonus is obtainable. Not only may these expressions of increased irritability be transmitted to the healthy side, but rigidity itself has been described as is occurring in the opposite leg.

It is commonly supposed that late rigidity is due to a secondary sclerosis of the lateral columns of the cord, its extent being determined by the degree of the irritative process.

Meningitis and various diseases of the spinal cord, *e.g.*, disseminated sclerosis, myelitis, &c., may cause rigidity of the lower extremities by inducing spasm. As a rule the thighs are strongly adducted, the knees extended, and the heels drawn up. The same condition often results from acute angular curvature of the spine, and in such cases recovery not infrequently occurs. Rigidity may also ensue in the late stages of atrophic spinal paralysis and peripheral neuritis. It is then due, not to spasm, but to changes in the muscles and the subsequent formation of adhesions in the joints and in the sheaths of tendons.

WILLIAM GAY.

RIGOR.—A fit of shivering indicated by tremulousness of the limbs and chattering of the teeth. The patient feels and looks very cold, his lips, cheeks, nose, and finger tips are livid, otherwise he is pale. In severe cases the fingers appear to be shrivelled. The pulse is small and frequent, the respirations hurried and shallow. The surface of the body is cold, but the internal temperature is raised. The sensation of cold, resulting in shivering, is due to the contraction of the peripheral arteries, which prevents the access of blood sufficient to warm the superficial tissues.

Rigors are common in all forms of malarial fever, and acute diseases, especially pneumonia and erysipelas, are apt to be ushered in by rigor. In children and persons of a neurotic tendency a convulsion may replace the initiatory rigor of acute disease. A rigor occurring in the course of an illness not due to malaria should always suggest the possibility of pus formation, or it may indicate the occurrence of thrombosis. During

the rigor, warmth should be promoted by hot drinks, hot water bottles to the feet, and by wrapping the patient in warm blankets; afterwards, treatment will be directed against the disease which was the cause of the rigor.

RINGWORM (*Tinea Trichophytina*).—A contagious disease of the skin due to the presence of a vegetable parasite.

Ringworm of the Scalp (*Tinea Tonsurans*; *Herpes Tonsurans*).—One of the commonest and most troublesome diseases among children of all classes in this country.

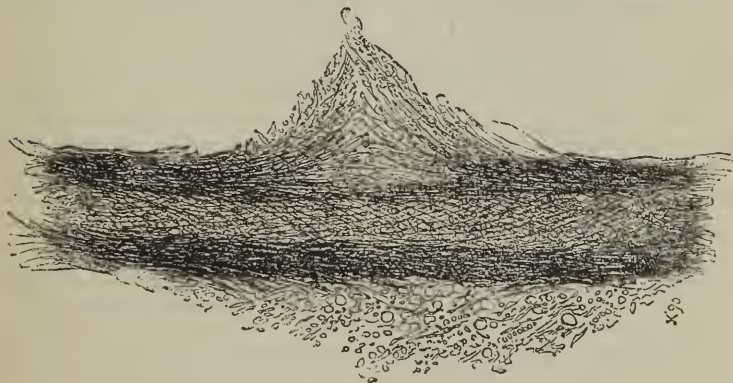

Eruption.—The disease first shows itself on the scalp, as single or multiple, circular or oval, irregularly distributed, reddish or greyish, scurfy spots, which may occasionally itch a little. In exceptional cases a little vesication may be present at the spreading edge, hence the misleading term, herpes tonsurans. The most striking feature of the spots is that the hairs over them are scanty, lustreless, stumpy, swollen at the root, with fringed or twisted ends, and often darker in colour than the normal hairs. The hairs surrounding the patch are also opaque and brittle. In very young children, or in those whose hair is fine, fair and scant, the ringed conformation of the patches is often marked, and the affected hairs, instead of sticking up from the surface of the skin, lie matted together. Generally, however, as the spots enlarge they lose their circular form, and by their coalescence form irregular patches which may finally involve the whole scalp. The rate of extension varies greatly in different cases. In a certain proportion, severe inflammation of the follicles and deeper structures ensues, producing tender, boggy, livid or red swellings, covered either with thick crusts and scabs or with numerous points of sticky, purulent fluid which correspond to the distended openings of suppurating hair follicles, from which pus can be easily expressed (*Kerion*). This condition is not exclusively confined to cases of tinea tonsurans, but is infinitely rarer as an epiphenomenon of other inflammatory diseases of the scalp; it seems to depend rather upon some constitutional peculiarity of the individual than upon special virulence of the micro-organism. As its consequence the fungus is destroyed, spontaneous cure occurs, but bald patches are very apt to result, from total destruction of the hair follicles.

In another class of cases—by no means rare—the hairs on the affected patches fall out with their root-sheaths attached, desquamation ceases, and absolutely bald, smooth, shining white patches, like those of alopecia areata, are produced (*bald ringworm*). Characteristic stumpy hairs can, however, almost always be found either at the margin of the patches or elsewhere upon the scalp; if one patch become thus affected others invariably follow suit.

The most obstinate cases are those of old standing in which the whole scalp is involved, much scaliness and baldness being thereby produced. The condition closely resembles dry seborrhœa or eczema of the scalp. Impetiginous inflammation may also arise either spontaneously or as the result of misdirected or too vigorous treatment; in either case it may play

or nearly cured cases, a useful adjunct or preliminary to microscopic examination is found in the application of pure chloroform, a drop of which, after evaporation, causes diseased hairs to become whitish, while healthy hairs retain their normal colour.

Pathology.—The fungus is best seen by examining detached hairs under the microscope (200–300 diameters) in weak liquor potassæ, after the removal of fatty matters by soaking in ether; the preparation is much more satisfactory if the hairs are immersed in liquor potassæ for at least a quarter of an hour before mounting. Some practice is also necessary for the detection of proper hairs for examination, only those which are broken and easily detached, carrying with them the root-sheath, being suitable. The brush-like distal extremity of the

Hair invaded by Fungus of Tricophyton.

havoc with the scalp, causing the disease to spread both in extent and severity, destroying the hair follicles and producing permanent—albeit usually partial—baldness.

Diagnosis is in many cases easy, but in others careful and repeated microscopic examination is necessary for the detection of the cryptogam. If the head be covered with crusts, scales or scabs, these must first be removed by poulticing or the continuous application of oil, after which the microscope will serve to differentiate the disease from impetigo, eczema, or the early stage of favus, with which it is readily confounded. Old-standing scurfy patches and cases supposed to be cured must be diagnosed from dry seborrhœa and psoriasis, and bald ringworm patches from alopecia areata. In dubious

hairs is characteristic. The hair-shaft is seen to be split up longitudinally by innumerable minute round polymorphous spores ($\frac{1}{1000}$ to $\frac{1}{5000}$ inch in diameter) and by long, wavy, transparent tubes or threads of branching mycelium. The spores and mycelium do not, as a rule, extend outside the inner root-sheath, a fact which explains the rapid cure of patches from which the hair falls spontaneously or which have been effectually epilated; but in very severe cases with perifollicular inflammation they have been described and figured outside the follicle and even throughout the papillæ and corium. The fungus probably finds entrance into the hair-shaft in two ways; after entering the orifice of the follicle and passing downwards along the hair-shaft (*a*) it may pass directly into it and

from this point of entrance spread up and down the shaft, or (b) it may penetrate as deeply as the soft hair-bulb and pass upwards with the growth of the hair. In ringworm of the scalp the mycelium is less abundant and less conspicuous than the spores.

Etiology.—The special frequency of the disease in England is generally ascribed to the favourable conditions for fungus growth afforded by a moist atmosphere and a mild winter. From its extreme contagiousness the disease frequently occurs in epidemic fashion in schools, villages, &c. Actual contact with an affected person, or with articles of toilet used by such, is probably necessary for its communication. As the result of infection from animals (cattle, horses, dogs, cats) it is much rarer than ringworm of the body, but when it does occur it assumes a specially virulent form. It is somewhat rare after puberty, and in the first year of life is only observed in much-neglected children, as repeated washing or any slightly irritant application (e.g., ink) easily cures it when the hair is fine and scanty. Ill-nourished, delicate, and especially strumous children are popularly—but probably incorrectly—supposed to suffer more frequently and more severely than the robust. Second attacks after complete recovery are very rare.

Treatment.—(1) *Preventive.*—This is important in large families and, if carefully carried out, is usually successful. In schools, however, it can seldom succeed; hence the necessity for the removal of affected children. The patient should be, as far as possible, isolated, should be furnished with separate brushes, towels, soap, &c., and should wear a light cap, loosely applied to the whole head, and lined with tissue-paper; the lining should be changed daily. Unaffected members of the family should have the hair cut short, washed night and morning with warm water and soft soap, carefully dried and scrutinized.

(2) *Curative.*—When a case is seen early, the hair is scanty and the distribution of the disease is ringed, any of the parasiticide remedies to be afterwards mentioned prove readily efficacious. In young children strong remedies ought never to be resorted to, as severe dermatitis is liable to be set up. Tincture of iodine, sulphur, and white precipitate ointments are specially valuable and simple applications for such subjects. "Bald" ringworm and kerion undergo almost spontaneous cure, but permanent,

patchy baldness is apt to result, especially in the latter case; for such, soothing applications—e.g., ointments of calamine or lead—are indicated.

The great majority of cases, however, come under observation when the disease is diffuse and of old standing, and their obstinacy depends upon the difficulty of directly attacking the parasite which lies, not on the surface of the skin, but deeply, at or near the bottom of the hair follicles. Mere irritation—e.g., by blisters—with a view to stifling the micro-organism in inflammatory products is distinctly less successful than the employment of direct parasiticides, which also have generally some irritant action that is in itself of service. Careful attention and considerable personal experience are always necessary to control the effects of treatment and to arrest inflammation at a point beyond which it is attended with dangerous consequences.

In every case the ground must be first cleared for action by the removal of crusts, scabs, scales or scurf, by poultices or rags soaked in oil, and by cutting the hair close with scissors. In severe diffuse cases shaving is imperative both for purposes of treatment and observation. Opinions differ as to the propriety of frequent washings, probably the rule laid down by Dr. Liveing is a good one, that the head ought to be washed with soap and warm water once a week if ointments are being applied, but daily if lotions are being used; in either case the scalp ought to be thoroughly dried after washing.

The multiplicity of methods and drugs recommended as infallibly curative is the best possible proof of the unsatisfactory character of our present remedies against the disease. Only those which the writer has tried and considers satisfactory are here enumerated, and all require careful watching, alteration according to circumstances and persistence in their application whenever improvement, however slight, is being obtained from them.

The treatment of diffuse cases with much scaling is often beneficially initiated by vigorous washing with hot water and soft soap, the scalp being carefully dried afterwards; pure turpentine is then poured over it till pain—usually described by the child as "nipping"—is complained of. The turpentine is then rapidly washed off, the head being again thoroughly dried. Colourless tincture of iodine is then painted over it. This

treatment may be repeated in two or three days according to the amount of follicular dermatitis set up. Usually a large number of hairs with root-sheath attached are loosened by it, and may be removed by subsequent washing. One or other of the following ointments, diluted or concentrated according to the results produced, may be vigorously rubbed into the scalp for ten minutes night and morning. In all lanolin is of special value as a basis, as it facilitates deep penetration of the active parasiticide ingredient, but it must be combined with olive or almond oil to obtain a workable and pleasant consistence. Salicylic acid (gr. x to ʒj ad ʒj), appears, to the writer, perhaps the most satisfactory and agreeable and manageable of all remedies. The pure oleates of copper (gr. xxx to ʒij ad ʒj) and of mercury (ʒj to ʒij ad ʒj), are also very valuable. Although the former is possibly the more active parasiticide, its bright green colour is in many instances objected to, and it seems more prone to provoke unduly severe dermatitis than the latter. Another useful and popular ointment—the “compound citrine ointment”—is composed as follows:—*R* Acidi carbonici (Calvert's No. 2), ung. hydrargyri nitratis, ung. sulphuris aa partes æquales; it must be made without the use of heat, the citrine ointment being rubbed into a mixture of the other two ingredients. It is best used to more limited areas of disease than the preceding.

In *active spreading inflammatory ringworm* the following lotion is often useful by producing a sort of artificial seborrhœa:—*R* Acidi boracici ʒj, ætheris ʒss, spiritum vini rectificatum ad ʒvj. In similar circumstances a method of treatment advocated by Dr. Jamieson seems sometimes serviceable; this consists in washing the head with soft soap twice daily, carefully drying, then sponging on dilute acetic acid and, while the scalp is still wet, sopping it with the following lotion: *R* Sodii hyposulphitis ʒvj, glycerini ʒjss, aquam destillatam ad ʒvj; the nascent sulphurous acid thereby produced seems to act with more certainty and vigour than an ordinary aqueous solution. It must be confessed, however, that the results from various lotions containing the theoretically plausible solvents and penetrants (chloroform, ether, liquor potassæ, &c.) have proved very disappointing.

In *patchy cases* other methods of treatment are preferable. In quite recent

cases blistering with acetic acid, liquor epispasticus or a solution of corrosive sublimate (gr. iv ad ʒj) is often promptly curative, but the tendency of these remedies to provoke acute suppurative inflammation must always be borne in mind and due caution exercised in their application. In very young children where the hair is fine and the patches ringed, speedy cure is generally easily affected by less severe measures—*e.g.*, ammoniated mercury ointment, diluted compound nitrate of mercury ointment or tincture of iodine. To patchy cases, whether recent or old, the treatment by epilation is specially, or perhaps even exclusively applicable. As it is attended with considerable pain it cannot well be employed when dealing with young children, but above the age of six years they can generally be made to stand it. It is usually advisable to deaden the sensibility of the part by the previous prolonged application of glycerine of carbolic acid, or of a 10 per cent. solution of cocaine in oil and lanolin. In other cases the ground may be prepared by ointments of the oleates already mentioned, carefully graduated so as to cause effusion into the follicles short of supuration. After any of these preliminary measures, epilation may be effected either by attacking the hairs singly with fine forceps, a limited area—say half a square inch—being cleared daily, or with large forceps which extract several hairs at a time, but the latter process is the more painful and the less satisfactory. A parasiticide ointment ought subsequently to be well rubbed into the denuded area. Epilation on a large scale may be carried out, as Dr. Crocker suggests, by painting on Coster's paste (*R* Iodi ʒij, olei terebinthinæ decolorati, vel creasoti, vel olei cadini, ʒvj) with a hard brush for three or four days, after which a black crust forms; if this be removed with forceps a large number of diseased hairs are detached. The method is, of course, a rough one, but it may be followed by instrumental epilation, the patch being further prepared by washing with flannel and soft soap. Sometimes excellent results are obtained by covering the patches daily with a solution of salicylic acid in collodion (ʒss-ʒj ad ʒj) after epilation, or independently of it.

In a certain number of very obstinate localized or discrete patchy cases the only effectual means at our disposal is the artificial production of kerion, and this is best accomplished by plunging

into each hair follicle a fine needle previously dipped in croton oil.

Impetiginous inflammation, whether it arise spontaneously or as the result of over-zealous treatment, must be treated on the usual lines, by the removal of scabs, and the use of ammoniated mercury ointment.

Finally, it must be reasserted, that no case ought to be pronounced cured so long as any scaling remains, and until repeated microscopic examination fails to reveal the presence of trichophyton. Even then it is a wise precaution to continue the use of some mild parasiticide ointment for some weeks.

Ringworm of the Beard (*Tinea Sycosis*; *Mentagra vel Sycosis Parasitica*; *Barber's Itch*) is the result of the irritating effect of trichophyton upon the follicles of the hairy portions of the face, the beard and whiskers being very much more frequently attacked than the moustache.

The disease is much commoner than is generally recognized. Sometimes, and especially in children suffering from ringworm of the scalp, it affects the eyebrows. Much more rarely in adults the pubes or other hairy portions of the trunk are attacked. It is especially common in countries where the inhabitants do not habitually shave themselves but patronise a barber for that purpose, the disease being communicated by the soap, shaving-brush or towels rather than by the razor, and in either case some breach of surface (microscopic, it may be) is probably necessary for its communication. This also explains the comparative infrequency of infection from children to adults. In a few recorded cases the disease has been communicated from animals to man.

Eruption.—In persons who wash and shave regularly the disease usually presents itself as circular, scaly, itchy patches or rings in the beard, very rarely on the upper lip. These extend at the periphery and coalesce to form gyrate patches with convex spreading margins often slightly vesicular. In this stage the condition is easily curable, like ringworm of the body. Should its nature not be recognized, or should it be allowed to extend, slight pustular folliculitis supervenes. In less cleanly persons the progress is very rapid; glairy purulent discharge from the follicles becomes abundant, dries up on the surface to form thick crusts matting together the hairs, and violent peri-folliculitis ensues. This leads to the formation

of large red or livid, boggy or brawny lumps, practically identical with "kerion" of the scalp. Pus oozes from the dilated hair follicles of these lumps, and the loosened hairs can be painlessly extracted, this latter point being of diagnostic importance in differentiating the disease from simple follicular sycosis, in which, the inflammation being primarily peri-follicular, the hairs are not detached with the same facility. The frayed broken extremities of the hairs are not so marked a feature as in tinea of the scalp, but the other microscopic appearances are very similar. Generally speaking, the spores are larger than in tinea of the scalp and the mycelium more abundant.

Prognosis.—In cases seen early this is favourable, but old standing cases are remarkably obstinate, and the disease often breaks out afresh after apparent recovery. The cure is frequently followed by patchy baldness, the hair follicles having been irremediably destroyed. The microscope is necessary for absolute differentiation from simple follicular sycosis, eczema and pustular syphiloderma, all of which occasionally closely simulate parasitic sycosis.

Treatment.—Epilation is by far the most important factor in treatment. It is generally advisable to clear an area of about one square inch daily, and the process is comparatively painless, for reasons already explained. After each epilation one of the parasitic ointments mentioned under tinea of the scalp is advantageously employed. A diluted ointment of the red oxide of mercury appears occasionally of special service. A point worthy of note is that poultices do much harm, by causing the disease to spread.

Ringworm of the Body (*Tinea Corporis*; *T. Circinata*; *Herpes Circinatus*) is the condition produced by trichophyton, as it affects those parts of the skin which are only provided with lanugo hairs. It is, of course, of frequent occurrence in children suffering from ringworm of the scalp, and in them, as well as in the great preponderance of adult cases, recovery is easily brought about, and is frequently spontaneous, as the fungus does not find a favourable nidus among the surface epidermic cells. In cases communicated from animals, however, and in the tropics, peculiar virulence is often manifested. The patches are most commonly situated on the neck, face and hands, but may occur anywhere. They are at first sharply defined, circular,

slightly raised, pinkish, and covered with fine grey scales. They partially clear up in the centre, but extend peripherically to form rings, or even occasionally concentric rings, the margin of which is often faintly vesicular and rarely bullous, this latter condition being commonest in young children and in regions (*e.g.*, flexures) where the skin is thin. By the coalescence of adjacent rings and the disappearance of active disease at the points of coalescence, extensive gyrate patches with festooned margins are formed and may occupy large areas. Itching is seldom a prominent symptom.

Eczema Marginatum.—The disease described by Hebra under this name is the most severe form of ringworm of the body. It is rather rare in its most aggravated form, but moderately severe cases are not infrequent in this country. Its seats are the groins, fork, axillæ, and occasionally the popliteal spaces, where the apposition of folds of delicate skin, heat and moisture combine to afford the most suitable conditions for cryptogamic growth, and for the development of secondary dermatitis. The well-defined, festooned, raised margin is usually diagnostic, and microscopic examination of scrapings seldom fails to reveal conidia and mycelium.

Diagnosis.—Ringworm of the body may be mistaken for multiform erythema, pityriasis rosea, psoriasis—especially in young people and of the gyrate form—dermato-syphilis or eczema seborrhœicum corporis, to the separate description of which the reader is referred.

Treatment.—The great majority of mild cases are cured in a week or ten days by a sulphur or ammoniated mercury ointment, or a hyposulphite of soda lotion. The most severe form is, however, very obstinate; for such, salicylic acid is generally the most efficacious remedy, the solution in collodion being used. A 5 to 15 per cent. solution of chrysarobin in liquor gutta perchæ (B.P.), similarly applied, is also very efficacious, but its action must be carefully watched, as it is apt to cause violent dermatitis. Vigorous washing with soft soap followed by ointments of the oleates of copper or mercury is often curative in cases of intermediate severity. J. J. PRINGLE.

RÖTHELN (German Measles; Rubeola).—A specific and infectious eruptive fever, distinct and separate, neither a hybrid of scarlet fever and

measles, nor a modified form of either of those diseases.

The elementary nature of rōtheln has been ascertained by the observation of sequences of cases which have followed its introduction into more or less isolated communities; by which it has also been shown that rōtheln is infectious, that it breeds true, and that one attack of it affords great protection against a second one, but does not protect against scarlet fever or measles. Persons actually suffering from rōtheln have been known to contract scarlet fever, and being exposed to the infection of measles have developed a well-marked attack of that disease. The converse has also happened. In seasonal prevalence, also, it differs markedly from scarlet fever and more slightly from measles. An analysis of upwards of 500 cases which have come under the observation of the writer during a period of eight years shows that the great majority of attacks occur during March, April, May or June, agreeing in this with measles, but differing in that measles has a second period of prevalence in winter. The maximum prevalence of scarlet fever is in autumn.

Rōtheln attacks both children and adults, but as the majority of cases are of a very mild type, of which the infectiousness appears to be slight, many people escape until they have reached maturity, and very many seem to be insusceptible.

The period of incubation is most commonly eleven or twelve days, but not infrequently it extends to fourteen, and in some instances possibly to seventeen days.

Symptoms.—In mild attacks there are often no premonitory symptoms, but those most commonly present are sneezing, lachrymation (which latter, however, much more often follows, or is synchronous with the appearance of the rash than precedes it), and a more or less general enlargement of the superficial lymphatic glands, especially of those on the mastoid processes and behind the sterno-mastoid, and those of the posterior chain, of which the upper ones below the occipital protuberance are the more often perceptibly affected. The glands may be enlarged for some days (in a few instances for from eight to twelve days) before the appearance of the rash. The temperature seldom exceeds 100° F. at any stage of the attack, and is normal in many cases. The appetite for food is scarcely impaired.

Eruption.—This, which is often the

earliest sign of the disease, appears first upon the face and scalp, but quickly spreads to the trunk and limbs, being frequently well marked on the palms of the hands. Its appearance is seldom delayed beyond the second day of the illness. It consists of very slightly raised rose-coloured spots, varying in size from little more than a mere point to $\frac{1}{8}$ inch in diameter. They are scattered thickly and may be arranged in crescents, rings or masses. On their first appearance the spots are separated by intervals of white skin, and the rash is distinctly measly looking, but quickly, often within a few hours, a noteworthy change occurs in many cases. The spots upon the face, which had previously been visible quite up to the edges of the lips, become obscured and sometimes obliterated by an even pink flush, while those on the body are transformed into a more or less punctiform erythema which may very easily be mistaken for the rash of scarlet fever. This change soon spreads to the limbs, and the rash quickly disappears, usually within three days. Slight itching is sometimes complained of. A very slight branny desquamation of the face and neck may follow.

In more severe attacks of r  theln the symptoms are much more like those of measles, the prodromal period sometimes extending to three days, the catarrhal symptoms being much more marked and soreness of the throat seldom absent; the tonsils being red and swollen, and the palate reddened in small patches. The temperature may rise to 104   F., and there may be severe lumbar pain. The rash is darker in colour, the spots are larger, remain separate and distinct, and may leave a brownish or even a purple stain. Broncho-pneumonia and laryngitis have been known to occur as complications.

Melancholia or mania may follow even a mild attack of r  theln, as of morbilli or scarlatina.

Diagnosis.—From scarlet fever it may be distinguished by the measly character of the rash at first and by its appearing on the face and invading the oral circle; by the enlargement of the glands, by the coryza, and by the absence of the characteristic desquamation. In very young children the diagnosis is sometimes rendered difficult by the minuteness of the spots composing the rash.

From measles it is to be differentiated by the usually shorter prodromal period, the enlargement of the glands (nearly always), by the lighter colour and smaller

size of the spots. In some cases the diagnosis from measles is very difficult.

From variola, papular eczema, copaiabarash and urticaria the diagnosis is usually easy, but in a very small minority of cases of r  theln the spots are as much raised and as hard as are the papules of variola.

Prognosis is almost invariably favourable.

Treatment, except of the rare complications above mentioned, is unnecessary. In severe cases the attack should be treated as if it were one of measles.

The enlarged glands soon shrink. If very tender they should be shielded.

E. O. HORWOOD.

ROUND-WORMS.—The *ascaris lumbricoides*, or round-worm, is a nematode similar in shape to the common earth-worm. The head presents three labial papillae, the body is cylindrical, about $\frac{1}{4}$ inch in diameter, varies in length from 9 to 15 inches, and tapers at both ends, but especially towards the tail. The female is considerably longer than the male. The ova are very minute, elliptical and of a dirty brown colour, with a thick nodulated covering, and often exist in immense quantities in the faeces. There must be some intermediary host, presumably an animal that can live in water, for the drinking water has in many cases been proved to be the source of infection in man, but the complete life cycle is unknown. The round-worm lives in the jejunum and feeds on its contents, probably it does not remain more than a few months in the bowel and is then passed per anum; or, it may find its way into the stomach and be expelled by vomiting; occasionally it makes its way into the biliary passages or even into the thoracic or abdominal cavity. It may escape at the nose, or pass into the larynx. A single worm or a large number may be present; usually, however, there are only a few. Children are much more commonly affected than adults.

The *symptoms* are not characteristic; dyspepsia, shooting pains, nasal or anal irritation, may be complained of, and sometimes nausea, vomiting and diarrhoea. When large numbers are present there may be nervous symptoms, such as twitchings or actual convulsions and delirium; these occur especially in neurotic subjects. Death may result from peritonitis, following perforation, or laryngeal obstruction. Not infrequently no symptoms are observed until the child passes the worm.

Treatment.—Santonin in doses of from 1 to 3 grains for a child, or double the dose for an adult, followed by a purge of aloes, scammony, rhubarb or jalap constitutes the best treatment; the drug may be given every day, or occasionally, so long as any ova can be found in the fæces by microscopical examination.

Santonin in medicinal doses occasionally produces symptoms of poisoning, the most prominent being yellow vision (Xanthops) and high-coloured urine; these are less likely to occur if a purgative be given after the drug, and as a rule they quickly subside when the treatment is suspended.

RUPIA.—A superfluous term, but one still in current use to denote a variety of pustular syphiloderm characterized by the formation of large, dirty brown, stratified, conical crusts, like limpet shells. This form of scab is due to

the successive hardening of purulent discharge from the ulcer which is invariably present beneath, and which exhibits the typical foul base and punched-out edge of syphilitic ulcerations. The condition generally occurs in old syphilis, but in a much greater proportion of cases than is usually recognized it shows itself early within the first year. Its precocious development is an expression either of extreme virulence of the syphilitic virus, or of great constitutional depravity on the part of the patient. Scabs or crusts somewhat similar to those of rupia sometimes form in cases of impetigo, or of psoriasis (*P. rupioides*) but the presence and characters of the ulcer of syphilitic rupia easily determine the diagnosis. The scars left by the eruption are deep, at first much pigmented, and indelible. For details of treatment reference must be made to **SYPHILIS OF THE SKIN.** J. J. PRINGLE.

S

SARCINA.—A vegetable organism found in the vomit in gastric disorders of long standing, and especially where the food is retained owing to obstruction of the pylorus, or dilatation of the stomach from atony of the muscular coats.

Sarcinæ are present when the contents of the stomach have undergone a certain amount of putrefactive change, and are not diagnostic of any particular condition or disease. Sarcinæ are also occasionally present in the urine in cases of stricture of the urethra or of enlargement of the prostate.

Under the microscope the organism presents an appearance which has been compared to a corded wool-pack, its component cells being arranged in squares of four, sixteen, or thirty-two. (See Fig. 7, p. 521.) If a drop of liquor potassæ be added to some of the vomit on a slide the recognition of the growth is facilitated.

SCABIES (Itch).—A contagious dermatitis due to the presence of the arachnoid parasite—*sarcoptes* (vel *acar*—*scabiei*).

Description of *Sarcoptes Scabiei*.—The female is visible to the naked eye, is of a pearly white colour and is considerably larger than the male, measuring from $\frac{1}{16}$ to $\frac{1}{8}$ of an inch in length. The body is irregularly circular, the head conical and

armed with four powerful mandibles. A sucker is attached to each of its four short anterior legs and a strong bristle (seta) to each of its four long posterior legs which tilt the animal up and direct the anterior extremity downwards towards the skin. There are also a few

The Female *Sarcoptes Scabiei*.

bristles on the dorsal and ventral aspects of the body, which being directed backwards prevent the egress of the animal from the skin which it has once penetrated. They have a distinct curved

vagina, ovaries, and ovipositor. They pierce the epidermis and when impregnated penetrate deeper into the rete, forming burrows (cuniculi) in which they deposit their ova, probably two or three daily, up to the number of fifty, after which they die, the average duration of their existence being from two to three months. The male is about two-thirds the size of the female, and is provided with distinct testicles and a sucker on each postero-internal leg for purposes of copulation; the penis is supported by a chitinous framework. The male only penetrates the skin after fertilizing the female and in its immediate neighbourhood, where it soon dies.

The ova rapidly segment, becoming larvæ with six legs in about six days. At the end of about three weeks, after two or three moultings, they have eight legs and are sexually mature.

Eruption.—The dermatitis produced by *sarcoptes scabiei* and by the effects of consequent irritation and scratching is characterized by multiform, inflammatory lesions without definite grouping, but sufficiently characteristic in distribution to be generally easily recognisable at a glance. The initial lesion is a burrow, straight or irregularly sinuous, sometimes visible to the naked eye—and always easily discernible with a lens—as a whitish or reddish line with a white spot at the end which represents the insect. The burrows vary from $\frac{1}{8}$ to $\frac{1}{4}$ inch in length, but may be much longer; they are often brownish or black from accumulated ova, fæces, débris, and adherent dirt. The female lies at the distal, closed end, and the oldest, *i.e.*, most mature, ova nearest the entrance, from which they easily escape on maturity, as the surrounding epidermis is exfoliated. The seats of election correspond to those regions where the skin is most delicate and thrown into folds, and are:—the web between the fingers and toes, the inner side and anterior aspect of the wrists, the backs of the hands and forearms, the axillæ, mammæ, front of the abdomen, fork and penis. Only in young children at the breast and in excessively dirty persons are the face and head ever affected. Almost invariably a papular and vesicular rash, intensely itchy at night, results, which in children and unhealthy subjects becomes rapidly pustular and scabby. As the result of scratching, erythematous, urticarial, and “ecthymatous” rashes develop, even where burrows are scarce or perhaps absent; these are especially com-

mon on the anterior surface of the abdomen and thighs and on the buttocks, where scabbing is often a pronounced feature. These secondary lesions are often determined by friction or pressure, *e.g.*, of belts; thus tailors and shoemakers, who are constantly seated on hard boards, have them over the ischial tuberosities, and miners, who work leaning upon one elbow, over the olecranon process.

Diagnosis is generally easy, the polymorphism, distribution, and absence of grouping of the lesions being sufficient to distinguish the great majority of cases of scabies from eczema. The detection of burrows is of importance, and a sarcoptes can generally be discovered in the distal extremity of some of these and easily extracted with the point of a fine needle. In severe cases, however, the burrows may all be torn open by violent scratching, and in children or persons in general bad health their discovery is often rendered very difficult, from rapid vesication and abundant pustulation and scabbing.

Treatment, if carefully carried out, is almost invariably successful in the course of a few days. The burrows must be opened and foreign matters removed from the surface of the skin by a prolonged warm bath every night, followed by thorough soaping, preferably with soft soap, if the skin will stand it. Sulphur ointment (3j ad 3j) may then be applied all over the body in severe, or only to the affected regions in mild, cases; it is frequently prudent or even necessary to dilute the sulphur ointment. The clothes of the patient and the sheets between which he sleeps should be either destroyed or purified in a disinfecting oven, and it is, of course, necessary to treat similarly all persons in intimate contact with the patient suffering from, or even supposed to be suffering from, the disease. The sulphur treatment, if carefully carried out, is almost always effectual in bringing about a cure in three or four days, but is more suitable for public than for private practice as the odour of the ointment is offensive. It often causes severe and obstinate dermatitis which may be mistaken for a persistence of the malady, and it may reveal the nature of the disease, which it may be desirable to conceal from the patient. In place of the sulphur ointment Vlemingx's solution, or the liquor calcii sulphidi, may be painted on at night with a stiff brush and removed by a warm bath in the morning, six or eight hours afterwards. In private practice ointments containing

naphthol (3j or 3jss ad 3j) or styrax (3ij or 3iv ad 3j) are almost as efficacious as the sulphur preparations, do not cause dermatitis, and the former has the advantage of being inodorous.

J. J. PRINGLE.

SCARLET FEVER.—An acute specific infectious fever, characterized by the appearance upon the trunk and limbs of a minutely punctiform scarlet rash, which is followed by desquamation.

The *incubation period* is usually of about three days' duration, but it is said to have been much shorter in some cases and somewhat longer in others.

Symptoms.—The onset is sudden in well-marked cases, but in very mild ones both the pre-eruptive and the succeeding stages of the disease may escape observation.

Pre-eruptive Stage.—The most distinctive symptoms of this period are feverishness, pain and difficulty in swallowing, vomiting or nausea, and a white-furred tongue with red edges and prominent red papillæ; but any or all of them may be absent in very slight attacks, and some of them in more severe ones, although it is probable that in all cases some reddening of the fauces may be seen. Aching pains in the limbs or back may be complained of and there may be well-marked rheumatism even in this stage of the disease. The pulse-rate is much increased. The temperature in simple cases seldom exceeds 103° F. and may tend to fall, but in severe attacks it may be several degrees higher. In the mildest it may not reach 99° F. The state of the tongue is usually as described above, but there may be neither redness nor fur of more than ordinary thickness, nor enlargement of papillæ, conditions which, moreover, are found in cases of disease other than scarlet fever. The tonsils, uvula and soft palate are red, swollen and covered with sticky mucus, or dry and glazed. The inflammation may extend forwards on the covering of the hard palate, even as far as the teeth, or on the other hand, it may be limited to the tonsils, of which the follicles may be distended with secretion, or which may be the seat of abscesses. On the soft palate and uvula small congested points may often be seen, while in other cases the redness is uniform. A soft white film may cover the surface of the tonsils, but it rarely affects the uvula. The glands at the angles of the lower jaw are commonly enlarged. In very severe

attacks diarrhœa may come on at the same time as vomiting.

Drowsiness and listlessness are often among the earliest signs of the disease in children, in whom also delirium at night is not uncommon; but convulsions are rare unless the disease be of a grave type.

As a rule, this stage lasts about twenty-four hours, but it is sometimes much shorter, or may extend to three or four days in very exceptional cases.

The Eruptive Stage.—This is marked by the appearance, first upon the chest and neck, and shortly afterwards upon the rest of the trunk and on the limbs, of a finely punctated scarlet rash. This is not, however, the invariable order, the rash being in some instances seen first upon the limbs, more especially upon the front of the wrists or ankles, on the inner surface of the thighs, or in flexures. It very seldom appears upon the face, the cheeks being merely flushed, while a white ring surrounds the mouth. In a very small minority of cases the rash appears only on isolated tracts, or not at all.

The rash is made up of minute scarlet points lying very close together, separated by skin which is usually normal in colour, but is frequently of a pink or even darker tint. In the latter case, pressure may show that there is a persistent yellow ground-colour. Complete coalescence of the spots may take place; it is commoner on the trunk and thighs than on other parts, and in adults than in children. The elevation of the reddened spots is in most cases microscopic, except on the backs of the hands and feet, in which situations, as also amongst others, in front of the shoulders, minute vesicles may form. In severe cases, the rash is, as a rule, deeper and sometimes purplish in colour, or hæmorrhagic. Even after the fading of a well-marked rash, persistent blood-coloured lines may not uncommonly be found in the folds in front of the elbow, a point which is of some importance diagnostically. In a small percentage of cases there is swelling of the skin of the face; in many only the hands are perceptibly affected. Itching is sometimes complained of, more often when the rash is fading or desquamation is beginning. In the majority of cases the rash reaches its limits by the second or third day, and then fades within a few days, but in very slight attacks it may come and go within a few hours, whilst in severe ones it may not fade for a fortnight. With the rash, or

shortly after it, urticaria, eczema or acute dermatitis may make their appearance in exceptional cases.

Very quickly, often on the first, and usually by the second or third day of the disease, the temperature reaches its highest point, near which, with slight morning remissions, it remains for a period, the length of which depends upon the severity of the attack and the presence or absence of complications. It may not exceed 99° F., or may rise to more than 106° F. If death does not occur the temperature begins to fall, but not so rapidly as it rose, the morning remissions becoming more marked and the evening temperature falling gradually. The pulse-rate may not exceed 80 in very mild attacks, but, as a rule, it is much higher, and in severe cases may be uncountable. Signs of cardiac failure occur early, if the disease be of malignant intensity, but otherwise the heart very rarely appears to suffer, although acute dilatation has sometimes been noticed. Other affections of the circulatory system are rare, but in one case gangrene of the leg followed thrombosis of the femoral artery. Albumen may appear in the urine as during other fevers.

Slight delirium may come on at night, even in mild attacks in children, and during defervescence in adult males. In severe attacks it is often well marked, and may be followed by coma.

The inflammation of the throat may become more intense and, especially in children, may extend to the nose and thence by the Eustachian tube to the ear, or by the lachrymal duct to the eye. In the first case, perforation of the tympanic membrane, suppuration in the mastoid cells and meningitis may follow, and in the second lachrymal fistula, conjunctivitis and even destructive inflammation of the eyeball. The tonsils, soft palate or epiglottis may slough, but the process rarely extends to the larynx and trachea. Stomatitis and glossitis occur only in very exceptional cases, but superficial ulcers often form on the tongue. The glands at the angles of the lower jaw become swollen and abscesses may form in them, or a hard brawny swelling may take place, and either process, but especially the latter, may lead to extensive sloughing or melting away of the tissues of the neck and to hæmorrhage, or to septicæmia, or, more rarely, to pyæmia.

Pain, of a rheumatic character, in joints or muscles is complained of in most cases, and some joints may be swollen

and tender, but the heart is affected much less often than in rheumatic fever.

Pleurisy is of rare occurrence in scarlet fever, and would appear to be due to secondary septicæmia. If liquid be effused it usually rapidly becomes purulent. Bronchitis and broncho-pneumonia, cellulitis and jaundice may have the same septic origin.

Pregnant women do not, as a rule, miscarry when they are affected by this fever.

Desquamation.—After nearly all attacks of scarlet fever, even when there has been no rash, desquamation occurs and may begin as early as the third day of the disease, or not until some weeks later. It is an orderly process which in most cases is completed in from six to seven weeks, in some not for several months and in a very few within a month. It is usually seen first upon the face and neck, especially upon the eyelids and ears, and then in order upon the trunk, shoulders and arms, legs, hands and feet, but in warm moist parts the process may begin out of turn. As a rule, the hands begin to peel during the third week, and the feet during the fourth. The layer of skin may be shed in small scales or in large pieces, separation usually taking place by the widening of the areas of numerous small circles, "pinholes," which first form, but the patches of hard skin upon the hands and feet are in most instances attacked from their edges only, those upon the heels being nearly always the last to fall off.

Sequelæ.—It is while this process is going on, that is to say during the period of convalescence, that certain secondary affections or sequelæ may show themselves, especially in children, of whom the unhealthy and ill-nourished are the more liable to be attacked. There is a marked tendency towards the coupling or association of sequelæ in the same individual. How these affections are caused by an attack of scarlet fever is unknown, but it is conjectured that the elimination of some irritating substance produced by the virus of the disease may account for the nephritis which often follows. The case-incidence of nephritis is increased among scarlatinal patients if they be treated in buildings to which air from drains has access, possibly also in close rooms, and there is a well-marked "family predisposition."

The sequelæ most often met with are

kidney and ear disease and swelling or abscess of the glands at the angles of the lower jaw. More rare is rheumatism (late), and mania and melancholia are still more rare.

The disease of the kidneys (which is commoner among males and in childhood) is as a rule very slight, if indeed the mere presence for a short time of a trace of albumen in the urine may be taken as proof of its existence, but, on the other hand, it may quickly prove fatal. It most commonly commences at the end of the third week. Recovery from it usually takes place, but the disease may pass into the chronic form, although even in that case the patient's health may not be apparently impaired (*see* BRIGHT'S DISEASE, ACUTE).

Ear disease may come on many weeks after the inflammation of the throat has subsided and without there having been discharge from the nose. It rarely occurs in patients over ten years old. Suppuration takes place in the middle ear, and the membrana tympani is perforated. The process is frequently painless.

The disease may extend to the mastoid cells, and the usual serious consequences may follow, but as a rule recovery is complete in healthy persons.

A *relapse*, or true second attack of scarlet fever, occurs in about one-half per cent. of cases at any time from the tenth day of the first attack, and is followed by a second desquamation. It may be of any grade of severity.

Diagnosis.—The differential diagnosis of scarlet fever is a subject of much difficulty and cannot be briefly discussed, nor is mere description of much use. In its onset it most nearly resembles the illness which is sometimes caused by eating shell-fish, &c., in which, however, sore-throat is much rarer and when present is characterized by less swelling of the tonsils and by a more patchy redness of the fauces. The severe scarlatinal sore-throat is most like that caused by "drains," or that which is found in some cases of septicæmia. The "strawberry tongue" is not by any means a constant sign, nor is it diagnostic when present. The rash resembles in character that produced by eating shell-fish, &c., the fading Rôtheln rash, a prodromal variola rash, typhoid roseola, some forms of acute dermatitis, a rash which sometimes accompanies septicæmia, and the more or less punctiform erythematæ produced by various drugs and by other and unknown causes. The occurrence of nephritis or the appear-

ance of characteristic desquamation may confirm the diagnosis of scarlet fever in doubtful cases.

Prognosis.—The disease usually terminates by recovery, but the mortality varies much with age, with social status and with the epidemic type. Of patients under five years of age about 20 per cent. die, whilst above that age the mortality does not as a rule reach 5 per cent., and may be much lower if the prevalent type of disease be a mild one. The records of the London Fever Hospital and of the Hospitals of the Metropolitan Asylums Board show that as a rule the better the social status the better the chance of recovery, and the smaller the probability of complications and sequelæ arising. The prognosis is very grave if signs of collapse show themselves at the onset of the attack, or if there be persistent diarrhoea or vomiting. High temperature is not of itself necessarily dangerous, but if it be accompanied by delirium or coma, the probability of recovery is small, and it is not much greater if high temperature and sloughing of the fauces be associated.

Ætiology.—The *exciting cause* is almost certainly a micro-organism, as to the precise nature of which, however, observers do not agree. It is said to cause a disease in some other animals, especially in cows, whose milk when they are thus affected is believed to have originated scarlet fever in human beings. It appears to be most active in autumn, but whether this be due to meteorological conditions increasing the potency of the germ or the receptivity of the human organism is unknown. At least one-half of the population of this country never contracts scarlet fever. The virus is capable of retaining its vitality for a long time outside the human or other body, but is more easily destroyed by physical and chemical agents than are many other poisons. An attack of scarlet fever affords a large measure of protection against subsequent infection, but is not so effectual as is the case with most of the other acute specific diseases. The infection probably exists in all parts of the bodies of persons affected with the disease, even in its earliest stages, and is given off in all that comes from them, though it does not seem to be carried to any great distance by the air, or at least not in such a way as to be a source of danger. It attaches itself to fomites, and finds a favourable nidus in articles of food, especially in milk. It is not

readily carried from a person affected with scarlet fever to another by means of a third person who is not suffering from the disease, and free dilution with air appears to render it harmless.

The virus may obtain entrance into a house by means of defective drains, the type of disease being made much graver by the combination of poisons. Under such circumstances some of the inmates may suffer from "drain throats" only, and this may account for some of the cases of "scarlatinal sore throat."

The time which must elapse from the beginning of the illness before a patient ceases to be in an infectious state is not known. Instances have been given in which twelve, thirteen, or even fourteen weeks have seemed to be too short; and the continuance of infectiousness has been attributed to delayed completion of desquamation or to persisting discharges from the nose and ears, but it is extremely difficult to exclude imperfect disinfection of hair, clothing, &c., as a possible cause, and in other instances there is evidence that infectiousness has not lasted longer than a few weeks.

Of *predisposing causes* the most powerful is the age of persons exposed to infection. The liability to contract scarlet fever is greatest at about five years of age, and diminishes rapidly from this point onwards. Persons with operation or other wounds, burns, or scalds, and puerperal women appear to be very susceptible, but the subject is a difficult one, owing to the similarity between the rash of scarlet fever and one which not infrequently accompanies septicæmia.

Treatment.—An account of the measures necessary for the prevention of the spread of infection will be found in the article on DISINFECTION.

No means are known by which an attack of scarlet fever can be cut short, and in the most severe form of the disease no treatment is likely to avert a fatal issue, but there appear to be cases in which the scale may be turned in favour of recovery by the use of anti-pyretic measures and by the administration of stimulants. In the large majority of cases all that is necessary is to place the patient under such conditions as will favour his return to health. The room in which he lies should be kept comfortably cool and well ventilated, and, if his temperature be high, the bed-clothing should be light. During the pyrexial period the food given should consist chiefly of milk, which may with advantage be diluted with soda water or have

ice added to it. Cold water in moderate amount need not be forbidden, and the patient may have beaten-up eggs or beef-tea and jellies if he wish for them. In the most severe cases, especially if there be nausea or vomiting, peptonized meat jellies may be of service and the patient must be very carefully fed, rectal alimentation being occasionally necessary. In very mild attacks bread and milk may be allowed. When the fever has abated, appetite for food usually returns quickly, and may be safely satisfied without long delay, a more or less gradual return to full diet being permitted according to the severity of the attack. The time during which the patient is kept in bed need not exceed ten days in most cases. The ordinary ablutions of face, hands, &c., may be performed during the attack, and warm washing-baths be given afterwards (*see* DISINFECTION).

Gargles or sprays of solutions of chlorinated soda, or of chlorate of potash and hydrochloric acid, or of boric acid, may be used with a view to diminish the soreness of the throat. If the pain in swallowing be very great, a few drops of a 4-per-cent. solution of hydrochlorate of cocaine may be sprayed into the throat at intervals, care being taken that the total amount applied be not great. In some cases the pain seems to be lessened by warm water gargles, in others by sucking ice. Children who will not allow remedies to be applied to their throats unless force be used will often permit a powder, consisting of chlorate of potash, bicarbonate of soda, and borax, well sweetened with saccharine or sugar, to be placed on their tongues or between their lips whilst they sleep. The chlorate of potash may be omitted.

It may be said of the other complications and sequelæ generally that they may be treated as if they had arisen independently of scarlatina.

E. O. HOPWOOD.

SCIATICA.—This term is often used to designate pain in the district of the sciatic nerve, whatever its causation may be. Some, however, restrict its application to sciatic pain of primary nerve origin, but it seems better, while recognizing their secondary nature, to include also those cases in which the nerve is affected in the course of pelvic and other diseases.

Symptoms.—Primary sciatica is generally gradual in its onset, but in some cases is rather suddenly developed and attended with a certain amount of con-

stitutional disturbance and slight pyrexia. Pain is referred to the sciatic nerve in any part of its course. It is frequently localized to the upper half of the thigh, sometimes it includes the whole of the main branches, so that the patient is able to map out the general distribution of the nerve, and occasionally the terminal branches in the calf and foot are involved. Tender points may be found in the course of the nerve at some or other of the following positions:—the posterior inferior spine of the ilium, midway between the tuber ischii and the great trochanter, middle of the thigh, popliteal space, behind the head of the fibula and external malleolus. In certain cases the nerve becomes tender throughout its whole course.

The character of the pain generally differs considerably from that of ordinary neuralgia. It is not paroxysmal and subject to periods of complete remission, but usually constant, and described as heavy, burning and gnawing, and sometimes as darting and shooting. It may be so slight as only to be noticed after sitting in a cramped and confined position for a long time, or so severe that the patient is bedridden, and sleep is only obtained by means of narcotics. Exacerbations of the pain may occur and these may be spontaneous or induced by muscular movement. To prevent the latter as much as possible the joints of the affected limb are in the slighter cases flexed a little, and the patient walks on the toes, bearing most of his weight on a stick. In severe cases, the flexion is carried to a greater degree, and intense pain may be caused by any attempt at extension of the limb. Sometimes, though rarely, the pain seems reflected to the sciatic of the opposite side, to branches of the lumbar plexus, or even more distant nerves; it may be, however, that these are all involved in the same morbid process.

Other evidences of disordered sensation are frequently present, and consist of a feeling of pins and needles, numbness or tingling in the area of the distribution of the nerve, and sometimes of irregular patches of anæsthesia. The occasional occurrence of herpetiform eruptions may perhaps be ascribed to an abnormal trophic state and the frequent coldness of the limb to vaso-motor changes.

There is sometimes a considerable amount of muscular wasting, which is apparent in the buttock, back of the thigh or leg. This is not the result of disuse, but dependent upon an actual

paretic condition of the muscles, for it is often noticed soon after the development of symptoms and the faradaic excitability of the muscles may be much diminished, although the reaction of degeneration is very rarely obtained. Fibrillary tremors sometimes occur in the affected muscles, and painful cramps may add to the distress of the patient.

The *course and duration* of the disease vary considerably in different cases. Sometimes the attack is mild, the pain is never severe and passes off in a few weeks; or it may persist for years and be liable to slight exacerbations and remissions. In the severe cases of almost sudden onset, the patient experiences the most agonizing pain and speedily becomes bedridden; all the joints of the limb are rigidly flexed and the muscles waste. Such a condition may continue almost unchanged for months in spite of all treatment, or be subject to remissions and relapses. Recurrences of the disease, in which the same sciatic nerve or that of the opposite side is affected, are not at all infrequent.

In cases of secondary sciatica, pain is generally present in both lower extremities, and is experienced not so much in the main trunk of the nerve as its distribution.

Diagnosis.—Considerable difference of opinion has existed in regard to the nature of primary sciatica, which has been considered by some as always a pure neuralgia, and by others as more often inflammatory. Most, perhaps, will now admit that it is sometimes a neuralgia, but that far more frequently it is due to a perineuritis. If so, to the latter condition probably belong all those cases in which the nerve is tender to pressure, and patches of anæsthesia and other sensory and motor disturbances are present. The neuralgic variety would thus be limited to cases in which the pain was more typically neuralgic in character and referred more to the distribution of the nerve than its main trunk. Intermediate cases will occur, which it is impossible to refer positively to either class. If the symptoms of sciatica be borne in mind there is not much danger of mistaking it for diseases of neighbouring parts. In morbus coxæ there is neither painfulness of the nerve, nor tender spots in its course, but pressure on the great trochanter elicits pain, which is not obtained in sciatica. Similarly with sacro-iliac disease, in which pain is caused by pressure on the joint.

Myalgic pain is characterized by occurring only when the affected muscles are put in action. The lightning pains of tabes dorsalis are paroxysmal and fugitive, and other evidences of that disease will probably be found—*e.g.*, the Argyll-Robertson pupil and loss of knee jerks. Secondary sciatica is distinguished from the primary variety by its pain being often bilateral and referred rather to the peripheral distribution of the nerve than its trunk. Both these points should lead to a suspicion of pelvic disease, and suggest a rectal examination.

Prognosis.—Primary sciatica is not attended with any danger to life, but a very cautious opinion should be expressed as to the probable duration of the disease, for not only do the acute cases run a long course, but they are often subject to relapses and recurrences. The prognosis of secondary sciatica must depend upon its probable causation.

Pathology.—Although it can scarcely be doubted that neuralgia may be referred to the sciatic nerve, as it is to various other nerves, yet the weight of evidence, both clinical and pathological, seems to show that nearly all cases of primary sciatica depend upon a perineuritis, which may spread along the interstitial tissue and cause the nerve-fibres themselves to be affected. Some however, still hold to the opinion that sciatica is a pure neuralgia, whose symptoms are modified by the large size of the nerve, its superficial course and its proneness to mechanical irritation.

Ætiology.—Sciatica is a disease of adult life, most common at forty to fifty years of age, and attacking men far more frequently than women, probably in the proportion of four to one. It is often associated with gout and rheumatism, and has also been ascribed to syphilis and malaria, but in some cases no predisposing cause can be obtained. Exposure to cold is by far the commonest exciting cause, and in some cases over-exertion of the lower extremities seems to have elicited the disease. Secondary sciatica is usually the result of disease of the hip-joint or its neighbourhood, and tumours of the sacrum or os innominatum pressing on the sacral plexus. It may also occur in the course of cancer of the spine and tumour of the cauda equina.

Treatment.—It is always necessary to give the affected limb complete rest, which is sufficiently obtained in slighter cases by the recumbent position on a couch; in the acuter forms of the disease it is desirable to keep the patient in bed,

and in very severe and protracted cases a water-bed affords much comfort. Any constitutional disease, which may be supposed to underlie the affection, must be appropriately treated. Of these the most frequent is gout, for which alkalies, colchicum and iodide of potassium may be given as well as saline purgatives. Salicylate of soda does not often seem to afford much relief, but may be given when the rheumatic diathesis is pronounced. Syphilis and malaria must be treated with iodide of potassium and quinine respectively. The hypodermic injection of morphia becomes necessary to relieve the exquisite pain of the acute cases, but on account of the frequent long duration of the illness, it is essential to take precautions for preventing the development of the morphia-habit. For this reason the patient himself should not be trusted with the performance of the operation, and the dose should be kept as small as possible. This is the more important since a very small dose is sufficient in some cases to relieve the pain. The needle may be thrust into the nerve so as to combine with the sedative action what good may result from acupuncture. Cocaine may be similarly injected and sometimes affords considerable relief in doses of $\frac{1}{4}$ to $\frac{1}{2}$ gr. Many local applications are recommended. In mild cases, stimulating liniments, such as belladonna, chloroform and aconite, sometimes prove useful rubbed along the course of the nerve, but counter-irritation of the same region, by means of mustard plasters or flying blisters, is far more effective. Hot linseed poultices applied to the seat of pain are often soothing at the commencement of an acute attack. In the later stages galvanisation may be employed with advantage. It is necessary that the whole length of the nerve should be brought as far as possible under its influence, and for this purpose a large flat electrode is placed over the sciatic notch, and a smaller one successively over different points of the nerve and its distribution. Another method consists in placing one electrode over the sacrum, and the other in a tub of salt water, in which is the patient's foot. In each case the current is gradually turned on, two cells at a time, till from twenty to forty are in operation, the number depending on the fatness and tolerance of the patient. The application should continue for five to ten minutes, when the number of cells must be gradually diminished to zero, in order to avoid giving an unpleasant

and undesirable shock to the patient. In cases of considerable muscular wasting, the affected limb may be gently rubbed once or twice a day, or the muscles may be roused to action by a gentle interrupted voltaic current. In chronic and inveterate cases, acupuncture may be tried, although it is not often attended with marked success. Appropriate needles, two to four in number, are thrust in at the painful spots to a depth of one to two inches, and, if possible, into the nerve itself, where they are allowed to remain half an hour to two hours. The operation of nerve-stretching is sometimes attended with relief of the symptoms.

WM. GAY.

SCLEREMA NEONATORUM.

—A disease characterized by the development of extensive areas of induration or of hard patches in the true skin. The disease is either present at birth or develops in the few days succeeding it.

The colour of the skin over the affected parts is generally bluish-red; a fold of skin cannot be picked up by the fingers and thumb owing to the stiffening and thickening. It appears as if mummified, is hard, tense and shiny, but does not pit on pressure. The region of the shoulders and buttocks is very often affected; the extensor surface of the limbs and the back of the trunk are more affected than the thin-skinned flexor surface; the face is not often much involved; in one case symmetrical indurations existed in the cheeks; in another a patch was situated over the left parotid gland.

The lesions spread at varying rates and in such a manner as sometimes to involve large tracts of skin; indeed, the induration may affect the whole trunk, rendering it rigid.

The temperature of the body tends to fall in sclerema, especially if the debility progresses. The mode of dying may be by convulsions, diarrhœa, syncope, or asphyxia.

Many cases are congenital in date and rapidly prove fatal from asthenia, the cry gradually growing weaker and sucking being impossible from the rigidity of the lips. In these atelectasis pulmonum is often found. All cases are not rapidly fatal, sometimes the spread of the induration is very slow, there being no weakness of the heart or lungs, and the voice remaining strong.

The writer has had under observation the cases of three female children in one family who were affected fatally with a

chronic sclerema and paralysis simulating "infantile palsy."

Sclerema may be associated with œdema of the subcutaneous tissues, but in pure œdema neonatorum the course of the disease is like any case of cardiac dropsy, and no doubt it is the expression of cardiac weakness.

Morbid Anatomy.—The epidermic layers are normal, the rete and corium thinned, and the connective tissue dense and compressed.

Parrot described sclerema in cases of rapid athrepsia (marasmus).

Treatment consists in maintaining the vitality by warmth and stimulation. The body should be swathed in a cotton wool dress; washing of the skin should be done so as to cause as little exposure as possible. The mechanical nurse or *couveuse* should prove valuable. Brandy in five-drop doses should be given in real tea, or in whey. Vomiting and indigestion have to be contended with by the use of peppermint, aniseed or dill, given cold with a little brandy. The debility may be so great that sucking is impossible, if so the food should be placed at the back of the throat by means of a small spoon, or it may be syringed into this region, or it may be inserted into the rectum.

The inunction of camphorated or olive oil into the indurated patches does good, especially in the chronic cases which can be restored to health. Warmth is certainly beneficial.

In two cases the recovery appeared to be promoted by the inunction of mercury.

ANGEL MONEY.

SCLERODERMA.—A rare disease occurring chiefly in adults, in which the skin becomes hard and bound down tightly to the subjacent tissues. It occurs in two distinct forms—diffuse and circumscribed, but these may co-exist, and there are so many connecting links that it is impossible to consider them as separate and distinct diseases. There are, however, generally, considerable differences in their clinical characters, and the two types are here described separately.

Circumscribed Scleroderma (*Morphea*; *Keloid of Addison*) is the less rare form. It occurs more frequently in females than in males, and especially in early adult life. Its commonest seats are about the breasts and neck. The patches often show marked nervous distribution, those on the trunk following the course of the intercostal or lumbar

nerves and terminating abruptly at the middle line; those on the face usually occurring in the distribution of the supra-orbital or some other branch of the fifth nerve; those on the limbs being longitudinal in the direction of the principal cutaneous nerves. Their locality may also be determined by injuries, friction or pressure (*e.g.*, of clothes, stays, garters). The subjects of the affection are very often neurotic, and its development frequently follows mental shock or anxiety.

The first appearance of the disease is generally unaccompanied by subjective symptoms and its discovery, unless situate upon an exposed part, is often accidental, but occasionally slight itching or discomfort attracts attention to the part. A characteristic patch is at first slightly elevated above the general surface, and is pink in colour, but it soon subsides to the skin level or below it; its form is often roughly circular or oval; the outline is generally irregularly tongued or sinuous, but well defined, and outside it there is a marked zone of pink, lilac, or purple colour due to minute capillary telangiectases. The size of the patch or patches usually varies from that of a coin to the palm of the hand, but they may be more punctate, the size of a split pea or smaller (*macule atrophice*) or, on the other hand, as large as a dinner plate. Their surface is smooth, devoid of hair, of a waxy, dead yellowish or ivory-white colour, the pinkness previously noted being of brief duration. They are firm, brawny, and inelastic to the touch, and the skin is picked up with some little difficulty. Sensibility is seldom markedly affected, but sometimes there is anaesthesia, sometimes hyperaesthesia and pain. Sweat secretion is usually diminished or arrested, the results being some dryness, desquamation and cracking. Extension of the disease occurs by the development at the periphery of small, circular, atrophic spots, which ultimately coalesce with the original patch. In other cases, especially upon the limbs and in young subjects, the distribution of the disease is in longitudinal, depressed, cicatricial-like bands or stripes, the minutest forms of are represented by *lineae atrophice*. The more marked examples often cross joints and fix them, being bounded on either side by infiltrated and hyperaemic skin.

The disease is characterized by the infinite variety of its objective characters, clinical history and associated pheno-

mena. Thus the patches may be single or multiple; depressed, flat or considerably elevated and bossy; symmetrical or asymmetrical. Their size and distribution vary widely in different cases, as well as the subjective symptoms (itching and pain) attending them. In old standing cases there may be considerable brown pigmentation round about. The patches may develop and disappear rapidly, in the course of a few days or weeks, or may persist for months and years. Recovery is often ultimately perfect, as fatty degeneration and absorption of the new cell products occur, but on the other hand a permanently atrophic patch of parchment-like skin may be left. The disease may be associated with atrophy of subjacent muscles, unilateral atrophy of the face, alopecia areata, canities, and other tropho-neurotic conditions.

The *differential diagnosis* of the patchy form must be established from leucoderma, anaesthetic leprosy and true keloid of Alibert; that of the linear form from *lineae albicantes*.

Pathology.—We owe all our positive knowledge of this to Dr. Crocker, who thus sums it up:—"The pathology appears to be that, owing probably to some defect in innervation, an exudation occurs round the vessels, narrowing the lumen, obstructing therefore the blood-flow and leading to thrombosis and sometimes to a real rupture and effusion. Each atrophic spot seen near a growing patch is the base of a cone from which the blood supply is cut off, the violet zone being due to collateral hyperaemia round an anaemic area. The patch, or atrophic spot, thickens by the fibrillation of the effused cells. Where the arterial supply is completely cut off, an atrophic spot is produced; where it is merely diminished partial atrophy with connective tissue hyperplasia or morphæa is the result."

Diffuse Symmetrical Scleroderma (*Scleroma*; *Scleriosis*) is an even rarer condition than the preceding. It is also much commoner in women than in men, and occurs especially in early adult life. It begins by a dense infiltration and thickening of the skin, which gives rise to a sensation of stiffness, almost always first noticed at some point above the level of the waist, and most commonly about the shoulders, back of the neck, chest or arms. Sometimes there is antecedent oedema, with pitting on pressure, the duration of which may vary within wide limits. At the onset of the disease there may or may not be

slight elevation of the local temperature, according to the amount of erythema present but, as a rule, it is not marked. The spread of the condition varies much in rapidity in different cases, but generally it extends over a period of months or years; it occurs by periodic exacerbations, the whole of the arms, neck, scalp, face, and upper half of the trunk being ultimately involved; it is also usually present, although to a less degree, on the feet and legs, but it is stated that the lower extremities are never involved alone. The skin becomes intensely hard, stretched, devoid of its natural furrows and wrinkles, and cannot be picked up from the tissues beneath. Its surface is generally smooth and glossy, but sometimes is drier than natural, desquamating and cracked, owing to the diminished secretion of sweat and sebum. Its colour may deviate but little from the normal, or it may be pink, purplish, fawn-coloured, deep brown, or mottled, while the parts where the pathological process is most advanced and the vessels completely strangulated are quite white. Here and there over the affected area are groups or tufts of teleangiectases. The surface temperature is now usually a little below normal. The margin of the diseased area may be well defined and easily seen, or only determined by the sense of touch. Not infrequently itching is a troublesome symptom, but sensibility is seldom affected. Pain and tightness are the subjective sensations generally complained of. The size and appearance of the affected portion of the skin, as well as the subjective symptoms, are liable to considerable variations from day to day, dependent perhaps chiefly upon external temperature, the effects of cold—to which the patients are peculiarly susceptible—being especially deleterious. The joints, over which the skin has a peculiar tendency to be involved, become fixed in a position of semiflexion, the hands being clawed, the patient becoming literally hide-bound. Ulceration is very apt to occur over the articulations from over-stretching or from pressure. The limbs shrivel and become of ivory-like hardness, but the palms and soles almost always remain unaffected. The face becomes absolutely fixed and expressionless, owing to obliteration of its natural lines, and thus some old and middle-aged persons appear rejuvenated; ultimately the eyelids are fixed, the mouth motionless, and the patient may die of starvation from incapacity to take or masticate food. On

the trunk the process extends to the intermuscular connective tissue or the muscles themselves undergo atrophy; thus respiration becomes embarrassed, the patient often dying of bronchitis and asphyxia. In a few cases the mucous membrane of the mouth and pharynx has been involved.

Dr. Crocker maintains that the cases preceded or ushered in by cedema inevitably go on to irremediable atrophy, while those which begin by tense solid infiltration have a decided tendency to clear up sooner or later, the skin ultimately resuming its natural fineness, softness, and elasticity. In all cases the process is very slow and interrupted, and the patients are prone to be carried off by intercurrent diseases, especially nephritis, pneumonia, and bronchitis.

No difficulty in *diagnosis* can possibly arise, except when the case is seen in the initial cedematous stage, and at that period no definite diagnosis can be established.

Pathology.—Of the nature of scleroderma we know nothing, but there is undoubtedly a close relationship between it and the condition we term rheumatism, the latter disease frequently preceding or being associated with it. In other cases evidences of endocarditis are present, or so-called rheumatic nodules. Exposure to cold and privation are probably responsible for the occurrences of a certain number of cases, but the majority remain totally unexplained.

The morbid *microscopic appearances* are found in the corium and subjacent connective tissue, and comprise dense accumulation of cells of doubtful nature round the blood-vessels, which they compress, and may even obliterate, and especially round the sweat and sebaceous glands—which they ultimately destroy—and the production of excessively abundant and dense connective tissue.

Treatment.—The patient should be clothed in flannel, and take every possible precaution against exposure to cold or draughts. Turkish baths give, at all events, a temporary sense of comfort, probably by promoting sweating, as well as by the shampooing. If they cannot be procured, vigorous rubbing and the inunction of oils of any sort impart some suppleness to the skin. Galvanism is certainly of use in some localized cases. No drug administered internally is of the slightest service.

J. J. PRINGLE.

SCROFULODERMA (Strumous or Scrofulous Ulceration of the Skin).—A clinical term used to describe a number of cases of true tubercular disease of the skin attended with ulceration, and intermediate in point of acuteness between lupus and acute tuberculosis.

Strumous ulceration usually occurs in children or young persons, but is liable to recur in more advanced life. Its subjects almost always exhibit the aspect and other evidences of the strumous diathesis. It may affect almost any part of the body, but its commonest site is the neck, where its first manifestations are found in the submaxillary or nuchal or post-sterno-mastoid lymphatic glands. These are enlarged, hard and indolent, seldom tender; slowly the caseous matter, of which the masses are mainly composed, softens, breaks down and suppurates. The skin above becomes implicated, adherent, red or purple, and inflamed; numerous sinuses, through which gummy pus is discharged, riddle and undermine it in all directions. In other instances the initial nodules are formed in the subcutaneous or cutaneous lymphatic tissue, but they follow the same course as those originating in glands. Ultimately large unhealthy ulcers are formed with steep or overhanging edges which, if they spread at all, do so very slowly. In form they are often oval: their surface, which bleeds readily, is uneven and covered with luxuriant, pale granulations and pus, which dries up to form thin, brown or yellow crusts. Various such lesions often co-exist or occur successively on different parts of the body. There is little tendency to spontaneous cure, but they generally yield rapidly to appropriate treatment, when the scars left are often thick, hard, nodular and very disfiguring.

The *pathology* is similar to that of lupus, from which there is no advantage in differentiating it. Congenital syphilis may closely simulate scrofuloderma and must be eliminated, but careful examination of all the features of any given case makes its nature clear.

Treatment.—Constitutional remedies in a certain proportion of cases are by themselves curative. The food must be digestible and nourishing, butchers' meat with plenty of fat being specially recommended. Eggs, milk and cream ought to be given freely. Good hygienic surroundings should be provided, and sea air is especially beneficial.

Cod-liver oil, arsenic, iodides and ferruginous tonics are all of real service, and may be administered separately or

collectively in combination with the employment of local measures. The remains of caseous glands should be removed by scraping. Ulcers may be washed with mild mercurial lotions and afterwards dusted with iodoform or iodol.

J. J. PRINGLE.

SCURVY (Scorbutus).—A disease due to imperfect diet, chiefly characterized by anæmia, a swollen spongy condition of the gums, and by the occurrence of hæmorrhages in the skin.

Symptoms.—The disease is somewhat insidious in onset, the characteristic symptoms of the scorbutic state being preceded by a period in which the patient suffers from languor, lassitude, debility, and pains in the limbs, whilst his complexion assumes a sallow, cachectic appearance. He may be listless and drowsy but has no fever. In a few days, petechiæ appear, generally (as in all purpuric affections) first upon the lower extremities. It is pointed out as characteristic of scurvy that the hæmorrhage occurs mainly at the orifices of the hair follicles. As the disease advances the purpuric condition extends, and large discoloured patches, like bruises, cover the limbs, whilst anæmia becomes more marked, with concomitant dyspnœa. The hæmorrhage may take place in the loose tissue of the eyelids and the face assume a puffy, bloated aspect. Further, hæmorrhage occurs in the deeper tissues, and painful swellings from extravasation into the substance of muscles, possibly unattended by any cutaneous discoloration, make their appearance; or there may be hæmorrhagic effusion into joints, or beneath the periosteum. In infantile scurvy hæmorrhage is especially liable to occur in this latter situation and about the epiphysial junctions.

The pathognomonic symptom of scurvy is the spongy, swollen state of the gums around the implantation of the teeth, which may become loose and fall out, the gums bleeding on the slightest touch, and in bad cases, sloughing and ulcerating. This ulcerative stomatitis produces a foul odour of the breath. Ulcers may also form on the limbs where there has been much subcutaneous hæmorrhage.

The constitutional symptoms are those of anæmia. Besides the dyspnœa, which increases in intensity with the progress of the disease, there is a great tendency to syncope. Except in very severe cases, there is not much liability to hæmorrhage into the internal viscera, but there

may be gastro-intestinal hæmorrhage, or pulmonary hæmorrhage. Dysenteric symptoms and pneumonia or gangrene of the lung may complicate the case. Other complications consist mainly in inflammation of serous membranes which may be accompanied by hæmorrhage. Retinal hæmorrhage is not common, at least in milder cases, and hence its occurrence has been attributed to the degree of anæmia produced by the disease rather than to the hæmorrhagic tendency that characterizes it. A remarkable symptom connected with vision is nyctalopia or "night-blindness."

The *course* of scurvy is, as a rule, slow and prolonged, owing to the extreme debility and marked emaciation.

Pathology.—The pathology of scurvy has been made the subject of much speculation. There can be little question that it is essentially a blood disease, and its ætiology suggests that there is a deficiency of some element in the blood, which is supplied in fresh vegetable food. Garrod considered that deficiency in potash was the cause, since this element was wanting in scorbutic but present in anti-scorbutic diets. But this theory is not borne out by the treatment of the disease by potash salts. On the other hand the organic acids, which are present in fruits and vegetables, may with even greater reason be the essential factor. Dr. Ralfe, however, from a careful study of the urine, concludes that the essential cause is a diminished alkalinity of the blood. He finds the acidity of the urine is diminished, and that there is a great reduction in the alkaline phosphates, confirming in this respect Garrod's observations on the deficiency of potash salts. Dr. Ralfe's view is, that as the alkalinity of the blood depends upon the carbonates and bicarbonates, the withdrawal from the food of organic salts—such as the lactates, malates, and citrates—from which these carbonates are derived, affords a satisfactory explanation of the dietetic associations of the disease, since, on this view, the blood may be de-alkalised by the introduction of a preponderating excess of acids or acid salts in the food.

Ætiology.—Scurvy is therefore due to an insufficient diet. All other circumstances may be favourable, but if there be a deficiency of vegetable food, scorbutic symptoms may arise. Naturally, the most severe cases of such an affection are to be met with amongst those who are subjected to other depressing influences; but it has been proved that, given the

absence of a proper vegetable diet, exposure to cold and damp are not necessary to its occurrence, although together with other debilitating conditions they may favour it. The most striking examples of its ravages occur in military and naval and Arctic service, where, from defects in commissariat or impossibility of obtaining fresh vegetables, scurvy has at times prevailed to an extreme degree during war or protracted sea voyages. It has occurred also in association with a potato famine, or failure of other vegetable crops, and to a more limited extent in prisons and reformatories, when the diet has been defective in the above particular. Sporadic cases are to be met with in most large towns, and are invariably to be traced to the same essential cause, affecting both young and old alike. Of recent years attention has been drawn to a condition closely analogous to scurvy, and associated with rickets in young infants; this "infantile scurvy" or "scurvy rickets" being also traceable to improper feeding, especially the lack of fresh milk.

Treatment.—There are few diseases which better illustrate the value of appropriate and rational treatment. In the milder cases—such as are now commonly seen—where there may be little but sponginess of gums, slight purpura, with debility and anæmia—recovery is soon brought about by the free use of fresh vegetables and fruit (especially lemons, oranges, &c.), to which may be added the administration of potash salts, the citrate or tartrate, and hæmatinics, as iron or arsenic. Fresh meat in lieu of salted meats, and fresh milk in place of preserved milk, are excellent adjuvants. Indeed, as the cause is largely dietetic—so must the treatment be. Prophylaxis is of the greatest importance, armies in the field and ships should be supplied with tinned vegetables, and fruits, and, when these are inaccessible, with good lime juice. It is astonishing how even severe cases of the disease may be cured by a prompt resort to an anti-scorbutic regimen.

SIDNEY COUPLAND.

SEA-SICKNESS.—Vomiting, excited by the pitching and rolling of a boat or ship at sea.

Symptoms.—There is at first a feeling of gastric uneasiness, intensified by the ingestion of food. This is followed by nausea and a swimming sensation in the head, which may be accompanied with flushing or pallor of the face and sweating. There soon arises not only a dis-

taste for food, but a repulsion from it, and a feeling of nausea is induced by its very smell. These symptoms may be relieved by vomiting, but very often its frequency only increases the distress, especially if the stomach be empty. The vomit is generally very acid, and may be mixed with bile and mucus. At this period everything swallowed is at once ejected. The tongue is now thickly coated, the breath foul, and there is often an excess of salivary secretion. The bowels are, as a rule, obstinately confined, but occasionally there is diarrhoea. The urine is scanty, dark, strong-smelling, with a thick deposit of urates, and sometimes a trace of sugar. The continuance of these symptoms renders the individual wretchedly helpless, he wraps himself in his rugs, for he feels excessively cold, takes no interest in his surroundings, is continually dropping off to sleep, and refuses food. If this go on for long, a period of exhaustion sets in, the pulse becomes very weak, and actual syncope may occur; sometimes a condition of stupor comes on, from which the patient is with difficulty roused. When these symptoms of depression are long continued, the case is one to excite considerable apprehension, for death sometimes results, usually from syncope. Women sometimes abort, and the secretion of milk may be arrested in mothers who are suckling. Such extreme cases are, however, rare, and generally after a few days the symptoms gradually abate, and are followed by a state of mental and physical exhilaration and an enormous appetite. Some people only suffer from a feeling of heaviness, anorexia, and frontal headache, which may be very persistent. Others experience no discomfort at all, and this is particularly true of the extremes of life. As a general rule women are more often and severely affected than men. Sometimes an individual gets so accustomed to the movements of the ship that it takes him some time to recover his land legs, and in rare cases vomiting and retching occur upon landing. The writer has been assured by two or three people that their return to terra firma is accompanied with severer symptoms of sea-sickness than they experience during a voyage. Retching and vomiting may continue for some time after landing from a short and boisterous voyage.

Prognosis.—Complete recovery may generally be expected in from three to five days; but very severe cases often give rise to considerable anxiety.

Pathology.—Many opinions are held in regard to the nature of sea-sickness. Some believe that the pitching and rolling of the ship cause disturbances of the endolymph in the semicircular canals, giving rise to erroneous impressions, which induce vertigo. Others would ascribe the condition to an active hyperæmia of the semicircular canals. Another theory refers the symptoms to a congestion of the centres of the cord and medulla, which renders them more excitable and sensitive to reflex influences. In this manner the vomiting, constriction of arterioles and increased flow of mucus to the stomach and intestine are explained. Such are a few of the many theories which have been suggested. In considering the pathology of sea-sickness, it is essential to remember that similar, if not identical, symptoms may occur under circumstances in which an individual's relationship to surrounding objects is not quite clear. In this way many people cannot enjoy a swing, and some experience a mild form of "sea-sickness" whenever they travel by train. Others are so far unable to adapt themselves to new conditions that not only is their gait uncertain upon landing, but they may even feel sick and actually vomit. All these cases are probably explained by the fact that equilibrium and the conception of relationship to space are maintained by a most delicate co-ordination of impulses from very numerous and widely separated parts of the body, and that in some people the slightest disturbance of these impressions is sufficient to cause a feeling of uncertainty and insecurity, which results in vertiginous sensations, nausea and vomiting. So marked may be this want of adaptability to varying external conditions, that imagination alone may give rise to symptoms of sea-sickness, as is shown by its occasional occurrence before the ship has left dock. According to this view, the sickness of *mal de mer* differs only in degree from that induced by swinging, &c.

Treatment.—This must be conducted on general principles, for although most new remedies are vaunted as specifics, none of them really deserve the title. A seat in one of the warmest parts of the deck should be chosen, not only because fresh air is desirable, but objects are seen on a larger scale there, and appear therefore less "out of joint." Some people who can remain on deck all day vomit only when they get up and go to bed, because they are then in the con-

finer area of their cabin, where all the movements of the ship appear exaggerated, since they are seen within a small compass. When the patient is unable to leave his cabin, he should lie in his berth on his back, and keep his head low. The obstinate constipation should be treated with aperients and the dyspepsia of the early stages, if necessary, with alkalies or prussic acid and diffusible stimulants, but in the later stages of long protracted cases acids are indicated. Opium or the hypodermic injection of morphia is sometimes useful by procuring a prolonged rest. It is very difficult to overcome the distaste for food, but it is necessary to insist on some being taken. This is best administered in a fluid or semi-fluid form, such as beef tea, arrowroot, which should be repeated frequently and in small quantities. Iced champagne is an admirable stimulant, and is frequently tolerated when nothing else can be taken. When the stomach becomes more tractable, cold toast with ham and chicken or other meats may be given. Many drugs, of a more or less specific nature, have been recommended, and are occasionally useful, but very often fail to have the desired effect. Among these may be mentioned the bromides, chloral, nitrate of amyl, nitro-glycerine, cocaine and antipyrine. Dr. Chapman's spinal ice-bag sometimes affords considerable relief to the general symptoms, and alleviates the headache, which may be very distressing.

WM. GAY.

SEBACEOUS GLANDS, DISEASES OF. — Miliun (*Grutum*;

Strophulus Albidus of Willan).—A hemispherical, whitish or pearly projection from the skin, usually about the size of a millet seed, and formed by the accumulation of altered sebum, epithelium, fat and small hairs in a sebaceous gland, the excretory duct of which is obliterated. They often cretify and constitute so-called cutaneous calculi. They are usually multiple; the condition is chronic and painless, and is commonest about the eyelids and forehead, penis and scrotum. The general aetiology is the same as that of acne, but the disease is one of middle rather than of early life. Miliun may occasionally be mistaken for xanthoma or molluscum contagiosum.

Treatment consists in puncturing the sac and expressing its contents; the lining membrane may be scraped or lightly cauterised. Frequent washing

with soap and warm water is a useful preventive measure.

Keratosis pilaris (*Lichen pilaris*, *pityriasis pilaris*).—A chronic, acquired disease of the skin, characterized by the formation of minute, pale, conical elevations about the openings of the hair follicles, caused by the accumulation of sebaceous matter and epithelial cells, and usually enclosing a twisted or stunted hair, the end of which may appear as a dark point. These prominences are greyish or dark from adherent dirt, can be removed from the orifice of the hair follicle, and arise from skin which is usually normal, but may become inflamed. In well-marked cases the skin becomes dry and harsh, feeling like a nutmeg-grater when the hand is passed over it.

The disease is commonest in working men of uncleanly habits, but also occurs in scrofulous children, and as a sequela to pityriasis rubra. It attacks chiefly the extensor surfaces of the thighs, arms and forearms, and frequently also the buttocks and shoulders. It gives rise to no subjective symptoms. The condition closely resembles true, inflammatory lichen pilaris, and congenital ichthyosis follicularis, and must also be distinguished from lichen scrofulosorum, the minute papular syphilide and cutis anserina. It has recently been shown to be due to the presence of pathogenic coccidia or psorospermia.

Treatment consists in vigorous washing with soap and water, and the subsequentunction of glycerine, oil, or a mild petroleum ointment.

Colloid Miliun (*Colloid degeneration of the skin*).—A rare skin affection characterized by the presence of minute, shining, flat or slightly raised lesions of a pale or bright lemon colour, especially on the bridge of the nose, forehead and cheeks, and occasionally on the upper extremities. To touch they are hard and elastic; after incision homogeneous, gelatinous matter can be expressed. The disease affects persons of middle or advanced age. The lesions may disappear spontaneously, or inflame and scab, leaving an ill-defined, often umbilicated scar. They are due either to colloid degeneration of pre-existing miliun bodies, or of the connective tissue of the corium. Xanthoma is the only disease for which this can be mistaken.

Other affections of the sebaceous glands will be found treated under the headings, ACNE, ASTEATOSIS, COMEDONES, SEBORRHOEA.

J. J. PRINGLE.

SEBORRHŒA (Steatorrhœa).—A functional non-inflammatory disorder of the sebaceous glands characterized by the excessive secretion of altered sebum and its accumulation on the skin, along with epithelial debris, in the form of an oily coating, greasy crusts, or fine, branny scales.

The condition may be (1) universal, or (2) local. The vernix caseosa existing at birth may be considered as a physiological seborrhœa, but if it be excessive in quantity, or persist after the first month of life, it becomes pathological.

Universal Seborrhœa is rare; three principal forms are recognized:—

(1) *Seborrhœa squamosa neonatorum* (ichthyosis congenita) in which the accumulated sebum forms thick, yellow plates firmly adherent to the skin and fixing it; deep rhagades form at the articulations, the eyelids are tightly stretched, the lips retracted, causing the gums to be exposed; the fingers, toes and ears are badly developed. The subjects invariably succumb in a few days.

(2) *Seborrhœa universalis (vel pityriasis tabescentium)* occurs only at the end of wasting diseases (e.g. diabetes mellitus), and consists in the existence of a universal, branny desquamation, especially over the trunk and extremities.

(3) *Cutis testacea* is a condition closely resembling ichthyosis hystrix, in which the trunk and extensor surfaces of the extremities are covered with large thick plates of greasy, inspissated sebum, usually greenish or blackish from accumulation of dirt upon them. The subjacent skin is not inflamed, and the sebaceous nature of the disease is clearly shown by the presence of processes from the under surface of the plates penetrating the dilated sebaceous ducts.

Treatment may be conducted on the same lines as for the local forms of seborrhœa.

The various forms of **Local Seborrhœa** are among the commonest skin diseases presenting themselves for treatment. They most frequently develop about the period of puberty, like the other forms of sebaceous disease with which they are often associated, and they affect the female more than the male sex. Occasionally they occur in healthy persons, in which case they are usually very amenable to treatment, but the greatest number of cases arise in persons suffering from anæmia, weak circulation, dyspepsia, menstrual disorders or phthisis. Personal uncleanness strongly predisposes to the disease. Authorities differ

as to whether it is worse in summer or in winter, the majority leaning to the latter view. Many arguments have lately been advanced in favour of the view that this disease is due to a micro-organism, but no definite specific form has yet been detected.

In *Seborrhœa oleosa* the sebaceous discharge is very abundant and gives a glossy or greasy appearance to the skin, or may even form large oily drops upon it, causing a distinctly rancid odour. The condition is physiological among the negro races, but somewhat rare among whites, and affects chiefly brunettes. The nose, forehead, and the bald scalp are the chief seats of the disease; on removing the secretion the openings of the sebaceous gland ducts are seen to be very patulous and the oily discharge rapidly reaccumulates. The condition frequently complicates rosacea, and is specially common in alcoholic subjects.

Seborrhœa sicca is by far the commonest form of the disease; the sebum is secreted less rapidly and in smaller quantity than in seborrhœa oleosa, and is mixed with epithelium from the sebaceous glands and excretory ducts so as to form fine greasy or branny scales; the underlying skin is pale and leaden. No subjective symptoms are present, but decomposition of the sebum may give rise to eczema and itching (*vide ECZEMA SEBORRHŒICUM*). The disease presents certain peculiarities according to its sites.

(1) *Seb. sicca capillitii* (dandruff, pityriasis simplex) is usually diffuse over the whole hairy scalp, but most severe at the vertex. It may be so slight as only to occasion a little furfuraceous scurf, or the secretion may be so abundant as to mat the hairs together. The disease, if of long standing, may cause permanent baldness (alopecia pityrodes vel furfuracea) from destruction of the hair bulbs, and even in mild cases the hair usually falls to some extent. When it extends over the forehead a little eczema is usually set up. The disease must be differentiated from eczema, psoriasis, tinea tonsurans and the secondary squamous syphilide, all of which it usually complicates.

(2) *Seb. faciei* is a common sequela of variola and other exanthemata, and a frequent concomitant of the composite disease rosacea. It affects chiefly the forehead, superciliary regions, sides of the nose and cheeks, and is specially liable to produce secondary eczema. Marked disfigurement is often caused by

the greenish or blackish colour of the scales. Cases in which the plugs of sebum penetrate the patulous excretory ducts simulate closely or may prove to be the early stage of lupus erythematosus, hence the name *seborrhœa congestiva* originally applied to that disease by Hebra.

(3) *Seb. genitalium* consists in the accumulation of smegma beneath the prepuce in males, about the clitoris and between the labia and nymphæ in women. Decomposition of the sebum frequently causes balanitis in the male, and in the female a condition liable to be taken for gonorrhœa.

(4) *Seb. corporis* is the disease formerly described as *Lichen circumscriptus*, *circinatus*, *marginatus*, *annulatus*, *gyratus*, &c. Its characters vary considerably from those of the forms just described. The eruption usually occupies a triangular patch between the scapulæ, the base being directed upwards, and the sternal and clavicular regions; it consists of groups of minute pink papules, which form rings with well-defined margins, spreading centrifugally and coalescing to form gyrate figures. In old-standing and extensive cases, the rings may be only observable at the outside of the patches. In the centre of each ring is a thin, greasy scale frequently detached by the clothing. Persons who wear flannel clothing, and especially those who wear the same night and day, are frequently the subjects of the disease. *Seborrhœa capitis* is almost invariably present, and acne is frequently intermingled with the disease. Moderate itching is usually complained of. The condition has little tendency to cause eczema, except perhaps in rheumatic subjects. The disease is apt to be confounded with *tinea versicolor*, *tinea circinata*, *pityriasis maculata*, and the early circinate syphilide.

Treatment of Seborrhœa.—(1) *Constitutional*; fresh air, exercise and proper feeding must be enjoined. Cod liver oil, iron, arsenic, and the sulphide of calcium are the drugs most generally used.

(2) *Local*; crusts and scales must be softened with rags soaked in diluted liquor potassæ or, preferably, with oil, and removed; in cases of *seborrhœa capillitii* it is as well to apply the oil freely at night and wear a flannel night-cap; then vigorous friction made with an alcoholic solution of soft soap (*spiritus saponis alkalinus* of Hebra) which removes loose hairs and further cleanses and stimulates the skin. Mild astring-

ent ointments containing alum, borax or tannin should then be applied, or more stimulant applications, such as diluted red oxide or white precipitate ointments. The addition to these ointments of salicylic acid or resorcin (2-5 per cent.) is beneficial and prevents decomposition of sebum with its deleterious results. The habitual use of soap containing carbolic acid, sulphur or tar is usually advisable. Should eczema arise as the result of too vigorous treatment, it must be dealt with on general principles.

J. J. PRINGLE.

SEPTIC DISEASES (*Sapræmia*, *Septicæmia*, and *Pyæmia*).—These affections, though usually observed as secondary consequences of wounds or other injuries, occasionally arise under other circumstances, and are therefore briefly noticed here.

In *Sapræmia*, or septic intoxication, the symptoms are produced by the absorption of soluble products of bacterial action. These bacteria are probably those present in ordinary decomposition, and are not themselves capable of surviving or producing any effect in the living blood or tissues.

By *Septicæmia* is to be understood a condition in which the blood becomes itself infected by microbes, ordinarily associated with suppuration. There is no one microbe constantly present; the *staphylococcus pyogenes aureus* or *albus*, or the *streptococcus pyogenes*, may one or all be the active agent in suppuration and in *septicæmia*, but it is probable that the last named is the most malignant, and most often associated with severe *septicæmia*.

Pyæmia is to be regarded as a form of *septicæmia* characterized by the occurrence of multiple or so-called metastatic abscesses. Clinically, no hard-and-fast line can be drawn; pathologically, the microbes found in the blood and in the affected tissues are the same, and the morbid anatomy renders it probable that the essential event in *pyæmia* is the occurrence of phlebitis at the seat of the primary lesion. As this phlebitis is infective, it is reasonable to suppose that particles of the clots in the veins are detached and become impacted in the lungs, or if the radicals of the portal system be the veins involved, in the liver, and there set up a suppurative process.

No organ of the body enjoys immunity, but the most frequent seats of destructive purulent inflammation are

the joints, the pleura and peritoneum, the meninges, the endocardium, the eye, the muscles, the liver, and the spleen. The infective factor is undoubtedly a microbe, the streptococcus pyogenes, or one or both of the two above-mentioned staphylococci. The probable sequence of events is that a minute vessel or capillary becomes plugged by an infective embolus—a collection of cocci, or a clot containing cocci. Each embolus is a focus of inflammation, leading to coagulative necrosis in its immediate neighbourhood, with minute extravasations around. Secondary inflammation ensues about the necrotic focus, and the inflammatory process becomes, through the agency of the pyrogenic cocci, suppurative.

That a very slight wound may be followed by a severe septic disease is a well-established clinical fact, but a satisfactory explanation of it has not yet been afforded by the observations of bacteriologists.

As has been stated already, the microbes found in the most acute forms of septic disease are specifically identical with those present in a trivial furuncle, or in the so-called "laudable pus." Why in certain cases these microbes are the determining cause of so malignant a process as septicæmia or pyæmia is not very clear. In some cases a partial explanation may be found in a neglect of the old maxim: "If there be pus, let it out." In others the debilitated condition of the patient may be a contributory cause. In others, again, the anatomical relation of the parts primarily involved is of importance; this is the case in puerperal fever, and in pyæmia secondary to inflammation of the vermiform appendix. But a considerable proportion of cases remain, in which it seems necessary to suppose that the microbes themselves are more virulent—i.e., possess a greater power of growing and spreading in the tissues, than is ordinarily the case. Some importance may also attach to the dose, that is to say, to the number of microbes reaching the blood from the primary focus.

Symptoms.—The general symptoms of these three varieties of septic disease are described in the article on PUERPERAL FEVER (*q.v.*). Those of sapræmia will not be further discussed, and it will suffice here to point out some of the morbid conditions under which septic diseases are liable to occur as complications, for the proportion of cases in which either septicæmia or pyæmia arises spontaneously is very small, and it is doubtful whether even in these cases the spontaneity is not more apparent than

real. The specific poison may obtain entrance through a slight abrasion of the skin, or through a bed-sore, which may even heal under suitable local treatment while yet the general systemic poisoning progresses; or the point of entrance may be an ulceration of the mucous membrane of the pharynx, intestine, or urethra. The cases in which septicæmia (or more probably, perhaps, pyæmia) seems to be most distinctly spontaneous are examples of *Acute Osteomyelitis*, where without any abrasion of surface, an acute infective process originates within the cancellous structure of the long bones; here, however, a previous traumatism has probably in all cases lowered the vitality of the bony tissue. A specific infection of the endocardium may occur in the course of septicæmia or pyæmia, and may be the intermediate process which converts the former into the latter, but in a considerable proportion of cases the lesion of the endocardium is the most prominent, and, at least appears to be, the primary lesion. Such cases come within the definition of ulcerative or malignant endocarditis (*see HEART, ACUTE DISEASES OF THE VALVES*).

The temperature is of the remittent type; the initial rise in septicæmia is generally sudden and may be accompanied by a rigor; the exacerbations are apt to occur daily in the evening, giving the temperature curve a general resemblance to that of enteric fever. The development of pyæmia is marked by wider fluctuations. The temperature rises rapidly, often to 105°–106° F. during the rigors; the subsequent remission, which is accompanied by copious perspiration, may bring the temperature down below the normal point.

The skin, which soon assumes a sallow or more distinctly icteric tint, may be the seat of minute petechiæ or of larger ecchymoses; an erythematous eruption is frequent, and has been mistaken for that of scarlatina; septic disease is however not an infrequent complication of scarlatina anginosa; roseolar, urticarial, and pustulous eruptions may also be met with.

The pulmonary symptoms, even when abscesses exist, are often obscure; patches of broncho-pneumonia may be discoverable, but the amount of dyspnoea may be out of proportion to the physical signs. Bronchitis is a frequent complication.

The spleen is enlarged at an early stage and may subsequently become the

seat of infarcts which break down into abscesses. Hepatitis occurs with great frequency in those cases in which the primary lesion is within the domain of the portal system; multiple hepatic abscesses and general pyæmia may thus have their origin in suppurating hæmorrhoids, in inflammation of the vermiform appendix, or in ulcerative enteritis. Colliquative diarrhœa is frequently present, and is not always due to enteritis discoverable after death.

The serous cavities may be the seat of purulent inflammation, generally produced by extension from the viscera; thus pericarditis and empyema are common complications.

The renal symptoms vary very widely; an acute septic nephritis with miliary abscesses, or one or more suppurating infarctions may be present, in which case the urine is highly albuminous, and contains casts, or epithelial cells and blood. In other cases, in association with ecchymoses in the substance of the kidneys, or hæmorrhage into the mucous membrane of the pelvis, or miliary abscesses, a small amount of albumen and perhaps traces of blood are present, while in others little or no albumen may be detectable.

The occurrence of suppuration in and about the joints, in the muscles, and aponeuroses, as well as the occurrence of panophthalmitis, are mentioned in connection with the pyæmic form of puerperal fever.

The cerebral symptoms are of the same typhoid character as those produced by other severe and exhausting fevers. More rarely meningitis, cerebral hæmorrhage, or abscess may be observed.

Diagnosis.—The diagnosis of septic disease is usually in the early stages very difficult. The resemblance of certain cases to scarlet fever has already been mentioned; cases of purpura variolosa, that is to say, cases of small-pox, in which before the papular eruption comes out numerous widespread cutaneous ecchymoses appear, have been confounded with septic disease. The true nature of such cases can only be recognized by a careful consideration of their ætiological relations. The same remark applies to those somewhat chronic cases of septicæmia, in which the general prostration, enlarged spleen, diarrhœa and perhaps roseola, present a general resemblance to enteric fever; the history of the case, the character of the stools, and the temperature curve may afford valuable information: care-

ful examination ought also to be made for cutaneous ecchymoses, swelling of the joints, and retinal hæmorrhages.

The resemblance of some cases to acute miliary tuberculosis may lead to considerable difficulty, and in view of the pathological affinities of acute tuberculosis and pyæmia this is not surprising, nor is it always possible to remove all doubt until the development of some distinctive symptom, such as well-marked arthritis or choroidal tubercle.

In those cases of septic disease which present at an early stage arthritis of many joints, endocarditis and high temperature, the diagnosis from acute rheumatism is not at once possible. The effect of salicin in reducing temperature and relieving articular pain is very much more marked in acute rheumatism than in pyæmia and, later on, the occurrence of icterus and cutaneous ecchymoses, of retinal hæmorrhages, of bronchopneumonia, and of marked splenic enlargement will point to pyæmia, though cutaneous ecchymoses and bronchopneumonia are occasionally observed in severe cases of acute rheumatism.

If severe acute nephritis be developed early in the case, it may be impossible to distinguish it from one of acute Bright's disease, and indeed such a case may be in one sense considered to be a variety of acute Bright's disease, with the superadded danger that the inflammation is secondary to an infective inflammation of some other organ or tissue.

Prognosis.—The prognosis of sapræmia is, speaking generally, less favourable than that of septicæmia, since if the cause can be discovered and removed, the poisoning will cease; the prognosis of sapræmia therefore is dependent on the nature of the causative malady. The prognosis of acute severe septicæmia is extremely unfavourable and death may ensue in a few days; in less severe cases, if the primary lesion can be discovered and treated, the prognosis is more hopeful.

When pyæmic abscesses have formed the prospect is much more gloomy, since each such abscess is a fresh focus from which the infective particles may be distributed.

Treatment.—The treatment of sapræmia has already been indicated; it consists in removing the source from which the poisonous matter is derived; the application of this principle to the special case of one form of puerperal fever is fully discussed in the article on that

subject (*see* sub-head Septic Poisoning). The treatment of septicæmia is not hopeful; internal medication is only palliative, but large doses of quinine reduce the temperature, probably conserve the patient's strength and may tend to check the morbid process, but no radical benefit can be hoped from such means. If suppuration be known or surmised to exist in any organ or tissue, exploration at the earliest possible date is advisable. This is the more necessary since it is impossible to say with certainty in the early stage of any case whether it is an instance of sapræmia, or of true septicæmia. Acute pyæmia is almost invariably fatal. Subacute cases, however, occur; in them, especially those in which the earlier abscesses are in easily accessible situations, much may be hoped for from persistent treatment; every abscess must be evacuated and its cavity rendered antiseptic, the patient's strength being maintained by the administration of easily digestible or pre-digested food, and by the exhibition of stimulants (champagne, old port wine) in moderate quantities. DAWSON WILLIAMS.

SINUSES OF THE DURA MATER, THROMBOSIS OF. —

Thrombosis of the cerebral sinuses is undoubtedly favoured by the peculiar conditions under which the venous circulation is carried on within the cranial cavity. These sinuses are little else than channels formed in a fold of the dura mater, and have consequently rigid walls and an unvarying capacity. They must then always contain the same amount of blood, notwithstanding the more or less engorged state of the rest of the venous system. Unlike the rest of the veins the circulation within them is removed from the influence of atmospheric pressure, and of muscular contraction, whilst in the case of some of the sinuses the current is against the influence of gravity. Moreover, in the case of the superior longitudinal sinus and some others the entering veins may have a direction contrary to that of the main current in the sinus. Lastly, some sinuses are curiously traversed by fine trabeculæ which must further retard the flow of blood. Hence of all venous channels in the body the cerebral sinuses are perhaps the most favourably disposed for the spontaneous coagulation of their contents, and there can be no question that such an event comparatively often occurs. But they are also the seat of thrombosis which is secondary to inflammation of their

walls or due to extension of clotting from some of their tributary veins.

Anatomy of the Sinuses.—It may be useful to recall the leading facts of the disposition and relations of these channels, as serving to explain the manner in which they may become thrombosed and also the effects of such obstruction. Some of them are single, others are in pairs. They are usually divided into those of the vertex and those of the base. In the former category are the superior longitudinal, inferior longitudinal, straight, occipital and lateral sinuses: in the latter, the cavernous, circular, transverse, the superior and inferior petrosal sinuses. The blood from all these sinuses finds its way eventually into the jugular veins by the lateral sinuses. Posteriorly there is a confluence of sinuses in the torcular Herophili, whence the lateral sinuses take their origin: similarly, anteriorly the cavernous sinuses receive the petrosal and, through them, communicate with the lateral.

The *superior longitudinal sinus* runs in the upper margin of the falx cerebri, from its anterior extremity at the crista galli, to the torcular Herophili, which is seated at the posterior junction of the falx with the tentorium, opposite to the internal occipital protuberance. There is a groove on the occipital bone indicating the position of this sinus, which is triangular in section, and enlarges in size from before backwards. The sinus is traversed internally by a number of fibrous bands, and at places there may even be seen projections into the sinus of Pacchionian granulations. This sinus receives blood from a large area of the surface of the cerebral hemispheres, and most of the veins opening into the posterior part, have a forward direction, contrary, that is, to the direction of the blood current. Veins from the cranium and the scalp also open into this sinus.

The *inferior longitudinal sinus* is situated in the lower, short margin of the falx, and ends in the *straight sinus*, which runs along the line of junction of the falx and tentorium to open into the torcular. The former receives blood from the inner surfaces of the hemispheres, the latter has the important office of receiving the veins of Galen, as well as veins from the upper surface of the cerebellum.

The *lateral sinus* is partly contained in a wide groove which winds across the occipital and temporal bones, terminat-

ing in the jugular foramen. It is connected with the foregoing sinuses by its junction with the torcular, and receives in its course the occipital and petrosal sinuses whereby it is connected with the cavernous sinus. It is also fed by veins from the cerebellum, from the diploë of the occipital and temporal bones, and it may be especially noted, from the mastoid process of the latter. It terminates in the jugular vein, and is therefore the main channel whereby the blood passes out of the cranial cavity.

The *occipital sinus* runs in the attached border of the falx cerebelli to end in the torcular, and anastomoses anteriorly with the posterior spinal plexuses.

The *cavernous sinus*, so called from its being filled with a delicate spongy mesh-work, is an irregularly shaped sac placed on the side of the sphenoid bone, from the sphenoidal fissure to the apex of the petrous bone. It is of great importance, owing to its receiving the ophthalmic vein, which has such free anastomoses with the facial, nasal and frontal veins: posteriorly it communicates with the petrosal sinuses. It is also remarkable from having its wall traversed by the third, fourth and sixth cranial nerves, and the ophthalmic division of the fifth, and also by the carotid artery.

The *circular sinus* surrounds the pituitary body, and connects the two cavernous sinuses.

The *superior and inferior petrosal sinuses* run respectively along the upper and lower margin of the petrous bone between the cavernous and lateral sinuses, receiving in their course venules from the bones they traverse.

Ætiology of Sinus Thrombosis.—Obstruction of the cerebral sinuses by coagulation of their contained blood during life, may be brought about in several ways. At least two main divisions are met with.

(1) There are cases where thrombosis occurs in the weakly, in states of exhaustion, however produced, such, for example, as are met with in the very young or the aged, from exhausting diarrhoea, in the course of lung disease, or following prolonged fever; and, at other periods of life, in the anæmic, or the subjects of phthisis or cancer. Rarer are to be met with similar spontaneous thromboses in the states of pregnancy or the puerperal period, and perhaps rarest of all, in organic heart disease. It is obvious that these are also conditions which are the most favourable to thrombosis in veins generally. This is not the

place to discuss the general pathology of thrombosis, but it may be pointed out that we have, in these conditions, all the known factors which favour this process. First, there is feebleness in the propelling power of the heart, which is most felt in the cerebral sinuses, and most of all in the superior longitudinal sinus, which is, *par excellence*, the seat of this form of thrombosis. Secondly, there is probably a greater tendency to coagulation of the blood in such conditions (*e.g.*, anæmia, puerperal state), and, thirdly, the nutrition of the vessel wall may share in the lowered vitality, and thus favour coagulation of the blood in contact with it. The essential feature of these cases is the condition of exhaustion or depressed vitality, and hence the term *marantic* applied to this form of thrombosis.

(2) The other form is that which is due to *inflammation* of the vessel wall, and with this may be allied those cases where the thrombosis, originally of phlebotic origin, spreads by continuity into the tributaries of the inflamed vein. Examples of this form abound in the case of the cerebral sinuses. Perhaps the most frequent is thrombosis of the lateral sinus by direct inflammation of the sinus secondary to disease of the temporal bone, and associated with pachymeningitis at the same spot, but often the thrombosis in this sinus is set up by continuity from its tributaries, the venules from the bone itself, or from the petrosal sinuses. Indeed, we may have the sinus blocked by extension of the clotting from the longitudinal sinuses on the one hand, or the cavernous on the other. These latter sinuses may be thrombosed secondarily to phlebitis in connection with the facial, nasal or pterygoid veins, as well as the orbital and ophthalmic veins. Hence it is that cavernous thrombosis may arise as a sequel of erysipelas of the face, or facial carbuncle, alveolar abscess, maxillary periostitis (it has followed extraction of a tooth), injuries or diseases involving the jaws, nose or face, and orbits. Occasionally cavernous thrombosis may arise apparently spontaneously, or may be due to pressure from tumours or aneurysms, which are more often to be found in its vicinity than in that of the other sinuses.

Morbid Anatomy.—From the foregoing it will be seen that the sinuses most likely to be the seat of thrombosis are the superior longitudinal, lateral, and cavernous, and that the first is more liable to marantic, the others to phlebotic

thrombosis. The post-mortem appearances differ somewhat in the two varieties. In *marantic* thrombosis the sinus is filled by a clot, pale, firm, laminated, and but slightly adherent to the wall, unless it have been formed for some time, when it may be undergoing organization. To this clot may be attached more or less coagulum, obviously of more recent date. If, on the other hand, the greater part, or the whole of the sinus has been recently occluded, then the thrombus has a less pale appearance and is less firm. The tributary veins are also distended, and appear as solid cords, from being filled with clot. As before said, the process may extend from one sinus to another, although mostly limited to the superior longitudinal, or to only a portion of this. Owing, however, to the sinus receiving blood from the brain, the portions of this organ, whence the blood stream is thus arrested, undergo red softening. The cortex and centrum ovale will be studded with minute hæmorrhages, and in places there may be considerable sub-arachnoid hæmorrhage. If the straight sinus be blocked, then the softening will involve the basal ganglia, and the ventricles be filled with blood-stained fluid. An excellent illustration of the effects of the thrombosis of the superior longitudinal sinus is to be found in Bright's Medical Reports. The appearances of *phlebitic* thrombosis vary according to the nature of the primary source of inflammation. In the most frequent example—that of inflammation of the lateral sinus secondary to disease of the ear—the conditions are such as to give rise to a septic inflammation. Accordingly, in such cases, the sinus is found to be occupied by a pultaceous, semi-purulent, or ichorous mass, sometimes of greenish-black appearance. This can in great part be washed away by a stream of water, leaving the thick-walled sinus lined by a ragged layer of disorganized clot, except at the extremities, where the channel is occupied by a parti-coloured thrombus. The softened thrombus may extend far down the jugular vein, or, on the other hand, be limited to only a small part of the sinus; it is invariably accompanied by a purulent or adhesive pachymeningitis in its vicinity, or with more wide-spread dura-arachnitis. No situation could well be more favourable for pyæmic infection, and therefore it is common in these cases to meet with pulmonary abscesses, which obviously own this origin, the septic material being conveyed direct to the lung. Of

the other sinuses the most frequent to be the seat of this secondary form of thrombosis is the cavernous, owing to its free venous communications through the ophthalmic vein, as already mentioned. This sinus may indeed be involved by the extension through the petrosal from lateral, and often the thrombosis extends from one cavernous sinus to the other.

Symptoms.—Except in the case of the cavernous sinus, there are no constant or definite symptoms of this condition, and it must be confessed that in the majority of cases its occurrence, although suspected, can hardly be proved during life. This, however, it is justifiable to say, that whenever in a patient who is suffering from marked anæmia, wasting disease, exhaustion, or other state favouring thrombosis, brain symptoms supervene, commencing with headache, often of great and increasing intensity, followed, it may be, by delirium, convulsions, hemiplegia, or other paralyzes, and passing into coma, sinus-thrombosis may reasonably be expected. The headache may occur for days before any other signs arise, and optic neuritis is not usually present. These remarks apply chiefly to the ordinary form of marantic thrombosis—that, namely, in which the *longitudinal* sinus is primarily concerned. The paralytic and other objective phenomena are in this case due to the extension of the process to the cerebral veins, and the resulting hæmorrhage. It depends upon the seat of the latter whether or not there are any convulsive or paralytic symptoms, and that again is determined by the situation and extent of the thrombus. But as regards the *lateral* sinus, it may be said with truth that there are no symptoms directly referable to its occlusion. It is the collateral circumstances that suggest its occurrence. Great and undue distension of the jugular vein on the affected side, and in rare cases actual evidence of the plugging of this vein, with enlargement of its collaterals, would point to involvement of the lateral sinus—*e.g.*, in a case of chronic ear disease. Rigors and other indications of pyæmia may also occur. It is different with thrombosis of the *cavernous* sinus, for owing to its intimate relation to the orbital circulation and the fact that its wall is traversed by certain cranial nerves, its occlusion is generally marked by very definite signs. Amongst these the most constant is proptosis, which may be very slight or produce marked exophthalmos, its occurrence being due, for the most

part, to venous congestion and œdema of the orbital tissues. It may be quite transient, for collateral circulation may become established. When the proptosis is very slight, it may be solely attributable to the paralytic condition of the ocular muscles. Œdema of the eyelids, chemosis, and facial œdema, are associated with thrombosis of the sinus when (as often happens) there is also ophthalmic and facial phlebitis. An enlargement of the frontal veins is sometimes apparent, from the diversion of the blood stream through the orbito-facial anastomosis. Contrary to general belief, retinal congestion and swelling of the disc are not distinctive signs of occlusion of this sinus, and, when present, indicate the involvement of the ophthalmic and retinal veins in the thrombotic process. Next to proptosis are the signs of involvement of the nerves which run in the walls of the sinus. Severe frontal headache or supra-orbital neuralgia, indicating disturbance of the first division of the fifth nerve, may be one of the earliest symptoms. The third, fourth and sixth nerves may all be affected, producing complete ophthalmoplegia externa, or only one, most commonly the third, may be paralysed. At first there may be myosis, but commonly mydriasis, ptosis and external strabismus occur. No doubt there must be phlebitis, as well as mere thrombosis, to produce total ophthalmoplegia, and if first one eye and then the other be thus affected, the inference of cavernous thrombosis is made almost certain, since such a sequence indicates the extension of the process from one side to the other. Of thrombosis of the remaining sinuses there are no distinctive signs.

Diagnosis.—It is thus apparent that, except in the case of the cavernous sinus, the diagnosis of sinus thrombosis is little more than conjectural. It must mainly depend, not upon direct signs, but on the existence of antecedent conditions favourable to thrombosis, conditions, that is, of debility and exhaustion, of impoverished blood and cardiac enfeeblement, in the marantic form; conditions of inflammation in the vicinity of the sinuses or their tributary veins, in the phlebitic. The differential diagnosis will have to be made from meningitis, tumour, hæmorrhage, or cerebral abscess, and as each of these lesions may coincide, either as antecedents, concomitants or results of sinus thrombosis, it is often impossible to determine the presence of the latter to the exclusion of the former.

The duration of the symptoms is no safe criterion, since the thrombosis may be very gradual and slow in producing complete occlusion. In a case of ear disease, undue fulness, and perhaps actual thrombosis of the jugular vein, will suggest that thrombosis of the lateral sinus is concerned in the production of any cerebral symptoms that may be present. In cases of marantic thrombosis of the longitudinal sinus, the only symptom may, as has been said, be severe persistent headache, until the occurrence of convulsions, paralysis, speedily followed by coma, point to the secondary production of meningeal hæmorrhage and red-softening.

Prognosis.—Although the majority of cases are fatal within one or two weeks of the appearance of cerebral symptoms, yet, in a few cases, there has been evidence of a slight amount of thrombosis being recovered from. This is more likely to be the case in the marantic than in the phlebitic form. In any case it is a rare event. Again, some cases of cavernous thrombosis, though ultimately fatal, have been of long duration.

Treatment.—There is little to be said on this head. The enforcement of absolute rest is imperative, and the symptom of pain needs to be dealt with. Ammonia and bark should be given in the marantic cases; bromides and even morphine may be required for the severe neuralgia and headache. If the symptoms be of long duration then iodide of potassium or sodium may be given, in the hope that the thrombus may be absorbed. The phlebitic cases are usually characterized by pyæmic symptoms, and therefore the treatment must be as for pyæmia. Prof. Horsley advocates the excision of the thrombosed lateral sinus in cases of ear disease as anticipatory of pyæmia, and has performed this operation in one case.

SIDNEY COUPLAND.

SIXTH NERVE, DISEASES OF.

—This nerve, which supplies the external rectus muscle of the eyeball, arises from its nucleus in the floor of the fourth ventricle, runs forwards in the substance of the pons and emerges near the middle line at the level of the junction of the pons with the medulla. Its nucleus is surrounded on three sides by the fibres of the facial nerve in their course from their nucleus to the surface of the medulla.

Paralysis is the most common affection of this nerve. The nucleus itself may

be involved in a tumour, especially of the substance of the pons. Outside the medulla and pons the nerve may be affected by syphilis, meningitis, tumours about the cavernous sinus, or in the orbit. One of the commonest causes is cold. The resulting paralysis is different according as the nerve or its nucleus is the seat of lesion.

In the case of the *nerve* there is internal strabismus of the eye of the same side, and the eyeball cannot be turned outwards. There is diplopia on looking towards the paralysed side, the false image being on the same side as the affected muscle, and the two images become more separated as the eyes are turned further out towards the affected side; in looking at an object above the horizontal line the false image is slanted so that its lower end is nearer to the true image than the upper, and with objects below the horizontal line the upper end is nearer to the true image than the lower. Secondary deviation is shown by the other eye moving outwards in fixing an object when the affected eye is covered up.

When the *nucleus* is affected there is, in addition to paralysis of the external rectus, inability of the internal rectus of the opposite eye to turn that eye inwards. As a consequence of this the axes of the eyes are kept parallel, and both are conjugately deviated to the opposite side, away from the side of lesion. The reason of this is that the nucleus of the sixth nerve sends fibres up in the pons to that part of the nucleus of the opposite third nerve which supplies the internal rectus; we thus have paralysis of the internal rectus without the nucleus of the third nerve being involved, owing to its receiving its nervous impulses for parallel movement from the sixth nucleus of the opposite side. As the sixth nucleus is in such close proximity to the facial nerve in the substance of the pons, it is frequently found that the whole of the face on the same side is paralysed, and gives the electrical reaction of degeneration, so that with a lesion of the *left* sixth nucleus there is conjugate deviation of both eyes to the *right*—i.e., paralysis of the left external and the right internal rectus, and sometimes complete paralysis of the *left* side of the face.

Diagnosis.—Paralysis from lesion of the nerve is usually diagnosed without much difficulty, especially if the secondary deviation of the sound eye and diplopia be noted. Lesions of the nucleus

are well shown by the above symptoms. Affections of the nerve just outside the medulla may also be associated with complete facial paralysis of the same side, but there would be no conjugate deviation of both eyes.

Tumours about the cavernous sinus or in the orbits would probably cause paralysis of the third nerve and optic atrophy of the same side.

Prognosis.—When the lesion is produced by tumours in the pons or at the base of the brain the prognosis is hopeless, but when in the orbit the growth can sometimes be reached. When due to cold or syphilis recovery usually occurs, especially in the former case.

Treatment.—When caused by cold, hot fomentations to the head, followed in the chronic condition by blisters to the temporal region of the affected side, and tonics internally are indicated. In cases where tumour is diagnosed, mercury and iodide of potassium in full doses should be given on the chance of its being syphilitic. In cases of paralysis due to cold, a very weak constant current of two or three cells, or more if the patient can bear it, may be applied to the closed eyelids.

C. E. BEEVOR.

SLEEP, DISORDERS OF.—It is necessary for the maintenance of health that sleep of a certain quality and quantity be regularly enjoyed. The exact amount required varies in different individuals and at various periods of life. Some people are naturally light sleepers and easily disturbed. It is evident that, *cæteris paribus*, such persons need more sleep than those whose slumber is profound, and in whom therefore the degree of rest is the more complete. The amount of sleep demanded varies very considerably, and probably largely depends upon the recuperative power of the individual and the extent of exhaustion, mental or physical, which the day's work entails. Sleep is generally more profound during the developmental period of life, and at that time the amount necessary is considerably in excess of what is subsequently required. Thus, a healthy new-born infant will sleep for twenty hours in the day, whilst during the prime of life some persons can maintain a condition of health upon five hours' sleep only, and others can occasionally go without sleep for thirty or forty hours with no apparent discomfort.

It is almost as requisite for the procuring of normal sleep that the body be

in a condition of health, as that sleep is necessary for the preservation of health. Disorders of sleep are therefore extremely common, and depend upon a multiplicity of causes. They also vary much in their nature, but may be roughly arranged, for purposes of classification, into three groups; in the first of which sleep is excessive, in the second defective in quantity, and in the third partial in character.

(1) **Excessive Sleep.**—An unusual amount of sleep may be a normal occurrence after prolonged labour, either physical or mental. It is also not uncommon at sea, but is most marked in cases of sea-sickness. Sleep, bordering on stupor, sometimes persists for days and even weeks after typhoid fever, and the same condition is frequently present in the course of many cerebral disorders.

Cases are occasionally met with in which there is a tendency to fall into a profound sleep, lasting, as a rule, a few minutes only, but sometimes persisting for an hour. Such attacks frequently occur in those affected by dreams, and may or may not accompany them. It is generally possible to awaken the patient, and, indeed, in most of its characters the sleep appears to be purely physiological. As such it must be carefully distinguished from a dreamy state, which sometimes occurs as a warning in cases of *petit mal*.

The condition called *trance* consists of a profound sleep lasting for hours or weeks. The subjects of it are usually liable to functional nerve disorders, and often come of a neurotic strain. In severe cases the organic functions of the body may be so lowered in their intensity that death is closely simulated, whilst in slighter attacks the patient may be perfectly sensible of his surroundings, though apparently quite unconscious. All grades exist between these two extremes. In some cases the condition seems closely allied to that which is induced by hypnotic suggestion.

The *sleeping sickness* is a disease which exclusively attacks the negro inhabitants of the West Coast of Africa. Its chief symptom is a gradually increasing somnolence, which ultimately ends in a profound sleep, from which the patient cannot be aroused. Emaciation occurs, and the termination is nearly always fatal in from three to six or twelve months from the commencement. The affection has been supposed to be in some way related to an enlargement of the cervical glands,

which sometimes takes place at the onset, but this is extremely doubtful.

(2) **Sleep Deficient in Quantity.**—An insufficient quantity of sleep may be obtained on account of restlessness, a condition arising from a great variety of causes, which need not be here detailed. It is essential for the treatment, however, that its causal relationships be recognized and appropriately remedied.

Much more important than restlessness, because more persisting and difficult to relieve, is inability to go to sleep—*insomnia*. This occurs in its most aggravated type in cases of delirium tremens, syphilitic insanity, acute and acute delirious mania, in which no sleep may be obtained for several days. Much more commonly the complaint is that it is impossible to get off to sleep for one or more hours after going to bed. In other cases again, a few hours normal sleep is succeeded by a prolonged state of wakefulness in the early morning. Insomnia is very often of purely functional origin, occurring in the nervous and impressionable, and depending upon mental overwork, worry, anxiety, &c. It is also frequently the result of various organic disorders, and may occur in the course of phthisis, pneumonia, Bright's disease, gastric or intestinal irritation, heart disease, senility and febrile conditions. Pain, too, is a common cause of sleeplessness.

Treatment.—As many conditions of ill-health contribute to the causation of insomnia, it is necessary that a very careful inquiry be made into the general state of health and habits of the patient. Some of the most difficult cases to cure are those which arise from worry, &c., because it is often found impossible to get rid altogether of the exciting cause. These patients should be recommended to indulge, when possible, in such exercise during the day as to create a feeling of moderate fatigue, and to read some light and interesting literature before retiring to bed. Among other homely devices, which sometimes succeed, may be mentioned bathing the feet in warm water and the taking of a cup of warm gruel, beef-tea, or dilute alcohol before going to bed. These means are not often successful of themselves, and then arises the question of hypnotics, in the administration of which great care and discretion are always necessary. Of these opium and chloral hydrate must still be regarded as the most reliable, but, until other measures have failed, should not be prescribed in cases of simple sleepless-

ness, for fear of developing the opium or chloral habit. Bromide of potassium, butyl chloral and cannabis indica, singly or combined, are frequently useful in the insomnia associated with neuralgia and headache. Paraldehyde is a safe and efficient hypnotic, but its nauseous taste is a great drawback to its general use. Sulphonal is a favourite remedy, but its insolubility, on account of which some hours may elapse before the desired effect is produced, is an objection in some cases. Both amylene hydrate (soluble in 1:8 of water) and chloralamide (soluble in about 1:3 of rectified spirits) promise to be of considerable value. Urethane is very unreliable, and the other recently introduced hypnotics, acetal, methylal, hypnone and chloral-urethane need only be mentioned. Sleeplessness resulting from pain or associated with heart disease is best treated with opium, which in lung disease is contra-indicated. In delirious states chloral hydrate, bromide of potassium, or hyoscine should be administered. In the treatment of the insomnia of various forms of insanity, paraldehyde, sulphonal, and amylene hydrate are at present the most popular remedies.

(3) **Sleep Partial in Character.**—During normal sleep the whole of the higher functions of the brain are in abeyance, and there is a persistence only of "vital" actions. It often happens, however, that some of the higher centres retain their activity although the functions of the highest are suspended—a condition, which may be termed "partial sleep." In this manner two great classes are formed, in the first of which there is a defect of consciousness and a correlative wildness of ideation—sleep with dreaming. In the second there is loss of consciousness and correlative elaborate motional actions—sleep with somnambulism.

In the course of *dreams* the most incongruous ideas are generally associated together into an ataxic whole, but in some people the flow of thought is to a certain extent sequential and orderly. Dreams are occasionally so vivid that they leave a lasting impression on the individual; at other times the images recalled during sleep are so faint that they pass unremembered. Children are peculiarly liable to dreams of a terrifying nature, possibly constructed upon the idle tales of servants and others. They awake screaming loudly, and such is the impression made upon them, that it takes a long time to make them disbelieve in

the actuality of all they have seen and heard. These children have generally a neuropathic hereditary or personal history. Happily, bromide of potassium in moderate doses is able to hold these so-called "night terrors" in check.

Somnambulist states are closely allied on the one hand to those unconscious and elaborate actions, which characterize post-epileptic automatism, and on the other, to one of the forms of unconsciousness produced by hypnotic suggestion. The somnambulist may retain his faculties of sight and equilibration to a really remarkable extent, but yet be altogether unconscious of his surroundings. And more, he may be able to exercise his intellectual faculties to an equal, and in some cases it is asserted even to a greater, degree than obtains during the state of wakefulness. Somnambulism must undoubtedly be regarded as one of the minor neuroses, and the subjects of it be looked upon as possessing a vulnerable nervous system, which may possibly break down in one way or another under any unwonted strain.

Treatment should be directed towards improving the general condition of the patient by placing him under favourable conditions of existence and by the administration of bromide of potassium at night.

SMALL-POX (Variola).—An acute infectious disease, characterized by a certain range of temperature and the development of a papular eruption, which becomes vesicular and ultimately papular.

Symptoms.—After an incubation period of from eight to fourteen days, during which, as a rule, there are no symptoms of ill-health, the disease commences suddenly with chills or actual rigors and high fever, with thirst, anorexia, a furred tongue, a full pulse, and nausea. Vomiting is an early, and common symptom, and usually there is constipation. Sweating is generally present from the first, and is often of diagnostic value. The temperature rises to a considerable height, 104° F. or 105° F. at the very outset; during the second and third day there are remissions, but it attains its maximum on the evening of the third day. Before the development of the characteristic eruption, however, certain *scarlatiniform eruptions* not infrequently appear, usually in the form of a more or less bright diffuse erythema in the lower part of the abdomen and legs, and also about the chest and trunk,

especially the axillæ and groins, and also at the bends of the elbows and in the popliteal spaces. A dusky erythema generally precedes a severe attack. About this time the papular eruption appears, and the severity of the disease will be directly proportional to the intensity and character of the eruption; the late appearance of the papules presages a mild attack; their premature appearance, on the other hand, is an evidence that the attack will be severe. The papules appear first on the face, scalp and neck, then on the chest and back, and subsequently on the extremities, about two days later than the face. They are at first solid, indurated and shotty, but gradually they become conical and may be surrounded by a red areola. The vesicular stage follows and umbilication takes place—*i.e.*, they have a central depression. The contents at this period become cloudy. At first the papules are separate and scattered (discrete); afterwards, when the eruption is more extensive and the vesicles are more closely aggregated, and when they run together, it is said to be confluent. Papules, or pocks as they are termed, may also appear on the mucous membrane of the mouth, throat and nose, and on the conjunctiva about the same time as on the skin.

The fever, constitutional disturbance and pains in the back remit when the rash comes out, and gradually disappear, so that at the end of the first stage—*i.e.*, about the eighth day, the patient may feel quite well. As a rule, the sweating is the only symptom which persists. About the ninth day the next stage—*i.e.*, the period of maturation, sets in, the pocks become larger and hemispherical in shape, and lose their umbilication, the surrounding skin becomes uniformly red or brawny and is swollen and painful; some of the pustules burst, their contents flow over the neighbouring skin and form large yellowish scabs, which, on the face, are very disfiguring. Salivation, a hoarse cough, nasal discharge and ophthalmia are all apt to be present, and sometimes there is purulent infiltration of the cornea. The fever now returns and is proportional in degree to the amount of suppuration. A disagreeable odour is often noticed about the patient.

In the confluent form all the above symptoms are much exaggerated, the face is covered with crusts, and the hands and feet are much swollen, whilst delirium or unconsciousness may be present. This

stage may last till the twentieth or twenty-second day. Confluent small-pox is particularly dangerous, death resulting from adynamia, gangrene or one of the complications about to be mentioned. In the less severe cases, about the eleventh or twelfth day, those pocks which have not ruptured begin to dry up, become brown in the centre, dry, sink in, and eventually form a round scab; the surrounding redness and swelling then subside, and the scabs come away in a few days, leaving violet-red elevations, which may, with time, completely disappear. In many of the pocks, however, the process will have gone deeper and will have involved the cutis vera; when such pocks fall off they leave a deep round scar with a punctated base, which at first is red, but ultimately becomes white and never disappears. In the confluent form the scars are larger and deeper, and the disfigurement is consequently much greater.

The most malignant form is the hæmorrhagic, here ecchymoses, petechiæ and vibices come out during the initial erythema, with hæmorrhages into the various mucous membranes and hæmaturia.

Sometimes death takes place before the typical eruption has had time to be developed, or before its characters can be recognized.

Modified Small-Pox (Varioloid).—Those who have been vaccinated, if they take the disease, usually have it in a modified form, “varioloid” as it is called. The initial fever is less, the pocks are less numerous and run their stages more rapidly; there is less surrounding redness, and the eruption hardly ever becomes confluent. There is no secondary fever, and as a rule the pocks fall off without leaving permanent scars; it is rarely fatal.

Complications.—Amongst the complications nephritis is one of the most common, especially in the confluent form; œdema of the larynx and purulent pneumonia also occur; both are very dangerous to life. During convalescence there is often a marked tendency to the development of boils. The initial pain in the back may be very severe, and is occasionally accompanied or followed by paraplegia.

Diagnosis.—In the early stages the chief points are the pain in the back and the sweating, signs which should always be regarded with suspicion in a pyrexial attack of unexplained origin. When the scarlatiniform rash is present the disease may be distinguished from that fever

by the absence of the throat symptoms and of the characteristic appearance of the tongue, and by the absence of a fall of the temperature after the appearance of the rash. The eruption of measles has some features in common with small-pox, but the spots are more minute; they are aggregated into clusters, they come out more rapidly over the whole body, and they are preceded and accompanied by catarrhal symptoms. The hæmorrhagic form sometimes presents difficulties in diagnosis which are almost insuperable; pain in the back is the symptom upon which the greatest stress should be laid in such cases.

Pathology.—The changes which take place in the skin leading to the formation of the papules are as follows: At first there is hyperæmia of the papillary layer of the corium, with thickening of the rete; the papillæ increase in size, forming the solid papules; between the meshes of the reticulum serous fluid is exuded, forming the vesicle. The umbilication is due to the lesion occurring at the origin of a hair follicle or duct of one of the sudoriparous glands. The epithelial septa gradually give way, and cause the pock to become hemispherical and to lose its umbilication, and its contents to become cloudy.

Ætiology.—The disease is both infectious and contagious, but the materies morbi has not as yet been isolated. It may be conveyed by the breath before the eruption has appeared, or by inoculation of the contents of the pock. No age is exempt, and during an epidemic all who are unprotected by a previous attack or by vaccination, as a rule take it; second attacks, though decidedly rare, are not unknown.

Treatment.—Vaccination or re-vaccination, if performed at any time before the symptoms have actually appeared, would probably be in time to modify the course of the disease. Careful dieting and nursing are all important; but during convalescence the diet should be especially nutritious. When once the disease has developed it will run its course without being materially influenced by treatment. Stimulants should be given or withheld on general principles. Various measures have been proposed to prevent the pitting, none of them are completely satisfactory; covering the face with a mercuric plaister, or puncturing each pock separately and inserting a little nitrate of silver, are methods recommended by persons of great experience. To allay the irritation, which, from the

swollen condition of the skin is always very great, cold compresses or a solution of corrosive sublimate may be used, or the face may be anointed with carbolised vaseline. JOHN ABERCROMBIE.

SNEEZING, PAROXYSMAL. —

A symptom most commonly met with in the subjects of asthma and hay fever. The attack may be excited by any direct irritant, a bright light, cold, dust, the pollen of certain grasses, or the presence of certain articles of food in the stomach. Gout and hysteria have also been assigned as causes. The attack is usually accompanied by intense itching of the interior of the nose, and sometimes of the conjunctivæ and throat also.

The most effective treatment is the insertion high up the nose of a tabloid of cocaine, or the interior of the nose may be painted with a 5 per cent. solution of cocaine. The inhalation of iodised vapour (tr. iodi π xx-xxx to a pint of boiling water) has also been found useful. Some cases are relieved by sniffing strong "smelling salts." (See also HAY FEVER.)

SORDES are the crusts which form about the lips and teeth in the course of a serious illness, which is most often of a febrile character. They are composed of debris of food and epithelium, schizomycetes and micrococci being present in great numbers. Sordes may be yellow, brown or black in colour, and vary in thickness according to the degree of prostration, and the length of time they have been allowed to collect. They only form on those parts of the lips, teeth and gums that are habitually exposed to the air. They are rather firmly adherent, and should be removed by careful sponging.

SOMNAMBULISM (Sleep-walking). An unconscious state of automatic movement, sensation and intellectual activity of various extent, and sometimes anomalous character, which is almost always continuous with normal sleep, occurring in it rarely and as an interlude.

In the simpler instances of such an affection, there may be no definite symptoms of bad health; the sleep-walker may for an hour or so during normal sleep get up and dress himself without losing his unconsciousness, and employ himself on something he has set his mind upon, or on his daily occupation. For example, a housemaid may begin

to dust the furniture; a chemist to make up the prescriptions, and having done so, may return to bed again and to natural slumber, waking subsequently without any recollection of anything that has happened, and without any power of recalling it, even when any evidence of the work done causes surprise and calls attention. Such conditions, though not very rare, have not as yet been sufficiently widely and accurately observed to make us thoroughly familiar with all their physical details and psychological characteristics. They are not common in childhood and youth, not markedly more common in girls than boys. They generally go along with a neurotic temperament or tendency to such general disturbance of nervous equilibrium as epilepsy, hysteria, chorea or megrim; but there are some cases which seem to accompany excellent health, and others only a passing emotional excitement, such as chagrin, anger, or surprise. To a slight extent the diathesis is hereditary; there are also some instances of the habit spreading from one person to another by the hysterical tendency to imitation (neuromimesis). It is very rare in idiots, and not more frequent in the insane than in the sane. In a case well observed by Mesnet, it came on about six months after a severe bullet wound in the left parietal bone, and the resultant state resembled very closely what Charcot has called the somnambulist stage of hypnotism. The man passed into a state in which he would write and talk reasonably, with open eyes and full apparent command of his senses, but without consciousness at the time or subsequent memory. There is hyperesthesia of touch and hearing in a few cases, and nyctalopia, and in a great majority good muscular sense; but frequently hearing and sensation are nearly or quite gone, and now and then there is loss of balance.

The term somnambulism has been used of late years, especially in France, to cover a wider range of mental abnormalities, among which are a state of profound lethargy which may simulate death (*cf.* TRANCE), and a condition of quiet secondary personality, which has in a few rare cases for long replaced the normal character. The memory in consecutive somnambulist attacks is generally continuous from one to the other, and entirely separate from that of the ordinary life, and it is remarkable that it has been revived by artificial hypnotism. M. Dufay observed a case

in which a lady's maid in a somnambulist state put away her mistress's jewels for safety, was accused of stealing them, could recollect nothing, and was unable to disprove the charge, and kept in prison until memory of the somnambulist act was revived by hypnotism; it was explained satisfactorily, and she was set free.

Of the *pathology* of this condition nothing is definitely known; the symptoms suggest a close analogy to the sometimes active state of post-epileptic automatism.

Treatment.—It is judicious to forbid and even punish the attack, although there is honestly no recollection of its occurrence, for as a rule the organic memory takes effect.

A. T. MYERS.

SPASM.—An abnormal contraction of striped or unstriped muscle fibre. The term *cramp* is generally used to designate spasm accompanied by pain.

1. *Spasm of involuntary muscle* is of common occurrence, as unstriped muscular tissue is present in the coats of most hollow organs. Excessive stimulation in any of these induces an increase of afferent impulses and a corresponding degree of muscular contraction, which persists as long as the irritation is continued. In this way reflex spasm arises—*i.e.*, a muscular contraction, abnormal in degree and duration, and depending for its production upon the presence of some local irritation. It would be needless to enumerate all the examples of this action, but as illustrations may be mentioned renal and biliary colic, œsophagismus, rectal and vesical tenesmus. The vaso-motor system is brought into connection with certain psychical states, and it happens, therefore, that although spasm of the arteries may result from reflex action, it may also occur as an expression of emotion—*e.g.*, fear and rage. Bronchial spasm is in some cases undoubtedly due to peripheral irritation, and in others it is as clearly of central origin.

2. *Spasm of voluntary or striped muscle* manifests itself in various ways. The contractions may be continuous and *tonic* in character, or they may be subject to regular relaxations, and are then termed *clonic*. In some cases more or less extensive movements are produced, which may be rhythmical or disorderly, in others tremor only results. Tonic spasm may occur as a functional affection, from organic cerebral, or spinal disease, and

probably also from direct irritation of the nerve trunks in cases of spinal meningitis. For a consideration of the contractures which occur from these causes, the article on RIGIDITY may be consulted.

In regard to the origin of the spasm in cerebral disease many opinions are held. Hitzig believes that the late rigidity of hemiplegia represents the sum of the associated movements, which are no doubt often increased in that condition, and seem in some cases to increase the spasm. The persistence of the rigidity during complete rest, as in sleep, tells strongly against this view. Others look for the cause in the removal of cerebral influence, but this does not sufficiently explain the occurrence of spasm some weeks after the onset of the lesion, unless indeed it be allowed that the action of the anterior cells of the cord gathers in intensity and undergoes a sort of dynamical hypertrophy, after the restraining influence of the brain is taken away. Hughlings Jackson regards the cerebellum as possessing motor functions, supplementing those of the cerebrum, and being in a way antagonistic to them. He considers late rigidity to be due to an unantagonized cerebellar influence. Charcot and others consider that the initial increase of reflexes, which occurs a week or two after a hemiplegic seizure, is possibly due to moderating cerebral influence, but that the rigid spasm of contracture is caused by a sclerosis of the lateral columns of the cord, irritating, and producing an over-action of, the anterior motor cells.

Clonic spasms are typically seen in an epileptic fit, after the stage of rigidity is over. They probably depend upon exhaustion of, the discharging cortical motor centres, which are no longer able to keep up a tonic contraction. Irregular or mobile spasm sometimes occurs in cases of hemiplegia, in which some power is regained, but it may also exist as a primary affection. The movements may be constant and may even persist during sleep, but they are usually most marked during voluntary effort. They are much more frequent in the arm than the leg, and are often associated with hemianæsthesia. Little is known with regard to the nature of these spasms. They are more common in children, and after embolism rather than hæmorrhage. In adults the lesion is always in the optic thalamus or its neighbourhood, and very often in the posterior part of the internal capsule. Similar choreiform spasm has been

noticed in cases of tumour near the optic thalamus and of growths involving the parietal lobe. The characteristic spasm upon voluntary movement in cases of disseminated sclerosis is probably due to irregular wasting of the white substance of Schwann, on account of which an impulse meets with unequal resistance in different parts of its course, and a disorderly movement results. The same symptom is rarely met with after hemiplegia, and in some cases of tumour of the pons or crus.

Spasm in Spinal Disease (Pathology of).

—Spasm is a frequent result of those lesions of the cord in which the lateral columns are affected—*e.g.*, spastic spinal paralysis, disseminated sclerosis, myelitis, &c. It has not yet been definitely settled whether the rigidity in these cases is due to loss of cerebral control, to irritation of the anterior motor cells, or to the combined influence of the two.

WM. GAY.

SPHYGMOGRAPH.—The sphygmograph is an instrument by which what is known as the pulse of an artery may be graphically recorded. It consists essentially of a lever, the short arm of which presses on the artery, while the long arm magnifies the movements transmitted to the short arm, and records them upon a moving surface. A simple sphygmograph may be made by crossing one leg in the flexed position over the opposite knee. The popliteal artery of the crossed leg is then pressed between the two knees and its movements are transmitted to the leg of the same side, being amplified by the length of the leg. If then by some means the foot of the superimposed leg be made to write on a revolving cylinder, the pulse will be recorded graphically.

For practical purposes three varieties of instrument are employed:—Marey's original sphygmograph, its modification by Mahomed, and the simpler instrument of Pond and Dudgeon. The latter two are provided with an arrangement by which graduated pressure can be applied to the artery, and by means of a dial the pressure can be read off in ounces. This, however, is a source of fallacy, for so much depends upon the way in which the instrument is applied, its mode of contact with the artery, and the substance against which the vessel is pressed, that little reliance can be placed on comparative measurements of the pressure exerted at different times. Nevertheless, when the instrument is properly applied,

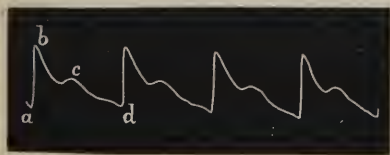

by an experienced observer, and the artery duly pressed against a bone in a direction at right angles to its length, the indications of the dial afford some idea of the relative pressure under which different tracings are taken. It must not be supposed, however, that what are termed, on the dial, "ounces," represent, in fact, ounces of pressure. They represent simply degrees of pressure, and the degrees are not by any means equal.

Of the three instruments mentioned, that of Pond and Dudgeon is the most convenient of application, but is also the most erroneous in its records. Of the other two, that will be preferred, to which an observer has accustomed himself, and, possibly for this reason only, the writer prefers Mahomed's modification of Marey's instrument.

A tracing being required of the radial pulse and the Mahomed sphygmograph being used, the hand is laid on a wooden rest in an easy position of supination, with the wrist somewhat extended. The site of the artery is then ascertained, and an ink mark made over the artery where it lies upon the styloid process of the radius. The instrument is then placed on the fore-arm, with the button immediately over the ink mark, and is secured to the rest by means of straps. Pressure is applied by the screw and excentric, with which the instrument is provided, until the recording needle shows the most ample movement, when the degrees of pressure (so-called "ounces") are noted. The needle being then brought into contact with a blackened plate which travels by clockwork, a tracing results which records the movements of the artery.

Normal Pulse.—Fig. 1 represents the tracing obtained from a normal

FIG. 1.

pulse. It consists of:—(1) An ascent more or less vertical (*a* to *b*), (2) a summit (*b*), and (3) a descent (*b* to *d*) which is broken by a second elevation (*c*) the dicrotic wave. The horizontal line from which the up-stroke starts is called the base line. The height of the ascent represents the degree of change of shape of the artery, which, as stated previously,

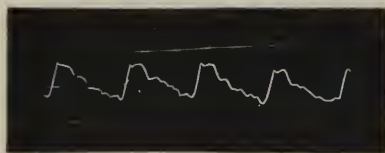

is really what we feel as the normal pulse. Thus the height of the ascent is a measure of the "size" of the pulse. The sudden or gradual manner in which the pulse impresses itself upon the finger is represented in the tracing by the vertical or sloping direction of the ascent. The summit is often broken by a small wave, which is usually known as the "percussion wave." Its origin has been somewhat questioned; probably it is not related to any change in the artery, but is due simply to the needle being jerked by the artery to a greater height than is warranted by the change in the shape of the artery. The needle therefore soon descends slightly to the level corresponding with the true movement of the button in contact with the artery. The total summit is known as the tidal wave, its horizontal extent from the beginning of the summit to the beginning of the descent, represents the "length" of the pulse, and is a measure of the length of contraction of the left ventricle, or at least of the time during which the contraction of the ventricle increases the tension in the arteries. The portion of the tracing which extends from the end of the tidal wave to the base line is the descent. Its sudden or gradual progression to the base indicates the manner in which the increase of tension, due to the ventricular systole, is lost in the arteries. The notch in the descent, formed by the dicrotic wave, is known as the dicrotic notch. Its height above the base line indicates inversely the time which elapses after the systole of the ventricle is completed before the elastic recoil of the arteries increases the tension in the radial artery. It is one measure, therefore, of the degree of arterial tension and in time it corresponds with the closure of the aortic valves. The height of the dicrotic wave is a similar measure of tension in the arteries, being the more marked when the tension is low. Generally speaking, the higher the dicrotic notch above the base-line the less marked is the dicrotic wave, and *vice versa*. The base line is often not perfectly horizontal, but shows a curve of its own, comprising in its extent four, five, or six tracings of individual pulse beats. This is the respiratory curve, and is due to the alterations of arterial pressure produced by respiration. It is not uncommon to meet with numerous small waves in addition to the dicrotic wave; these result from vibrations of the needle not communicated to it by the artery. They are to be avoided to a great extent by a proper

application of the instrument, but some are inherent in the sphygmograph; they are most numerous with the Pond-Dudgeon instrument, least numerous with that of Marey.

Irregular Pulse.—The various forms of irregular pulse which are described in the article on PULSE, will be indicated in the sphygmographic tracing, to the same degree in which they are detected by the finger. These do not need further mention here. In certain pathological states, however, the tracings are characteristic, and are a useful help to the mere digital examination.

High Arterial Tension.—The tracing of high arterial tension shows a somewhat slanting ascent of no great height, a square or rounded summit, a lengthened tidal wave, a gradual descent, a high dicrotic notch, and slightly marked dicrotic wave (Fig. 2). The explanation of

FIG. 2.

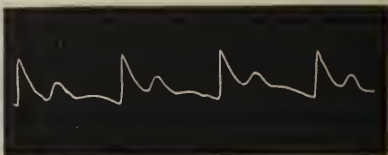

these peculiarities which appears most probable is the following:—The arteries are contracted, and therefore do not admit of a pulse of great "size," consequently the lever of the sphygmograph is not greatly raised, and the ascent is low. The ventricular contraction is somewhat slow in increasing the already high tension, and thus there is produced the gradual pulse and the sloping ascent of the tracing. The left ventricle must maintain a prolonged contraction to drive the blood onwards against the increased resistance, and thus the tidal wave is long and the summit rounded. The recoil of the arteries, when their tension is great, must occur very shortly after the ventricle has ceased acting, and, consequently, the dicrotic notch appears early in the descent of the needle and high above the base line. The tense arteries do not allow themselves to be greatly distended by the blood forced into them by the ventricles, and as a result of this their elastic recoil, which produces the dicrotic wave, is but slight.

Low Arterial Tension.—In low arterial tension we have an ascent which is extensive, and is perpendicular or even sloped backwards (Fig. 3). The ascent is either high or low, according as the left

ventricle is acting forcibly or feebly, either of which conditions may exist.

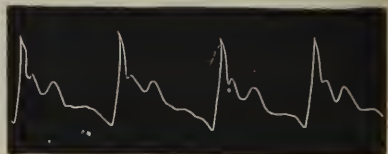

FIG. 3.

The summit is sharp, the tidal wave short, the descent sudden, the dicrotic notch low, and the dicrotic wave well marked. Here the relaxed arteries allow themselves to be suddenly and greatly expanded by the blood forced into them from the ventricle, and thus cause the extensive and perpendicular up-stroke; no prolonged contraction of the ventricle is necessary, hence the sharp summit and short tidal wave. The relaxed arteries lose the temporary tension imparted to them by the ventricular systole as easily as they gain it, and consequently the descent is abrupt, while their laxity favours an extensive but delayed recoil, and causes the well-marked dicrotism and low dicrotic notch.

Virtual Tension.—In "virtual" tension (*see* PULSE) we find a tracing showing a combination of the characters of high and low tension (Fig. 4). The up-

FIG. 4.

stroke is extensive and high, the summit sharp, the tidal wave short, the descent somewhat sudden, the dicrotic wave well marked; but the dicrotic notch is high above the base line. As already stated, this form of pulse indicates peripheral resistance with a failing left ventricle and dilated arteries.

Aortic Regurgitation.—In aortic regurgitation the tracing usually shows a high and perpendicular ascent, a sharp summit, short tidal wave, and an abrupt descent, in which there is scarcely any indication of a dicrotic wave (Fig. 5). The latter two features are characteristic. As has already been stated, the pulse in aortic regurgitation is quite a different phenomenon to the normal pulse. Here the

radial artery is really distended by blood with each ventricular systole, becoming

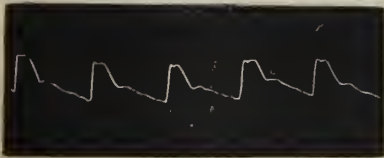

FIG. 5.

empty during each diastole. The tension is suddenly increased, to be just as suddenly decreased. This explains why the descent of the tracing is so abrupt. The recoil of the arteries after the ventricular systole can only influence the tension in the general arterial system when the aortic valves close perfectly, and offer a sufficient *point d'appui*. When the valves are incompetent, the recoil of the arteries will be greatly spent in forcing blood back into the left ventricle, and consequently no dicrotic wave will be seen.

Aortic Stenosis.—In aortic stenosis the systole of the left ventricle can only gradually influence the general arterial tension, and its force will be exerted for a considerable time (Fig. 6). As the result

FIG. 6.

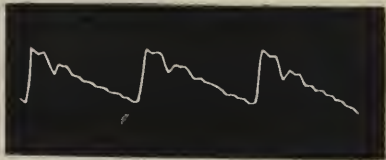

of this we find a tracing showing a gradual and low ascent, a rounded apex, and a long tidal wave. The descent is gradual, because the arteries "contract down upon the diminished blood-stream" (as Dr. Broadbent has put it), and as a consequence the increase of tension due to the ventricular systole is only gradually lost. There is no great distension of the aorta by the systole, hence but a small recoil, and therefore little or no dicrotic wave appears in the tracing. The tracing very much resembles that which is found in aneurysm, to be described later, but it is to be obtained usually with the application of a much lower pressure than suffices for the aneurysmal tracing. Such is the usual tracing of aortic stenosis, but occasionally another and quite different one is obtained. Here we find a trace with three separate summits, but

at different heights above the base line, the first being generally the highest. The first is probably a percussion wave, the second a tidal wave; the conditions of dicrotism are not present, consequently the third summit cannot be that of a dicrotic wave, but Dr. Broadbent explains it as an instance of *pulsus bisferiens*, due to a reinforcement of the ventricular systole near its close by a further muscular spasm.

Where aortic stenosis and regurgitation are combined, as is commonly the case, the characters of the tracings are to a certain extent also combined. It will mainly be noticed that the sudden ascent and descent characteristic of aortic regurgitation are lost.

Atheroma of the Arteries.—In atheroma of the arteries, affecting amongst others the arch of the aorta, a tracing is obtained which shows a well-marked, but not high percussion wave, a prolonged tidal wave, a low dicrotic notch, and an ill-marked dicrotic wave (Fig. 7). The

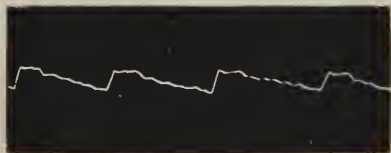

FIG. 7.

rigidity of the arteries, possibly, accounts for the appearance of the first. The necessarily hypertrophied condition and prolonged action of the left ventricle causes the prolonged tidal wave, while slight expansion and consequently small recoil of the arteries produce the condition of the dicrotic wave.

Aneurysm.—The typical aneurysmal pulse gives a tracing characterized by a low sloping ascent, rounded summit, prolonged tidal wave, and a gradual descent, in which the secondary waves are lost (Fig. 8). This tracing resembles that of

FIG. 8.

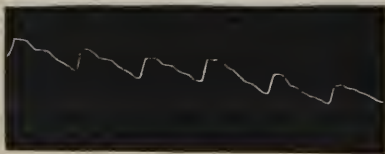

aortic stenosis, but is obtained in its best form with the application of a much higher pressure than is required for the

tracing in the latter disease. In its typical condition the characters of the tracing are due to the interposition of the elastic reservoir formed by the aneurysm, between the ventricle and the artery examined. The impact of the ventricle, as well as the shock of recoil of the arteries, is absorbed by the aneurysmal reservoir, to be distributed more gradually to the arteries. The form of the tracing is thus easily explained. But the aneurysm acting in this way maintains a constant supply of blood to the arteries, thus accounting for the great amount of pressure usually necessary to bring out the tracing. Yet the conditions of the circulation in aneurysm are not always those just described. The aneurysm may press on the artery examined, or on a trunk from which it springs; and again it may narrow the mouth of an artery which arises from the sac. In these conditions a similar tracing is obtained, but, the writer thinks, by the application of a lower pressure than when the typical aneurysmal conditions are present. In fact, the conditions, and therefore the tracing, resemble those of aortic stenosis.

It is in respect to the diagnosis of aneurysm that the sphygmograph is of most clinical value. Its indications are shown, when the unaided finger, no matter how highly educated, is sometimes at fault, whereas in other affections the findings of the finger are only recorded and supported by the tracing.

Mitral Stenosis.—Here the sphygmographic tracing resembles that of high arterial tension (Fig. 9). The ascent is

FIG. 9.

gradual and low, lower indeed than is ordinarily the case in simple high tension; the summit is rounded, the tidal wave moderately long, the descent gradual, the dicotitic wave slight, and the dicotitic notch fairly high above the base line. The conditions of the circulation are (1) that the left ventricle is imperfectly filled, and consequently its action produces only a slight rise of the sphygmographic lever; (2) the arteries contract down upon the diminished supply of blood, and so only gradually receive the

impact of the ventricle, causing the upstroke of the tracing to be sloping, and the summit rounded. The contracted state of the arteries also hinders their recoil, and tends to eliminate the dicotitic wave. It is to be specially remarked that the separate pulse tracings are uniform in character and equal in size.

Mitral Regurgitation.—The opposite is the case in this affection, for the tracings are pre-eminently irregular in size and character (Fig. 10). Their pre-

FIG. 10.

vailing type is that of low tension, a straight ascent, sharp summit, short tidal wave, sudden descent, moderate dicotitic wave, with low dicotitic notch. But the extreme irregularity in the action of the left ventricle, which is characteristic of the disease, causes all these appearances to vary greatly with the individual pulse beats.

ROBERT MAGUIRE.

SPINAL ACCESSORY NERVE

(the eleventh pair of cranial nerves).—This consists of two parts, the smaller or internal part (accessory), which joins the pneumogastric nerve, and a larger or external part (spinal), which is supplied to the sterno-mastoid and trapezius muscles. The accessory part arises from the continuation downwards in the medulla of the vagus nucleus, that part of it which lies behind the closed central canal of the cord and also just outside the point of the calamus scriptorius. The fibres from this part course through the medulla, taking the same direction as the vagus nerve above them, and they must be looked upon as a root of that nerve, which they finally join (*see PNEUMOGASTRIC NERVE*). The spinal part arises from the whole extent of the cervical portion of the spinal cord as far down as the fifth or sixth cervical roots, by a series of roots along the lateral column, from the intermedio-lateral tract and adjacent part of the anterior cornu below and the formatio reticularis and base of the posterior cornu above. The nerve ascends the spinal canal, passes through the foramen magnum, gives some branches to the accessory part, and

passes out of the skull by the foramen jugulare; it pierces the sterno-mastoid muscle, supplying it, and ends in the trapezius muscle, where it forms a plexus with branches from the cervical nerves. The nerve is liable to be affected at its nucleus as in acute bulbar paralysis, or in the more chronic form, but in these cases the accessory part is much more involved than the spinal, for whereas paralysis of the soft palate, pharynx and larynx are common symptoms of chronic bulbar disease (*see* PNEUMOGASTRIC NERVE), paralysis and wasting of the sterno-mastoid and trapezius are rare; in fact, the upper fibres of the latter are the last to be affected.

Both parts of the nerve are involved in meningitis, simple or syphilitic, tumours outside the medulla, and fractures or dislocation of the cervical vertebrae; in such cases there is paralysis of one half of the soft palate, one vocal cord and one sterno-mastoid and trapezius, all on the same side (Hughlings Jackson). The spinal part alone is apt to be implicated in its long course from the cord to the muscles, by growths or meningitis in the spinal canal, or by enlarged glands, tumours or abscess in the posterior triangle of the neck, or simply by cold. Here the sterno-mastoid and trapezius of the same side will be paralysed, but the latter not completely, as its middle and lower parts receive fibres from the cervical plexus.

The symptoms of paralysis of the accessory part are given with the description of the pneumogastric nerve. When the spinal part is paralysed the patient cannot rotate the head to the opposite side, and is not able to use the upper part of the trapezius in shrugging the shoulders, while complete fixation of the scapula cannot be affected, and muscles like the deltoid work at a disadvantage. The paralysed muscles waste and give the reaction of degeneration to electrical currents.

The *prognosis and treatment* depend very much on the cause; when the paralysis is due to cold the prognosis is favourable, but very unfavourable when caused by growths, unless they can be removed. In the early stage of the former condition a blister applied over the course of the nerve, and the use of the constant current to the muscles would be the suitable treatment.

Besides paralysis, the muscles supplied by the spinal accessory nerve are liable to be affected by spasm, giving rise to

what is known as torticollis or wry-neck (*q.v.*).
C. E. BEEVOR.

SPINAL CORD, ANÆMIA OF. —

Symptoms.—Little is positively known about the symptoms induced by diminished vascular supply to the spinal cord. In anæmia, simple and pernicious, weakness of the limbs is frequently present, and may be due in part to altered nutrition of the cord. It has been alleged that structural changes may develop from persistent anæmia, and the writer has seen one case, in which degeneration occurred in the white matter of the cord, in a patient suffering from pernicious anæmia. Paraplegia has been described as occurring after profuse hæmorrhage from the uterus, stomach and other parts; from obstruction of the spinal arteries, and from obstruction of the abdominal aorta by compression, thrombosis or embolism. Vaso-motor ischæmia of the cord from peripheral irritation has been invoked to explain various transient and subjective sensations in the extremities; but such an assumption is quite hypothetical.

Treatment.—General anæmia will require the usual remedies, of which iron and arsenic are the chief. When the symptoms depend on hæmorrhage, attention should be directed to the special organ at fault. At the same time the recumbent position, with the head and legs raised should be enforced. The use of the constant current to the vertebral column has been suggested, as well as the application of heat by means of sand bags or Chapman's spinal bags.

W. B. HADDEN.

SPINAL CORD, ANATOMY AND PHYSIOLOGY OF. —

The spinal cord extends from the foramen magnum to the level of the body of the second lumbar vertebra. The pia mater, which closely invests the surface sends a process into the anterior median fissure, is continuous with the fibrous strands penetrating the substance of the cord, and furnishes a covering to the nerve-roots. Superficial to the pia mater, and loosely united to it by fine strands of connective tissue, is the thin arachnoid membrane. The interval between the two is the sub-arachnoid space which is in direct continuity with the sub-arachnoid space of the brain, and through the foramen of Majendie with the ventricles. The ligamentum denticulatum passes on each side between the spinal arachnoid and pia mater, midway be-

tween the anterior and posterior roots, thus dividing the spinal sub-arachnoid space into an anterior and posterior part. The external membrane of the cord, or dura mater, is separated from the bony canal by venous plexures and loose areolar tissue.

The spinal cord presents two enlargements, the cervical, extending from the level of the third cervical vertebra to the second dorsal; the lumbar beginning at the tenth dorsal vertebra and reaching to the second lumbar. Between the second and tenth dorsal vertebra the cord is small and of uniform size. In the middle line of the cord in front is the anterior median fissure which reaches as far as the anterior commissure. The posterior median fissure, really composed of connective tissue, extends to the posterior commissure and separates one posterior column from another. On each side of the posterior median fissure is the rather ill-defined posterior intermediate septum, which marks off the postero-median column (column of Goll) from the postero-external column (column of Burdach or posterior root-zone). The white matter between the posterior cornu and the anterior median fissure is the antero-lateral column, which is sub-divided into the anterior and lateral columns, the point of limitation being the most external of the anterior nerve-roots. The white matter is composed of nerve-fibres of different sizes, surrounded by and embedded in the nerve-cement or neuroglia, in which are scattered small nucleated bodies called the cells of Deiters.

Tracts or Systems of the Cord.—It has been shown by means of pathological investigation, by experimental observations on animals, and by researches in embryology, that the white matter of each half of the cord, which to the naked eye is of uniform appearance, is made up of definite tracts or systems having distinctive functions. Moreover, it has been found that these tracts of fibres degenerate according to a law, first propounded by Waller; efferent fibres, such as those of the pyramidal tracts, when destroyed at any part in their course, undergo *descending* degeneration; afferent fibres, such as those of the columns of Goll, undergo *ascending* degeneration.

On a transverse section of the cord (as shown in the diagram) the various areas alluded to are exhibited.

The *crossed pyramidal tract* occupies the posterior part of the lateral column, outside the posterior cornu, with which

it is in contact posteriorly, though anteriorly it is separated from the grey matter by the *lateral limiting layer*. This latter is made up of short fibres connecting the grey matter at different levels. In the lower dorsal and lumbar regions the pyramidal tract reaches to the surface; but in the greater part of the cervical and dorsal regions it is separated from the periphery by the *direct cerebellar tract*.

The *direct pyramidal tracts*, which are subject to considerable variations in size and form, are situated on each side of the anterior median fissure. Often they cannot be traced beyond the middle or lower dorsal region.

The *anterior ground fibres* occupy the rest of the anterior columns. They are probably commissural, connecting the anterior cornua at different levels and also those of the opposite side.

The direct and lateral pyramidal tracts transmit voluntary motor impulses from the brain. Tracing this motor tract from above, it may be stated briefly that the fibres pass from the central convolutions, with the multipolar cells of which they are supposed to be in relation, to the internal capsule, occupying the anterior two-thirds of its posterior segment. In the peduncle, the fibres form a compact bundle, lying in the middle third of the "foot" or lower layer of the crus. In the pons the fibres

are split up into bundles, so that they are not so readily distinguished as elsewhere. The tract again forms a compact area in the medulla oblongata, constituting the anterior pyramids. At the lower part of the bulb the decussation takes place, giving rise to the direct and crossed pyramidal tracts just described. There is little doubt that many of the fibres again decussate lower down in the cord, and it is very probable that an intercrossing also occurs to a varying extent at other levels above the medulla. It has already been stated that there is a strong presumption that each pyramidal tract fibre is in relation to a multipolar cell in the cerebral cortex. It is equally probable that the termination of each fibre is connected with a spinal multipolar cell. The lateral pyramidal tract, though mainly composed of large fibres transmitting motor impulses, contains in addition many nerve-tubes of small size, some of which belong to the same system as the direct cerebellar tract, and degenerate in an upward direction.

The *direct cerebellar tract* is situated at the periphery of the posterior half of the lateral column, just external to the crossed pyramidal tract. It begins in the upper lumbar or lower dorsal region, increases in size in passing upwards, and finally enters the cerebellum by the restiform body. This tract is supposed to be connected with the cells in Clarke's posterior vesicular column, but its exact function is still unknown.

The so-called *antero-lateral ascending tract* is situated in the anterior mixed region of the lateral column, lying in front of the direct cerebellar tract, with which it is in some places continuous. The other fibres of the anterior mixed region are partly connected with the anterior roots and partly commissural. The antero-lateral tract is roughly wedge-shaped, the base reaching to the periphery of the cord and sometimes extending nearly as far forwards as the anterior median fissure. This tract probably has its origin in the lumbar region, but its termination above is uncertain. The fibres appear to be in relation with the posterior nerve-roots, possibly through the posterior vesicular columns. The writer is of opinion that the fibres enter the cerebellum by the restiform body, but some observers believe that the tract is connected with the nucleus lateralis in the medulla.

The *postero-median columns* or columns of Goll, which are small in the lumbar region and increase in bulk in passing

upwards, enter the medulla as the fasciculi graciles and reach as high as the clavate nuclei. The fibres which compose these tracts are derived mainly from the posterior nerve-roots. The degeneration is ascending.

The *postero-external columns* or columns of Burdach are composed mainly of short vertical fibres, probably commissural, partly of horizontal and oblique fibres from the posterior roots, and partly of horizontal fibres passing between the posterior cornu and the postero-median column. The degeneration in this tract is of short vertical extent in an ascending degeneration.

Lissauer's tract is composed of fine nerve-fibres lying in front of and behind the entrance of the posterior roots. These fibres, which proceed from posterior roots at a lower level, are supposed to be in relation with the posterior vesicular column.

The *grey matter* is composed of the anterior and posterior cornua, an intervening lateral part, and the central grey matter, the latter being pierced by the central canal. The grey matter is subject to considerable variations in size and form, but into these details it is not now necessary to enter. Both anterior and posterior cornua are composed of a spongy network of fine fibres partly proceeding from the adjoining white matter, partly from the nerve-cells; in addition there is the neuroglia, and scattered through the network are cells of various sizes. The cells in the anterior cornu are mostly of large size (ganglionic or multipolar), are connected with the fibres of the anterior roots, and through them and the motor nerves control the nutrition of the voluntary muscles. These cells, when seen in a cross section of the cord, are arranged in groups, which are termed, from their position, *internal*, *anterior*, *antero-lateral*, *postero-lateral* and *central*. In the lower cervical and upper dorsal regions there is a group of cells occupying the external part of the root of the posterior cornu; this is Clarke's *intermedio-lateral tract*. In the posterior horns the cells are small, spindle-shaped and diffusely scattered.

At the inner part of the base of the posterior cornu, chiefly in the upper lumbar and lower dorsal regions, is Clarke's *posterior vesicular column*, in which are placed fusiform cells, some furnished with axis-cylinder processes. The cells in Clarke's columns are supposed to be connected with the fibres of the direct cerebellar tract, and possibly

with Lissauer's tract. Gaskell, however, believes that these cells are in relation with the vaso-motor and visceral nerve fibres which pass out of the cord by the anterior roots.

Anterior and Posterior Nerve-Roots.—Some of the anterior roots enter the anterior cornua directly and end in the ganglionic cells, some probably pass into the anterior grey matter at a different level after a short course in the anterior mixed region, and some cross to the anterior horn on the opposite side through the anterior commissure. The fibres of the posterior roots at their entrance into the cord divide into two bundles, the external and internal radicular fasciculi. The former passes into the substantia gelatinosa, some of the fibres entering the anterior commissure and finally reaching the cells of the opposite anterior cornu, some probably proceeding to the posterior vesicular column with the cells of which they are connected. Of the fibres of the internal radicular fasciculus some pass either directly or after a short upward course into the postero-median column; others probably decussate with the fibres on the opposite side in the posterior commissure; others pass into the posterior horn and possibly enter into connection with the cells in the posterior vesicular column.

The Sensory Path in the Cord may be referred to here. On this point our knowledge is still very imperfect. That the afferent fibres cross to the opposite side of the cord soon after their entry is undoubted; but the course and position of the fibres in their upward path to the brain is uncertain. It is probable that tactile sensibility travels mainly by the posterior columns, whereas painful impressions are believed to be conducted in the lateral columns. Many observers are of opinion that the antero-lateral ascending tract is the path for sensibility to pain, but this view must for the present be received with reserve. Impressions from muscles probably traverse the posterior columns, and there is reason to believe that these fibres, unlike other afferent fibres, do not decussate in the cord (*see TOUCH, DISORDERS OF*).

Vascular Supply.—The spinal cord receives its arterial supply from (1) the anterior median artery which courses along the anterior surface of the cord. This vessel is formed by the union of the two anterior spinal branches of the vertebrals. (2) The two posterior spinal arteries, which are also derived from the verte-

brals, and which pass down the cord on each side close to the posterior roots. In addition, small branches from the inferior thyroid, the intercostal and lumbar arteries, proceed to the cord and its membranes. From the anterior and posterior spinal arteries small vessels penetrate the cord, those from the former entering by the anterior median fissure, those from the latter for the most part accompanying the posterior-root fibres. These intra-spinal twigs ramify within the cord and anastomose with one another. From the anterior and posterior spinal arteries a plexus of arterioles in the pia mater is derived, and from this source numerous arterioles pass inwards to supply both grey and white matter. To the disposition of the main vessels must probably be ascribed, as the late Dr. Moxon pointed out, the peculiar liability of the lower part of the spinal cord to softening. The small calibre of the anterior and posterior spinal arteries, their unusual length, and the fact that the reinforcing vessels from the lumbar arteries have to pursue a much longer course than the analogous arteries in the cervical and dorsal regions predispose the lower portion of the cord to vascular changes. In consequence of the long and tortuous course of the spinal arteries the blood pressure is very low, and to this must be ascribed their relative immunity from rupture.

LOCALIZATION OF FUNCTION IN THE SPINAL CORD.—The various purposive movements of the trunk and limbs are controlled by special centres in the spinal cord.

Cervical Enlargement.—The upper part contains the centres for the muscles of the neck (mainly the sterno-mastoid and upper part of the trapezius).

The *diaphragm* is represented by the grey matter at the level of the fourth cervical nerve-roots.

Deltoid, scapular muscles, pectoralis, and serratus at level of fifth and sixth nerve-roots.

The clavicular part of the pectoralis is associated in action with the serratus, the costal with the latissimus dorsi. The centres lie close together, but are distinct.

Flexors of the elbow and supinators at nearly the same level as deltoid—namely, at fifth and sixth nerve-roots.

Extensor of the elbow (triceps) chiefly at level of seventh nerve-root.

Extensors of the wrist above centre for elbow, at sixth and partly at seventh nerve-root.

Flexors of wrist and pronators below

extensors, at level of seventh and eighth roots.

Long extensors of fingers about level of sixth root.

Long flexors of fingers below extensors at level of seventh and eighth roots.

Intrinsic muscles of hand at level of eighth cervical and first dorsal, the interossei being represented at the lower level, the thenar muscles at the upper.

LUMBAR ENLARGEMENT.—The localization here is not so definitely known as in the cervical region. The probable positions of the various centres are as follows: cremasteric at second lumbar, psoas at second, iliacus at third, adductors at fourth, glutei at fourth and fifth, extensors of knee at third and fourth, flexors of knee at fifth and first sacral, the muscles of the leg by various centres at level of fourth and fifth lumbar and first sacral, the intrinsic muscles of the foot at the second sacral nerve-root.

Influence of the Cord over Nutrition.—The nutrition of the muscles is controlled by the large multipolar cells in the anterior grey matter, through the anterior roots and the motor nerves. Disease of these cells, nerve-roots or nerve-trunks gives rise to rapid muscular wasting with paralysis, loss of faradic excitability, and loss of reflex irritability.

The nutrition of bones and joints is also under the influence of the spinal cord, probably through the motor cells. The nutrition of the skin is supposed to be controlled through the posterior roots (see TROPHIC DISORDERS).

Visceral Control.—The spinal cord contains independent centres for the viscera, of which the bladder, rectum and uterus are the most important. The centres for these, as well as for that controlling the sexual function, are situated in the lumbar region.

Reference has already been made to the path for the conduction of motion and sensation. Co-ordination and its disorders are dealt with under LOCOMOTOR ATAXIA. The reflex functions of the cord and its varieties are described under REFLEXES, SPINAL. W. B. HADDEN.

SPINAL CORD, HÆMORRHAGE INTO (Hæmatomyelia; Spinal Apoplexy).—Hæmorrhage into the substance of the spinal cord may be either primary or secondary. As regards the latter it may be briefly said that hæmorrhages are apt to occur at any stage of myelitis, and in tumours of the cord. Apart from pre-existing disease, small hæmorrhages are occasionally

found in the grey and white matter in all conditions causing chronic venous congestion, and in such affections as convulsions and tetanus.

Symptoms.—When motor or sensory disorder has existed for a few days or weeks, a sudden exacerbation is probably due to hæmorrhage occurring in the course of acute central myelitis. In more chronic affections, such as tumour, any abrupt change for the worse is also frequently dependent on secondary hæmorrhage.

In idiopathic spinal apoplexy the onset is quite sudden, and the symptoms rapidly attain their greatest intensity; violent spinal pain, and sometimes tenderness, local or diffuse, are frequent. The paralysed muscles are flabby, all the forms of sensibility are abolished, the reflex actions below the seat of disease disappear, the bladder and rectum are paralysed, cystitis results, and acute bed-sores form. When the hæmorrhage is above the lumbar region, reflex action soon reappears in the lower limbs, and later, descending degeneration ensues. Reflex action then becomes exaggerated and contractures of the legs supervene.

Secondary inflammation often succeeds the hæmorrhage, and within the next ten days or so death may follow. The symptoms in any case vary according to the size and position of the hæmorrhage. Small extravasations may be accompanied by slight and indefinite symptoms. When hæmorrhages involve the anterior grey cornua, as they frequently do in the cervical and lumbar regions, permanent wasting localized to certain muscles, will be the result.

Diagnosis.—The chief points of difference between myelitis and hæmorrhage have already been pointed out (see MYELITIS). In spinal meningeal hæmorrhage, there are signs of irritation, such as hyperæsthesia and spasm; whereas paralysis and impaired sensibility are comparatively slight. In acute anterior polio-myelitis, there is some initial fever, sensory disorders are absent, the bladder and rectum are unaffected, and bed-sores do not form.

Prognosis.—The higher the seat of the hæmorrhage the more grave is the prognosis as regards life. When the cervical region is implicated some of the respiratory muscles are involved, and if the hæmorrhage be above the origin of the phrenic nerve, death will ensue.

When recovery follows an attack of spinal apoplexy, some loss of power and,

very commonly, some muscular atrophy are permanent.

Morbid Anatomy.—Idiopathic spinal apoplexy almost invariably occurs in the central grey matter, this position being no doubt determined by the fact that the vessels are there more numerous and less supported than in the white matter. The hæmorrhage often extends a considerable distance vertically, and the substance of the cord around the clot is broken down, ragged, and, at a later stage, exhibits inflammatory changes. The effused blood undergoes the usual alterations of colour, and finally, if life be prolonged, a cyst may be formed. The cord is often swollen at the seat of hæmorrhage, and occasionally the white substance is lacerated and blood may escape into the membranes. The cervical and upper dorsal regions are most commonly affected.

Ætiology.—Spinal apoplexy is more frequent in males than in females, and most often occurs in youth and middle age. Injury is the common exciting agent. Over-exertion and exposure are said to be rare causes. It is curious that spinal hæmorrhage is but rarely found in those who are the subjects of arterial degeneration, this immunity being, doubtless, due to the arrangement of the vascular supply of the cord.

Treatment.—Absolute rest in the prone position should be enforced. An ice-bag should be applied to the spine. A few large doses of ergot, half a drachm of the liquid extract or five grains of ergotin, should be given at intervals of two or three hours. Cystitis and bed-sores will demand the ordinary treatment. At a later stage baths and the use of the constant current to paralysed and wasted muscles may be found of service.

W. B. HADDEN.

SPINAL CORD, HYPERÆMIA OF.—Hyperæmia of the spinal cord and its membranes has been described, usually quite gratuitously, as following on various conditions, such as sexual excitement, exposure to cold, suppression of habitual discharges, and some of the acute specific fevers. Acute hyperæmia, however, without doubt occurs in the early stage of inflammation, and as a secondary condition in some cases of hydrophobia, tetanus, and strychnia poisoning. Passive hyperæmia is present in the cord, as in other organs, in chronic diseases of the heart and lungs.

The chief *symptoms* of acute spinal hyperæmia are said to be pains along the

spine, relieved by assuming the prone position, slight sensory disorders with subjective sensations in the extremities, tremors and jerkings of the muscles, and erection of the penis.

Treatment.—The remedies suggested are leeching, the application of ice-bags to the spine, the recumbent position with the face downwards, saline purgatives, ergot, and belladonna.

W. B. HADDEN.

SPINAL CORD, SLOW COMPRESSION OF.—The subject of slow compression of the cord is also dealt with in part under the head of SPINAL CORD AND ITS MEMBRANES, TUMOURS OF. Here the symptoms will be discussed in a more general way, and the main distinguishing features between the various forms of compression myelitis pointed out.

The *symptoms* come under three categories, namely, (1) those of vertebral disease, (2) those due to pressure on the nerve roots, (3) and those due to pressure on the cord.

(1) **Vertebral Symptoms** occur especially in three conditions: caries, malignant growths, and eroding aneurysms. When there is irregularity or curvature of the spine, the cause of a slow compression-myelitis is unmistakable. Apart from deformity, pain in the spine increased by movement, localized tenderness and rigidity are significant of caries. Sometimes the signs of bone disease are so slight, that their importance is apt to be underrated. Since caries is the most common cause of slow compression of the cord, frequent examinations of the spine should be made in every case of compression-myelitis of doubtful nature, and the possibility of Pott's disease must not be hastily excluded.

Malignant growths involving the vertebræ may give rise to a rounded prominence of the spine, which may be mistaken for caries. The diagnosis between these two conditions may be impossible in the early stage, but it is well to bear in mind that spinal pain from malignant disease of the vertebræ is less severe and less influenced by movement than in caries.

(2) **Extrinsic or Root Symptoms** vary much in degree, in frequency, and in distribution in the various conditions, which give rise to compression. A feeling of constriction in the chest or abdomen (the so-called girdle-pain) may be present, or severe pains of a neuralgic kind, often accompanied by hyperæsthesia and occasionally by the development of an ery-

thematous, vesicular or bullous eruption in the course of certain nerves, may be experienced. Patches of anæsthesia are apt to develop in the hyperæsthetic areas, the pains still persisting (*anæsthesia dolorosa*), and at a later period when destruction of the sensory nerve roots has advanced marked cutaneous insensibility supervenes. Pressure on the anterior roots give rise to slow paralysis and muscular wasting.

(3) **Spinal Symptoms** usually succeed those due to compression of the roots. Gradual loss of power attacks the parts innervated by the cord below the seat of disease, sometimes the lower limbs only being affected, sometimes both upper and lower limbs, together with the muscles subserving respiration. The distribution of the motor paralysis and anæsthesia may be irregular. When, for example, pressure is exerted on one side of the cord, hemi-paraplegia results, motor paralysis without affection of sensation being present on the same side as the lesion, anæsthesia with preservation of motion on the opposite side. As the disease extends in the transverse direction the paraplegia becomes of the ordinary bilateral type. The paralysed members are affected by painful startings and cramps, and become permanently rigid, the muscles preserving their normal bulk and electrical reactions. The superficial and deep reflexes are exaggerated at an early stage, often when the loss of power is still indefinite and trivial. Clonus, spontaneous and induced, is frequently present. Sensation in the paralysed limbs may be normal, often it is incomplete, occasionally profoundly affected. Loss of control over the sphincters is not invariable. Sometimes an acute myelitis supervenes in slow compression of the cord, and then diffuse muscular wasting with profound and widespread anæsthesia rapidly ensues, the bladder and rectum become paralysed, and acute bed-sores form.

The symptoms of slow compression vary according to the seat of disease. When the cervical region is affected root-symptoms are often present in the arms, such as severe pains and hyperæsthesia followed by anæsthesia, paralysis with muscular atrophy, and abolition of reflex action. Later on, indications of pressure on the cord itself make their appearance, the lower limbs becoming paralysed and rigid. Other symptoms sometimes observed in compression-myelitis in the cervical region, are dilatation of one or both

pupils, with subsequent contraction, unilateral or bilateral sweating, vomiting, difficulty in breathing, dysphagia, slowness of the pulse with syncopic attacks, and occasionally epileptic seizures. When the pressure is exerted on the dorsal region of the cord, girdle pains and intercostal neuralgia, due to compression of the posterior roots, are often early symptoms. Subsequently, the lower limbs become paralysed and stiff, and the reflexes exaggerated.

The *course* of a compression-myelitis varies according to the pathological cause. Slow improvement often occurs in caries, and sometimes there is practically complete recovery. In tumours of the cord and its membranes the disease is usually progressive, and most frequently rapidly so.

Diagnosis.—Compression-myelitis may be assumed when signs of pressure on the anterior and posterior roots precede the indications of interference with the functions of the cord.

Root-symptoms may, however, be slight or absent, and then the difficulty in diagnosis is greatly enhanced. Hemi-paraplegia, followed by signs of a slowly progressing transverse lesion of the cord, points to compression.

The anatomical nature of the compressing agent is often difficult and sometimes impossible to determine.

Caries is usually indicated by the presence of the vertebral symptoms, to which allusion has been made. These may be so slight that doubt as to their significance may arise. It is therefore important to bear in mind that in caries motion is mainly or exclusively affected, that the symptoms are usually bilateral from the first, or soon become so, that pains are not generally severe, and that the functions of the bladder and rectum are often intact.

Paralysis with diffuse muscular wasting and anæsthesia of the arms, preceded by severe pains, such as occurs in cervical caries, may be due to primary chronic spinal meningitis, and especially to that variety known as cervical hypertrophic pachymeningitis. The chief distinguishing points are that in the latter the signs of vertebral disease are absent, and the symptoms arise at a later period of life than is usual in caries.

Vertebral cancer or eroding aneurysms may often be diagnosed by local indications. Apart from these, however, the former may be assumed when there is past or present evidence of growth in the breast, stomach or elsewhere.

Compression from malignant growth of the vertebræ is characterised by the early occurrence of excruciating pains, followed by the usual symptoms of interference with the functions of the cord itself. This form of paralysis has been termed *paraplegia dolorosa*. Meningeal hæmorrhage is indicated by the sudden onset of root-symptoms rapidly followed by paraplegia. The nature of other compressing agents, such as tumours of the cord and its membranes can rarely be determined.

The existence of a gumma or of a tubercular mass may sometimes be surmised from the history of the patient.

Morbid Anatomy.—The membranes may be thickened and adherent. In caries there is frequently inflammatory exudation between the dura mater and the bone, the membrane itself showing marked thickening externally and sometimes internally. The symptoms in caries are due to the pressure exerted by the inflammatory products and the thickened dura mater, rarely from actual displacement of the diseased vertebræ. The cord at the seat of compression is often much narrowed or flattened; its consistence in the early stage is softer than normal, but at a later period it becomes hard from the development of sclerotic changes. On microscopic examination some of the nerve fibres are seen to be disintegrated from acute inflammatory changes, others showing little alteration beyond reduction in size. Interstitial overgrowth is commonly present. The central grey matter exhibits the changes seen in acute myelitis though to a less degree. The nerve-roots are often grey, atrophied and degenerated. Above and below the seat of compression the usual secondary degenerations are present.

Treatment.—Prolonged rest in the recumbent posture, tonics, cod-liver oil, and counter-irritation by the actual cautery over the diseased part of the spine, are the chief therapeutic agents in paraplegia from caries. The usual measures for the avoidance of bed-sores and cystitis should be adopted. Suspension has been advised by some authorities. For the description of this method (*see* LOCOMOTOR ATAXIA). In obstinate cases the spine has been trephined, and the inflammatory products and diseased dura mater removed. Such a procedure should only be adopted in exceptional cases, since recovery of power in caries may take place after a very prolonged period of paralysis. Tenotomy or extension by splints may be necessary to

remedy deformities of the limbs when muscular power is regained. Electricity should only be employed when rapid muscular atrophy has supervened. In chronic meningitis, which is sometimes of syphilitic origin, iodide of potassium is of service, and counter-irritants may be used. In meningeal hæmorrhage, absolute rest, the application of ice to the spine and the administration of ergot are indicated. The treatment of other cases of compression-myelitis will be found under SPINAL CORD AND ITS MEMBRANES, TUMOURS OF.

W. B. HADDEN.

SPINAL CORD AND ITS MEMBRANES, TUMOURS OF.

—In describing tumours of the spinal cord and its membranes, it is essential to include growths involving the vertebræ, since these latter by extension, frequently give rise to symptoms due to pressure on the nerve-roots and cord.

The vertebræ are sometimes affected by primary or secondary growths, usually carcinomatous or sarcomatous, less commonly myxomatous. Carcinomatous disease of the spinal column is often secondary to malignant disease of the breast, stomach or other organ, and occasionally results from invasion of growths within the abdomen and thorax. It may be mentioned here that aneurysm of the abdominal aorta eroding the vertebræ may give rise to pressure on the cord and nerve-roots. In very exceptional cases, exostoses growing from the bodies of the vertebræ have extended into the spinal canal and caused pressure-symptoms.

Tumours Originating within the Spinal Canal.—(a) Hydatid cysts and lipomata are found, though rarely, in the loose alveolar tissue between the dura mater and spinal canal.

(b) The tumours involving the membranes are mainly gummata, sarcomata, fibromata, myxomata and tubercular growths; more rarely hydatids, cysticerci and lipomata.

(c) Growths originating within the cord itself are chiefly gliomata, gummata, tubercular tumours, sarcomata and myxomata.

Multiple tumours may arise either from the membranes or in the cord. In the former case, they are usually neuro-mata or sarcomata, in the latter, tubercular. Tumours of the cord have a limited transverse extent, but vertically they may pass for a considerable distance. By the pressure of growths, mainly those

connected with the membranes, the cord may become narrowed and flattened, and usually the ordinary ascending and descending degenerative changes occur. Extrinsic tumours rarely extend into the cord.

Myelitis, of more or less acute course, is not uncommon in cases of tumour within the cord, as well as in growths arising from the membranes and exerting pressure from without. Tumours of the cord often originate in the peri-ependymal tissue, and in such instances the central canal, which is obliterated at the site of the growth by pressure, is found dilated higher up (syringo-myelia).

Symptoms.—(1) *Tumours originating in the substance of the cord.*—The symptoms at first are often vague; later on sensation and motion are apt to be affected below the seat of disease and muscular atrophy from involvement of the anterior cornua may be present. Sometimes, as for example in central tumours, the symptoms are bilateral from the first; in other cases, when the growth is unilateral, cross paralysis is present at the outset, followed at a later period, in consequence of the horizontal extension of the growth, by the slow supervention of other symptoms.

Tumours of the cord are not usually attended with severe radiating pains or with pain, tenderness, and rigidity of the spine. In this respect they differ materially from growths arising from the membranes. The localization of a cord tumour may usually be determined by the level to which the motor and sensory symptoms extend and by the condition of the skin and tendon reflexes.

(2) *Tumours arising from the membranes* usually involve the sensory and motor nerve-roots at an early period. In most cases there is intense radiating pain, often limited for a long time to a definite spot or to the distribution of certain nerves. At a later period, as the growth extends beyond its original limits, sensory symptoms referable to other nerve-roots supervene. Hyperæsthesia is often present. Gradual impairment of sensation, commonly ending in complete anæsthesia, frequently occurs in the area in which the severe pains are felt. Twitchings and temporary spasm of certain muscles are of frequent occurrence and depend on irritation of motor nerve-roots. Paralysis, sometimes accompanied by rapid muscular wasting, almost invariably follows. The paralysis, which is gradual at its outset, usually affects at first one limb or part of a

limb, but as the growth increases and exerts pressure on the cord there supervenes more or less paraplegia, generally attended with rigidity and exaltation of the tendon reflexes. The distribution of the paralysis and the order of the symptoms will depend on the site of the tumour and its rate of growth. Occasionally acute or sub-acute myelitis occurs, and then rapid loss of motion and sensation are superadded.

(3) *Tumours arising primarily outside the membranes*, such as malignant growths of the vertebrae and eroding aneurysms, involve the neighbouring sensory and motor nerves long before the cord is affected. Pain of great severity, often accompanied by hyperæsthesia and followed by anæsthesia, is an early symptom. Muscular paralysis and wasting are frequent. The cord itself is involved late.

Diagnosis.—The chief points of difference between growths of the cord and those arising from without will be evident from the foregoing account. In spinal caries pains are not usually severe, the symptoms are at the outset bilateral or soon become so, and curvature or irregularity of the spine with muscular rigidity makes its appearance.

In cervical hypertrophic pachymeningitis the muscular paralysis and wasting of the arms are usually bilateral from the first, and the sensory symptoms are general in the arms and not limited to the distribution of definite nerve-trunks.

The initial sensory symptoms of tumours, especially those involving the nerve-roots, are sometimes looked upon as neuralgic, but the extreme severity of the pains and the constancy of their seat are highly suggestive.

Tumours of the cauda equina often give rise to pain in the course of both sciatic nerves. The bilateral character of the pain is significant, but not sufficient to warrant a diagnosis of tumour. The gradual onset of other symptoms will usually make the nature of the case clear.

A surmise may sometimes be made as to the anatomical nature of a growth, provided that the symptoms clearly point to tumour, by the existence of a syphilitic or tubercular taint in the patient. Symptoms of irritation of nerve-roots or of pressure on the cord occurring in a subject suffering from malignant disease of the breast, abdomen, or other part of the body are unmistakable in their significance.

Prognosis.—In all cases except gum-

nata the prognosis is very grave. The duration of life varies from a few months to two or three years. In exceptional cases, in which the tumour is of exceedingly slow growth, life has been prolonged for as long as ten years.

Treatment.—When there is any possibility of syphilitic taint, large doses of iodide of potassium, with or without mercury, should be given. In other cases drugs are only of service for the purpose of alleviating pain. Local applications of aconite, belladonna and the like may be used. Sedatives, such as cannabis indica, cocaine and opium are almost always necessary. Recent advances in surgery have shown that tumours of the membranes may be removed successfully. A full account of the method of procedure will be found in the paper by Dr. Gowers and Mr. Horsley in the *Medico-Chirurgical Transactions*, vol. lxxi.

W. B. HADDEN.

SPINAL PARALYSIS, SUB-ACUTE AND CHRONIC ATROPHIC (Sub-acute and Chronic Anterior Polio-myelitis; General Spinal Paralysis).—This disease was originally described by Duchenne in 1849, who termed it "Paralysie générale spinale antérieure subaiguë." The affection frequently assumes a chronic course, although not differing essentially in other clinical characters from the sub-acute form. This distinction into sub-acute and chronic is arbitrary, and hence the two varieties must be regarded as one disease.

The disease is characterized by paralysis followed by atrophy involving first the lower and then the upper extremities. The muscles present the reaction of degeneration. Sensation is preserved, and the bladder and rectum are unaffected. The anatomical change is atrophy of the ganglionic cells in the anterior grey matter of the cord.

Symptoms.—Very frequently at the onset, more particularly in the sub-acute cases, the patient complains of fatigue, pains in the back and limbs with tingling and sensations of numbness, and occasionally there is some pyrexia and general constitutional disturbance. The paralytic symptoms begin with muscular weakness of one or both lower limbs. After a variable period there is distinct paralysis, and later on the affected muscles waste. The flexors of the foot on the leg are apt to suffer first, then the flexors of the thigh, and subsequently the extensors of the leg on the thigh.

The paralysis and wasting, whatever be their distribution, attack the muscles in a progressive manner, and extend slowly from the lower to the upper limbs. In rare instances the arms are attacked first, but the rule is for the upper limbs to be involved a few weeks or even months after the onset. The fingers and hands are more affected than the other parts of the upper limbs. The extensor muscles on the backs of the forearms are often attacked early and suffer severely. In some instances the muscles of the back, abdomen and neck are implicated, usually at a late stage of the disease. In severe cases there is extension to the medulla oblongata, with its attendant dangers. The affected muscles generally present the reaction of degeneration, though it is said that in some of the chronic cases there is simple loss to both currents. There are commonly fibrillar twitchings of the atrophied muscles. The skin and deep reflexes are abolished in the paralysed parts. It is important to bear in mind that throughout the disease sensation remains unimpaired, the functions of the bladder and rectum are preserved, and there is no tendency to the formation of bed sores.

The Course of the Disease is variable. In many cases the wasting and paralysis, after slowly progressing for months or years, remain stationary, subsequently undergoing great improvement, and occasionally a practical recovery is effected. Partial recovery is more common, certain muscles or groups of muscles remaining permanently wasted. Broadly stated, amelioration is more marked in the sub-acute form, though even in very chronic cases great improvement, and occasionally actual recovery may take place. When death occurs it is usually from exhaustion, or from respiratory disorder dependent on implication of the medulla oblongata.

Diagnosis.—In the acute anterior polio-myelitis of adults (adult spinal paralysis) the invasion is abrupt and the muscles are affected coetaneously. In this latter respect adult spinal paralysis differs essentially from general spinal paralysis, in which there is slow extension from part to part.

In progressive muscular atrophy the paralysis and wasting are simultaneous and proportional, whereas in general spinal paralysis the weakness precedes the muscular atrophy. In general spinal paralysis also the atrophy is diffuse and attacks almost always the lower limbs first, thus differing essentially from pro-

gressive muscular atrophy. The course of the two diseases and the electrical reactions of the muscles are different, and in a doubtful case these points should be taken into consideration in differentiating the affections.

As regards amyotrophic lateral sclerosis, the paralysis precedes the atrophy as in general spinal paralysis. In the former, however, the arms are first attacked, and, what is more important, there is rigidity with exaltation of the tendon reflexes from the very onset. Acute ascending paralysis presents many points of resemblance to acute spinal paralysis, to which reference is made elsewhere. Certain cases of ascending paralysis are of slower development than usual, and then this disease has some features in common with the subacute variety of general spinal paralysis. In the former, however, the muscles do not waste, and their electrical reactions are unchanged—two points of primary importance in diagnosis. Until lately many affections of the peripheral nerves, such as alcoholic neuritis, were ascribed to disease of the anterior grey matter of the spinal cord. In multiple neuritis sensory defects are often temporary, and it therefore happens that great difficulty may exist in differentiating between it and polio-myelitis of subacute or chronic course. It should be borne in mind, however, that defective sensation, persistent pains in the limbs, and the existence of hyperæsthesia of the muscles and nerve-trunks are characteristic of multiple neuritis.

Morbid Anatomy.—In the few recorded cases in which the spinal cord has been examined, there has been found atrophy of the cells in the anterior grey matter together with degeneration of the anterior roots. Some degree of sclerosis, particularly of the anterior columns, has also been described.

Ætiology.—The causes of the disease are obscure. Injuries, exposure to cold and damp, alcoholism and lead-poisoning have been looked upon as exciting agents. The onset usually occurs between the ages of thirty and fifty.

Treatment.—Reliance is to be placed chiefly on massage of the affected limbs and the use of electricity, especially of the continuous current.

W. B. HADDEN.

SPLEEN, DISEASES OF.—The spleen is very seldom the seat of primary disease. But little is known of its being acutely inflamed or the seat of

suppuration, except in regard to the condition of acute swelling, to which it is liable in certain infectious diseases as typhoid, acute tuberculosis or pyæmia. But obviously in such cases the spleen is affected only secondarily. It is rare or almost unknown for new growths to originate in this organ, and, indeed, with the exception of splenic leucocythæmia, there is hardly any condition in which it can be said to be primarily affected. A few only of the more common lesions need be here referred to.

Chronic Venous Congestion.—This condition results from long-standing cardiac disease or obstructed portal circulation, as in cirrhosis of the liver. It is sometimes characterized by enlargement and always by induration of the organ. In those cases in which the spleen is not enlarged there is generally great thickening of the capsule (perisplenitis), which may explain the lack of increased size. The induration is due to great fibroid thickening of the trabeculæ. The organ is full of blood and has a dark colour on section. Beyond its palpability, and an increased area of dullness, there are no signs of the condition during life.

Hæmorrhagic Infarction occurs frequently in the spleen in cases of chronic heart disease, the source of embolism being either valvular vegetations or thrombi in the left cavities of the heart. A recent infarction is wedge-shaped, the base of the wedge being beneath the capsule, where it bulges prominently above the rest of the surface of the organ, the apex being directed towards the centre. The infarct has a deep red colour, and is sharply demarcated from the splenic tissue on section both by its colour and also by its consistence, which is firm and solid. The appearance has been aptly compared to that of damson cheese. Careful examination of the branches of the splenic artery will show that the branch supplying the affected area is occluded by a clot, and Cohnheim's explanation of the hæmorrhage is that the splenic arteries being "terminal," the territory cut off from its normal arterial supply is engorged with blood which flows back into it from the veins (*see also* EMBOLISM). Later the wedge-shaped area becomes decolorized, of a canary-yellow colour, and transformed into granular and fatty detritus with blood-pigment; but how long a time must elapse before an infarct undergoes this change is quite undetermined. Later still it shrinks in

bulk and becomes surrounded by a more or less dense and pigmented investment of connective tissue, so that little but a depressed tough cicatrix remains at the site of the original infarct. It is not unusual to find these lesions in all stages in the same spleen or in the advanced stage only, where they remain as prominent indications of previous blockage of the splenic arteries. Such infarcts do not tend to soften; but if the embolus be derived from a septic source, as in pyæmia or ulcerative endocarditis, *abscesses* will result. In the case of ulcerative endocarditis the infarcts are usually minute, represented in the early stage by scattered hæmorrhagic foci, and soon breaking down into minute (miliary) abscesses (see EMBOLISM).

Symptoms.—The occurrence of splenic embolism may be suspected when in the course of heart disease the patient suddenly experiences pain in the splenic region, and there is (especially in ulcerative endocarditis) also a rigor and a sudden rise of temperature concurrently with the pain. The organ, if palpable, is tender on pressure, and sometimes a friction sound can be heard the following day on auscultation in the lower axillary region.

Albuminoid or Waxy Disease.—This condition of the spleen is met with in two forms—one in which the degeneration is mainly limited to the Malpighian bodies (sago-spleen), and the other in which these structures are atrophied and fibrous, and the change involves the walls of the sinuses and blood-vessels (diffuse waxy spleen). In the former condition the organ is generally enlarged, and on section presents a number of closely aggregated translucent or glistening areas which correspond to the swollen waxy Malpighian bodies. In the latter the whole organ is increased in consistence and has a glistening appearance. The “sago” condition is the more common.

The *diagnosis* of albuminoid disease of the spleen is made during life when in a chronic suppurative disease or in a syphilitic subject, the organ is found to be enlarged, its margin firm and rounded, and there is in addition enlargement of the liver and albuminuria. At the same time the degeneration may be more advanced in one organ than in another, and it is not invariably the rule for liver, kidney, and spleen to be all affected.

There is a condition met with in rickets and infantile syphilis which leads to enlargement of the spleen, to which the

name of “albuminoid” degeneration is given by some writers. It is not the same change as that above described, and by some it is regarded as a mere hypertrophy of the organ.

Enlargement of the Spleen.—Apart from the above-named conditions, enlargement of the spleen occurs more or less acutely in most infectious fevers, especially when the pyrexia is high. The organ is markedly involved in typhoid fever, in which disease it may attain a considerable size. In all febrile states the swollen spleen is softer than natural, pale, or sometimes engorged. The spleen is also characteristically enlarged in malarial fever (*q.v.*), in leucocythæmia (*q.v.*), and in Hodgkin's disease (*q.v.*).

The clinical evidences of splenic enlargement are: (1) An increase in the normal area of dulness; (2) the detection, by palpation, of the lower and anterior margin of the organ, the “notch” in the latter being sometimes readily felt; (3) the direction taken by the enlarging organ, viz., downwards and forwards, in front of the intestines; (4) its mobility with the movements of the diaphragm.

A *diagnosis* has to be made from displacement of the spleen, as in left-sided pleuritic effusion or pneumothorax, and from a tumour of the left kidney which may come into contact with the spleen. In the former case the presence of the thoracic disease is readily determined, and in the latter the relations of the renal tumour to the colon (which is pushed forwards in front of it), as well as the existence of urinary symptoms and hæmaturia, may aid in the differentiation, which is, however, in some cases difficult.

Tubercular Disease occurs only as a part of a general tuberculosis, and in two forms:—(1) Miliary grey granulations, which may thickly stud the parenchyma and also be met with on the capsule; (2) large yellow granulations of the size of peas, firm and caseous.

Syphilitic Gummata are occasionally observed, mostly as masses of caseous or semi-calcified substance with dense fibrous investment, often associated with considerable thickening of the capsule.

Secondary Malignant Growths (sarcoma and carcinoma) are also occasionally found in cases of malignant disease, but the spleen is not a usual site for them. In Hodgkin's disease the enlarged organ is the seat of nodules of lymphatic new growth.

Hydatid Cysts are not nearly so com-

mon in the spleen as in the liver or lung, and seldom attain any large size in this organ. Their presence may thus be quite unsuspected during life, and, when found, they are mostly more or less degenerate and calcified.

The spleen during the **Ague paroxysm** undergoes temporary enlargement so as to become palpable. In fatal cases the organ is found to be swollen, soft, and congested, presenting hæmorrhages in its substance. In those who have been the subjects of malarial fever the spleen may become permanently enlarged. Anatomically it is then characterized by much fibrous induration and marked pigmentation (melanæmic spleen).

SIDNEY COUPLAND.

STERCORACEOUS is a term used in reference to vomited matters which possess a fecal odour and appearance, a condition met with in the course of intestinal obstruction and strangulated hernia (*see also* **ULCERATIVE COLITIS AND ENTERITIS**, **E. Stercoral Ulcers**).

STERILITY.—This may be either absolute or relative. Absolute sterility means that the patient does not become pregnant at all, or, if she become pregnant, miscarries so early that the pregnancy cannot be recognized. Relative sterility means that the patient does not produce as many healthy children during the time she lives in wedlock, as women upon the average do. Both kinds of sterility are produced by causes of the same kind, and the causes which in many women produce absolute or relative sterility, in others produce pregnancy resulting in abortions, monsters, plural births, and idiots.

The cause of sterility in a female may be either local or constitutional. The latter are the more common, but the former are the better understood, and more often remediable. Among the constitutional causes are deprivation of health from any cause, especially such as produce amenorrhœa. These probably act by preventing the proper formation of the uterine decidua, to which the impregnated ovum should become attached, and so retained *in utero*. The ill-understood condition of health which is attended by the excessive production of fat, often causes sterility. Habitual alcoholic excess (not necessarily to the point of drunkenness) may produce it. Marriage at an unsuitable age is probably the commonest of all causes of sterility. The marriages which most often

result in the production of healthy offspring are these which take place when the wife is aged between twenty and twenty-five. Before that age the wife is more likely to be sterile than at that age; and after twenty-five the likelihood of her proving sterile increases with age, especially after thirty. A woman may be still menstruating and yet have lost fecundity. Too close intermarriage of families often results in sterility. In some instances a tendency to sterility seems to be inherited, as in the frequent sterility of heiresses. Among the local causes, the commonest, and the one most often curable, is spasmodic dysmenorrhœa (*see* **DYSMENORRHŒA**). Barrenness may be due to absence of the uterus, or to deficient development or atrophy of the uterus and ovaries. We can only detect smallness of the uterus, for there is no method of examination fine enough to reveal the condition of the ovaries as to development. But as pregnancy may take place in an undeveloped uterine horn, it is probable that in a woman with a small uterus who is sterile, the ovaries share in the imperfect development of the sexual organs. In such cases the stimulus of marriage may sometimes bring about slow development of the generative organs, but this is rare. Disease of the uterus, such as fibroids, cancer of the body, or diseases of the Fallopian tubes, causing them to be blocked, may cause sterility. Excessive sexual intercourse may produce sterility, as is seen in the infrequent pregnancies of prostitutes. This possibly acts by producing a monthly miscarriage. Cervical endometritis has been stated to cause sterility, but there is abundant evidence to the contrary. Endometritis of the body of the uterus has been with more reason credited with sterility as its effect, but we have no exact knowledge as to the forms of this disease which cause sterility. Uterine displacements have had sterility attributed to them, but no evidence has ever been adduced to show that this is so in the smallest degree, and there is no doubt that pregnancy may take place with any displacement except inversion.

Statistics prove that until a patient has been married for three years without pregnancy, there is still a probability of offspring, which seems to show that there are some causes of sterility existing at the time of marriage which are capable of natural cure. It must be remembered in the investigation of any case of sterility that the cause may be in the hus-

band, and not in the wife. As this is so in a large proportion of cases, no treatment of a woman of a dangerous or protracted character should be undertaken on account of sterility, until inquiries have been made on this point. Lastly, sterility in a given couple may not be due to any disease either in husband or wife, but simply to an incompatibility (the nature of which we do not understand) between the germ cell and the sperm cell; for occasionally instances are met with in which a woman is sterile in marriage with a man who has had children by another wife, and herself is fertile when married to another husband.

G. E. HERMAN.

STERTOR: STERTOROUS.—

The noisy breathing of a person in a state of coma.

It is due to a paralytic condition of the muscles of the lips, cheeks, tongue, fauces, and soft palate, the latter becoming a flaccid curtain moving to and fro with respiration, a similar movement being often seen in the lips and cheeks. The tongue falls towards the posterior wall of the pharynx, mucus collects within the mouth and becomes frothy by admixture with the tidal air, the result being a snoring noise, in the production of which all the above-mentioned conditions have some share.

STOMACH, CANCER OF.—Cancer of the stomach is, as a rule, primary; but the disease may extend to the stomach from other organs. The epithelial, the encephaloid, the colloid, and the scirrhus varieties of cancer all occur in the stomach, the last being the most common. Any part may be affected, but the pylorus is the most frequent seat. The growth may infiltrate or be localized, it may form tumours or ulcerate, and may extend from the stomach to other organs.

Symptoms.—When the cancer is not pyloric, the symptoms are somewhat similar to those of gastric ulcer (*vide infra*), but hæmorrhage is more frequent, and usually occurs in small amounts at a time. Cachexia and wasting are marked from an early period. The bowels are usually confined. Sarcinæ and torulæ may be found in the vomita, which will also present the appearance known as "coffee ground," when there is bleeding from the surface of the growth. In pyloric cases the symptoms agree with those described under PYLORUS, OBSTRUCTION OF.

The *physical signs* vary according to the seat and extent of the growth. Local tenderness is usually present, but is less acute than in cases of ulcer. A sense of resistance may be felt over the gastric area, and when the growth is in front a distinct tumour can usually be detected. The characteristics of a tumour of the stomach are fully described in the article on ABDOMINAL TUMOURS.

Diagnosis.—This is often a matter of great difficulty; speaking generally, it may be said that in the absence of a distinct tumour it is rarely safe to come to a diagnosis of cancer of the stomach, so closely are the symptoms in some cases simulated by those of chronic ulcer. This subject is discussed in the article above referred to (page 5), and also in the article on HÆMATEMESIS.

The *prognosis* is necessarily fatal. Death occurs from exhaustion, usually in about eighteen months from the commencement of the symptoms, rarely later than two years. The progress of the disease is most rapid, as a rule, in pyloric cases.

Treatment can be only palliative. The diet must be restricted until vomiting ceases and tolerance of food is obtained. If necessary, rectal alimentation must be resorted to and the stomach left at rest. Pain may be relieved by the same means as in gastric ulcer, and fermentation by those described under PYLORUS, OBSTRUCTION OF. Hot turpentine stupes, hot fomentations, &c., are at times useful in relieving the pain. In pyloric cases the operation of gastrostomy may be resorted to as a means of prolonging life.

ISAMBARD OWEN.

STOMACH, DILATATION OF (Gasterectasis).—One of the chief causes of dilatation of the stomach is dealt with in the article on PYLORUS, OBSTRUCTION OF (*q.v.*), but this condition may also arise from muscular weakness, from habitual over-distension with food and drink, and from the excessive use of aerated waters. Rarely it occurs as an acute condition. Little or no hypertrophy of the muscular coat is found in these cases.

Symptoms.—The symptoms, generally speaking, resemble those of obstruction of the pylorus, but pain is either less severe or altogether absent. The vomita may contain bile as well as sarcinæ.

Physical Signs.—The characteristic signs of a dilated stomach are given in the article on ABDOMINAL TUMOURS (p. 5).

Prognosis.—This is favourable in fairly

healthy constitutions, provided treatment be carefully persisted in.

Treatment.—This mainly consists in giving partial rest to the stomach, so that it may gradually recover its muscular tone. Three light meals should be taken each day at intervals of about five hours. Only bland and easily digested forms of food are admissible; they must be free from excess of starchy and fatty matters, and the quantity must be restricted according to the severity of the case. It is important that the patient should take at least an hour's rest in the recumbent posture after each meal. Alcoholic liquors and aerated waters are to be prohibited. Gas-formation should be checked by carbolic acid, &c., as described under obstruction of the pylorus. Other drugs are of little value, but tinct. nuc. vom., in 10-15 minim doses three times a day, may help to restore tone to the gastric wall.

The stomach may each day be washed clear of the mucus which tends to collect on its wall with warm water, either plain or with 5-10 grains of sod. bicarb., added to the fluid ounce. This is best done by employing a long stomach-tube, fitted with a funnel at the upper end, to fill the viscus, and emptying it by lowering the upper end of the tube into a basin. The tube then acts as a siphon. An antiseptic solution may be substituted for the plain or alkaliized water.

The method of proceeding is more fully described in the article on PYLORUS, OBSTRUCTION OF.

ISAMBARD OWEN.

STOMACH, INFLAMMATION OF (Acute Gastritis).—Acute inflammation of the wall of the stomach is almost always due to direct irritation by ingested food or drugs, especially by very hot or very cold drinks, ardent spirits, irritating condiments, and the class of drugs known as irritant poisons (*q.v.*). The condition may also be set up by starvation, and it sometimes arises without known cause, or is attributed to chill. The affection varies, according to the intensity of the cause, from simple catarrh of the mucous membrane to severe inflammation of the whole thickness of the wall, with erosion and destruction of the mucous layer. Membranous exudations and perforations are rarely found; and diffuse suppuration is a condition very seldom met with.

Symptoms.—Pain, more or less acute, in the epigastrium, radiating, if severe, to the back and flanks, is invariably present.

Nausea, retching or vomiting, which may or may not relieve the pain, usually accompany it, whilst anorexia, intolerance of food or drink, which is speedily vomited, thirst and constipation, with pyrexia and febrile malaise, are symptoms seldom absent. In severe cases there may be much prostration and collapse. The tongue is red and dry, or may be furred and denuded of its epithelium in patches.

The *prognosis* is, on the whole, favourable, except in cases due to irritant poisoning. Chronic gastritis may remain after the acute symptoms have subsided (*see* DYSPEPSIA).

Treatment.—Rest in bed is essential, and only small quantities of easily digested food should be given. From half to one teacupful of lukewarm milk, or half the white of an egg beaten up with from half to one teacupful of lukewarm water, should be given alternately with a similar measure of thin gruel or barley water, every two hours. Rectal alimentation may be added if the case threatens to be prolonged.

The application of from four to eight leeches to the epigastrium and hypochondria gives great relief. Hot turpentine stupes, hot fomentations, hot dry flannels, or a large mustard plaster may be substituted, but they are less efficacious.

Liq. morph. hydrochlor. (5-8 min.) may be given every four hours to allay pain and irritation, with 3 min. of ac. hydrocyan. dil. to check vomiting, and 15 min. of glycerin, in 1 oz. of rose water.

If collapse threaten, it may be averted by the injection of 2-4 oz. of brandy per rectum, or of $\frac{1}{2}$ -1 drm. of ether subcutaneously. The medicaments will be reduced gradually, and the diet cautiously increased as convalescence sets in. Alcoholic liquors should be strictly avoided unless collapse be threatened. If chronic catarrh supervene, the case may be treated as one of dyspepsia (*q.v.*).

ISAMBARD OWEN.

STOMACH, ULCER OF (Gastric Ulcer).—Ulcers may occur on any part of the wall, but are most frequently met with on the posterior surface near to the lesser curvature, and to the pyloric end of the organ. The more *acute* forms are found chiefly in females from eighteen to thirty, the more *chronic* in men beyond middle age.

Symptoms.—The symptoms are, as a rule, well marked. Acute pain is complained of. It is referred generally to the epigastrium, but at times to the back,

right or left hypochondrium, right or left flank, according to the position of the ulcer; it is speedily aggravated by food and generally relieved by vomiting. There is often tenderness over the epigastrium, and, if the ulcer be in front, the tender area may be narrowly localized. Vomiting is present from an early period. It occurs, as a rule, within two hours after taking food. Any of the symptoms described under *DYSPEPSIA* may be added; and the patient rapidly wastes. In about half the cases profuse hæmorrhage occurs at rare intervals, the blood being vomited or passed downwards, or both.

Perforation, if it occur, is signalled by sudden severe pain in the abdomen, with collapse; followed by the symptoms and signs of peritonitis.

Diagnosis.—The diagnosis requires to be made from cancer of the stomach and the condition known as *ANOREXIA NERVOSA* (*q.v.*). As regards the former the reader is referred to the articles *STOMACH, CANCER OF*, and *ABDOMINAL TUMOURS, DIAGNOSIS OF*.

Prognosis.—In the great majority of cases the ulcer heals, but it is liable to re-open at any subsequent period. Death may occur from perforation, hæmorrhage, or exhaustion; or from obstruction of the pylorus by cicatrization. The liability to perforation is much less in chronic gastric ulcer than in the acute form.

Pathology and Etiology.—The origin of gastric ulcers is variously ascribed to injury, inflammation, spasm, thrombosis and embolism of minute arteries, but we have no certain knowledge of their cause. They are usually single, and vary in size from a shilling to a half-crown. The more acute forms have flat, clean cut edges and smooth floors, the more chronic are thickened in both. They may be merely superficial, or may penetrate the deeper coats, or actually perforate. In the event of deep penetration, adhesions form between the seat of the ulcer and the neighbouring viscera (*e.g.*, the pancreas), and these adhesions in most cases obviate the consequences of penetration. When deep, the ulcer is conical in shape.

Treatment.—This must be directed to protecting the ulcer as far as possible from irritation and to the relief of the pain and vomiting. At the same time the patient's strength must be supported. Absolute rest in bed is essential during the presence of any acute symptoms. The diet at the outset must be narrowly limited. It is best to commence with

fluid food, milk and plain broth, or one of the malted "infants' foods," given in quantities not exceeding $\frac{1}{2}$ pint at two or three hour intervals. In severe cases, no food whatever should be given by the mouth for a period the duration of which will vary with the severity of the symptoms and the strength of the patient. During this time the patient must be supported by nutrient enemata and nutrient suppositories, one of which may be given alternately every four hours. Bism. subnit. 10 grs. suspended in mucil. acac. $\frac{1}{2}$ drm. may be given every six hours, in order to form a protective coating to the ulcer; and liq. morph. bimec. 3-6 min. and ac. hydrocy. dil. 3-4 min. may be added to this to check the pain and vomiting; tr. belladonnæ 5-10 min. or tr. hyoscyami $\frac{1}{2}$ drm. may be substituted for the morphine.

At the same time portal congestion may be prevented by mild saline aperients,—*e.g.*, 20 gr. mag. carb. and 1 drm. mag. sulph., with $\frac{1}{2}$ drm. tr. hyoscyami, in 1 oz. of peppermint water, taken the first thing in the morning as required. Violent purgation should be avoided.

The amount and solidity of the food may be cautiously increased as the pain and other symptoms subside.

Nitrate of silver ($\frac{1}{4}$ gr. doses) or oxide of silver ($\frac{1}{2}$ gr. doses) in pill may be substituted for the bismuth in the later stages.

The treatment of hæmatemesis will be found under that heading. For the treatment in case of perforation, followed by peritonitis, the article on the latter subject may be consulted.

ISAMBARD OWEN.

STOMATITIS.—Inflammation of the interior of the mouth. This affection occurs under several forms, and great confusion has arisen in their classification. The most distinct varieties are the following:—

1. *Catarrhal Stomatitis*, the mildest and most frequent form, is that produced by irritants, such as, in adults tobacco-smoke, and in children sour milk; infants are specially liable to it, the mucous membrane being peculiarly vascular and delicate. This, which is sometimes termed "erythema neonatorum," varies very much in intensity. In a well-marked case the mucous membrane is much swollen, indented by the teeth or gums, and easily made to bleed; the catarrhal area may be limited, as is often observed in association with dentition. The tongue is

furred, the fur becoming detached in patches, leaving an intensely red surface. The symptoms are pain on sucking or mastication, and salivation.

Ætiology.—Catarrhal stomatitis is generally present in coryza, whooping-cough, measles, scarlatina and typhoid fever.

The *treatment* is simple, the removal of the irritant and the use of a mild astringent lozenge (*e.g.*, tr. krameria) being, in the case of an adult, generally sufficient; in infants and young children, attention to the cleanliness of the bottle, or mamilla, careful cleansing of the mouth after each meal with a soft mop, and the occasional application of glycerine of borax, generally suffice.

2. **Ulcerative Stomatitis** most commonly supervenes as an extension or complication of catarrhal stomatitis. Small ulcers form at points where pressure is exerted by the teeth, or where the mucous membrane is liable to be torn, as at the junction of the lip and gum; in other cases where the catarrhal process is more intense, numerous ulcers rapidly appear, on the cheeks, between the lips and the teeth, under the tongue, and on the hard palate; in a third variety the ulceration starts about the teeth, generally the lower incisors, and spreads along the gums; it may involve the periosteum of the jaw, leading eventually to extensive necrosis and exfoliation of bone. The last two forms are probably infective, and both, but especially that which appears to start on the buccal mucous membrane rather than the gums, are frequently observed in several members of the same family. Copious salivation, great pain on movements of the mouth, and very fetid breath are the marked symptoms; there is commonly some pyrexia, and from the pain and indisposition to eat or drink, the disease is often accompanied by much prostration.

The *treatment* of mild cases, where there is a single ulcer or but few ulcers, consists in the local application of chlorate of potassium (wash or lozenge); in severe cases, small doses of the same drug should be given internally at frequent intervals, best in a mixture with decoction of cinchona. Locally, the liquor hydrarg. perchlor. B.P., or glycerin of borax, or chlorate of potassium should be applied frequently. Washes of nitrate of silver (1 per cent.), permanganate of potassium, or sulphate of copper are also useful. In all cases, but especially where the ulceration has become

chronic or relapses have occurred, the general condition of the patient must be attended to.

3. **Aphthous Stomatitis**, is described under APHTHÆ.

4. **Stomatitis Mycosa** or Thrush is described under THRUSH.

5. **Gangrenous Stomatitis** or **Cancrum Oris** is described under CANCRUM ORIS.

Various other forms of stomatitis, differing chiefly in their ætiology, are also recognized. Thus, *mercurial stomatitis* begins as a catarrhal inflammation of the gums, which quickly runs on to ulceration; the simultaneous effect of the metal on the salivary glands causes profuse salivation, which is very characteristic. Copper and phosphorus produce similar forms of stomatitis; the ulceration if neglected may in time affect the bones. The mucous membrane of the mouth may become infected by diphtheria, and the disease has been known to commence in this situation. In syphilis there is a liability to catarrhal stomatitis in association with mucous tubercles; in hereditary syphilis a general catarrhal stomatitis producing a red glazed condition is an early symptom. The fissures of the lips, or rhagades, frequently extend into the mucous membrane of the mouth, which is then locally inflamed and infiltrated.

DAWSON WILLIAMS.

STRANGULATION.—In death from strangulation the fatal result is due to asphyxia brought about by compression of the air passages from without. Strangulation may be the result of an accident and it is conceivable that a suicide may end his life in this way, but there is always a strong presumption in favour of homicide, and if the marks on the neck showed that manual pressure had been used this would be conclusive of homicide. Usually much more violence is applied than is necessary to destroy life. The condition of the neck will depend upon the nature of the appliances used; a ligature, for instance, will leave a deep circular mark going all round the neck, the mark may be ecchymosed and sometimes the skin is abraded. It is by no means uncommon to find purpuric spots scattered over the trunk. Internally, fracture of the larynx or of the rings of the trachea may be found, or merely congestion of these parts; the thoracic viscera will present the appearances usual in cases of asphyxia, with sometimes superficial em-

physema of the lungs in patches, owing to rupture of the air vesicles. The treatment would consist in freeing the neck from the constricting band, if one existed, a free supply of air, and artificial respiration.

STRANGURY.—An urgent desire to pass urine, frequently recurring, the quantity passed being very small, sometimes a few drops only. The condition is generally accompanied by pain about the neck of the bladder, and the act of micturition is not followed by the sensation that the bladder has been emptied.

The two conditions in which strangury forms a prominent feature are poisoning by turpentine and by cantharides, the latter being sometimes induced by the action of a blister. It is also present in various inflammatory affections of the bladder and prostate, and when those organs are the seat of morbid growths.

The treatment will depend upon the nature of the exciting cause. Morphia and hot baths are, as a rule, the most efficacious remedies.

STROPHULUS.—An old-fashioned term used by Willan and Bateman to designate various ill-defined diseases of the skin which occur mainly in childhood. *Strophulus albidus* is probably identical with milium (see SEBACEOUS GLANDS, DISEASES OF), while *strophulus intertinctus, confertus*, &c., represent various urticarial and sweat eruptions.

STRYCHNINE, POISONING BY.—Strychnine is the alkaloid obtained from the seeds of *Strychnos Nux Vomica*.

Symptoms.—An intensely bitter taste is noticed as the poison is swallowed. The urgent symptoms usually commence suddenly, within twenty minutes of taking the drug. A vague sense of impending danger is experienced, the patient cannot get his breath, declares he is going to be choked, and cries out for more air. Twitching and jerking of the muscles, followed by general tetanic spasms, soon set in, almost all the muscles of the body are attacked at once, those of the back being most affected. During a paroxysm the patient lies on his bed in a state of extreme opisthotonos, his head and heels alone touching the bed, the arms are extended, the feet arched, the abdomen tense, and the chest fixed, so that respiration is greatly impeded; the face and lips are livid, the eyes staring, and the angles of the mouth drawn up so as to produce

the well-known and characteristic “risus sardonicus.” From a half to two minutes is the average duration of a paroxysm. The spasm passes off leaving the patient much exhausted and bathed in perspiration. His sensations warn him of the approach of another paroxysm, and he often screams out or asks to be held. As a rule there are absolutely no cerebral symptoms, and between successive paroxysms the patient often speaks of his impending death. In a case that is likely to terminate fatally the attacks increase in frequency, and the victim dies either from suffocation during a paroxysm or from exhaustion in an interval. The lower jaw is seldom affected until late in the illness. If the patient survive for two hours after the first appearance of the symptoms there is a fair hope of his recovery.

Diagnosis.—The condition has some points in common with tetanus, and might be simulated by hysteria, but a close attention to the symptoms should enable the observer to eliminate the latter without much difficulty. The chief point as regards tetanus is the condition of the lower jaw, in the latter disease the jaw is almost invariably the part first affected, and it remains affected throughout; whereas in poisoning by strychnine it is seldom affected until late, and then only during a paroxysm.

Post-mortem Appearances.—If the patient die during a paroxysm the body is found in a state of opisthotonos, as at the moment of death, otherwise there is nothing outwardly to suggest the cause of death, nor do the internal appearances help much, as a moderate degree of congestion of the cerebral or spinal systems may be all that can be recognized; the blood may be dark and fluid.

Treatment.—Vomiting should be encouraged, and, if the paroxysms have not set in, the stomach-pump may be used. The patient must be kept as quiet as possible, and should not even be touched unnecessarily, for fear of inducing a convulsion. To subdue the convulsions large doses of chloral hydrate or bromide of potassium may be given, separately or together, half a drachm of each for a dose, repeated in half an hour if required, or chloroform may be administered; artificial respiration may be required. Patients often derive much benefit during a paroxysm from being held or rubbed.

SUBSULTUS TENDINUM.—Spasmodic twitching movements of the

tendons, most easily perceived at the wrist. It is a condition met with in severe febrile affections, usually in association with delirium, and is of unfavourable augury.

SUFFOCATION.—Death from asphyxia, the obstruction to respiration being more or less mechanical, but not by violence applied to the throat.

It is usually accidental, very rarely suicidal, except amongst the insane, and occasionally homicidal. Over-lying, or smothering the mouth and nostrils with bedclothes, a towel or cloth, are the methods usually adopted in the latter class, but over-lying may be an accident, though this is not likely if the infant be robust and the mother not intoxicated at the time of the occurrence. Amongst the accidental causes may be mentioned, pressure on the chest in crowds, the passage of food into the glottis, either during the act of swallowing or during vomiting, the passage of blood or pus or a foreign body into the air passages, as in hæmoptysis, rupture of an aneurysm, or the bursting of an abscess in the neighbourhood of the larynx, wounds of the throat involving the trachea, and œdema laryngis, from the swallowing of boiling or corrosive liquids or from simple laryngitis.

The *diagnosis* is generally made from the presence of signs of asphyxia, and the absence of other sufficient cause of death.

Post-mortem Appearances.—There would be the usual signs of asphyxia (*q.v.*), in addition, sub-pleural ecchymoses (Tardieu's spots), consisting of small, round, dark, well-defined spots, are usually seen, especially at the root and base of the lungs, and similar extravasations of blood may be found throughout the lungs.

The *treatment* would consist in the removal of the obstruction to respiration, of whatever kind, if necessary by the performance of tracheotomy, and in the adoption of other measures for restoring natural breathing. The mode of performing artificial respiration is described in the article on DROWNING.

SUNSTROKE (Heat Stroke; Insolation; Coup de Soleil).—A condition resulting from exposure to the heat of the sun or to heat from other sources.

Symptoms.—Three varieties are usually described. 1. **Asphyxial form**, in which death may be almost instantaneous, the onset being sudden, with symptoms of cardiac and respiratory failure, cold skin,

gasping breathing and insensibility. Recovery, if it take place, is usually complete. This is the true sunstroke, resulting from exposure of the head and back of the neck to the direct rays of the sun.

2. **Hyperpyrexial form.**—This follows exposure to great heat from other sources as well as from the direct effect of the sun. It may come on after the exposure has quite ceased, whilst the person is in the shade or even at night. Usually premonitory symptoms are noticed, such as vertigo, headache, nausea, mental confusion, disinclination for exertion, insomnia, thirst, high fever, disordered bowels, or frequent micturition. Insensibility is an early symptom, and supervenes gradually, stertorous breathing in one supposed to be asleep being sometimes the first indication of the condition. There is great restlessness, the breathing is laboured and gasping, the face suffused or cyanotic, the pulse quick and jerking, the temperature very high (108° F. or higher). The pupils in the early stages are contracted, later they may be dilated; the pulse may subsequently become irregular and thready, subsultus tendinum may be present, and epileptiform convulsions, followed by deep coma, occur. Hæmorrhages into the skin are often seen and suppression of urine is nearly constant. Death from gradual asphyxia or from simultaneous cardiac and respiratory failure usually takes place within two days, often very rapidly. In this variety recovery when it occurs is seldom complete, the patient being afterwards unable to endure exposure to excessive heat in any form. Pain in the head, usually limited to one spot, but sometimes diffused, and liable to exacerbations, is a prominent after-effect, loss of memory, irritability, inability to fix the attention, imbecility or even insanity are common sequelæ, and occasionally paralysis or tremor follow the attack.

3. **Syncopal form or heat exhaustion.** The chief features are great prostration, lowering of the body temperature, a cool moist skin and feeble pulse; recovery is generally complete.

Post-mortem Appearances.—Rigor mortis sets in speedily and is followed by early putrefaction. The left ventricle is usually contracted, the right side of the heart and pulmonary vessels being engorged. The blood is generally fluid, and its physical characters altered.

Ætiology and Pathology.—The main cause is exposure to excessive heat, not necessarily to the direct rays of the sun, for it is often met with in stokers,

engine-men, &c.; over-heated air is much better borne when the atmosphere is dry than when it contains much moisture, a fact which is abundantly verified by the experience of the Turkish bath. Predisposing causes undoubtedly have some influence; vigorous persons of temperate habits and in good bodily health are much less liable to be attacked than others. Anything which tends to exhaust or impair bodily vigour will increase the liability to an attack, thus soldiers on forced marches, especially when clothed in a tight uniform, have succumbed in great numbers; sexual or alcoholic excesses are especially dangerous. Acclimatisation has some effect, for in hot countries Europeans suffer more than natives, and new comers more than those who have been some time resident in the district. Persons of spare build are more likely to escape than those who are portly. As regards the actual nature of the affection, it is probable that in the cardiac form the centres in the medulla controlling the circulation and respiration are first stimulated, and then paralysed. The explanation offered by Dr. H. C. Wood of the hyperpyrexial form is that there is an accumulation of heat, as the body is prevented from throwing off the heat which is constantly being formed, and also there is a sudden outburst of heat production. A centre in the pons inhibits the production of animal heat, and another in the medulla regulates the dissipation of heat. On the above theory both these centres must be disturbed (*see* FEVER, section Hyperpyrexia).

Treatment.—The avoidance of all known predisposing causes will go far to prevent an attack. The assiduous application of cold is the most important point in the treatment; this may be effected either by cold baths, douches or packing, or by rubbing the body with ice. A careful watch must be kept on the temperature, so as not to push the treatment to such a degree that the patient is unable to rally. The hypodermic injection of quinine in 10-grain doses, or of antipyrin in 20-grain doses, is worthy of trial. The sequelæ are practically always due to chronic meningitis, and should be treated accordingly.

SUPPOSITORIES are solid cones for insertion into the rectum, to be there dissolved and their active ingredients absorbed. They usually contain as their basis oil of theobroma, glycerin of starch or soap, mixed with which is the

special agent it is desired to employ. The substance introduced into them depends upon the purpose for which they are to be used; most commonly an anodyne effect is desired, when morphine is employed, or occasionally belladonna. Astringents are also used in this way to check diarrhoea, or in cases of constipation some local irritant may be introduced to excite the expulsive action of the bowel. *Nutrient suppositories* are employed where rectal feeding is necessary, either in addition or instead of nutrient enemata. The suppository should be oiled and gently introduced into the anus and slowly pushed up until it is beyond the sphincter, where it may be held for a few seconds to meet any temporary tendency to its expulsion that might at first be excited. Occasionally suppositories are introduced into the vagina; when so used, it is generally for some definite local effect, but sometimes for anodyne or nutrient purposes in cases where such a purpose cannot be effected through the rectum.

SURGICAL KIDNEY (Consecutive Nephritis).—These terms have been given to certain affections of the kidney which are secondary to disease of the lower parts of the urinary tract. They are of several kinds.

1. **Simple Distension** is produced when there is obstruction to the free passage of urine from the bladder or from the ureters. The urine secreted above accumulates, and gradually distends, first the ureters, then the pelvis of the kidney. Afterwards, increasing pressure causes atrophy of the kidney substance in the manner described in the article on **HYDRONEPHROSIS** (*q.v.*). A certain amount of interstitial inflammation is always found in the distended kidney.

2. **Pyelitis, Pyelonephritis, and Pyonephrosis** are occasionally the result of extension of inflammation from the bladder along the ureters to the pelvis of the kidney.

3. **Acute Suppurative Nephritis.**—This is the most characteristic form of "surgical kidney." The kidney is enlarged; its capsule peels off easily; the colour is yellow, mottled with red; the cortex is increased in size. Scattered through the kidney substance numerous small abscesses are observed, which vary in their distribution and shape. Some are found lying between the capsule and the kidney or but slightly invading the kidney substance; these are rounded in

shape. Others are seen to be situated entirely in the cortex of the kidney, and these are of an elongated wedge shape, having the base at the periphery of the cortex. A third kind is found in the medullary portion, and has the form of long yellow streaks running parallel to the straight tubes of the kidney.

On *microscopic examination* it is seen that in addition to the abscess formation there is a considerable amount of cell infiltration of the general interstitial tissue of the kidney, together with proliferation, swelling and degeneration of the cells of the tubules. In fact, combined with the suppuration, there is interstitial and parenchymatous nephritis. By suitable staining agents colonies of micrococci can be demonstrated in various parts of the kidney substance.

4. Interstitial Inflammation.—When this affection is present in the acute stage the kidney has the appearances just described as characteristic of the preceding variety, but without the points of suppuration.

In the chronic stage the kidney is smaller than normal, the capsule is adherent, and the surface granular, in colour yellow mottled with grey. The cortex is diminished in extent. On microscopic examination the interstitial tissue is found to be increased in amount, and the glomeruli and tubules more or less atrophied and degenerated.

5. The Cicatricial Kidney is the final result of some of the former varieties. It is produced by the absorption of the abscesses and the formation of a cicatrix, and by the still further contraction of the increased interstitial tissue. The kidney is irregular in form, always diminished in size, and is converted into a mass of fibrous tissue in which but few renal elements can be detected.

The mechanism of the first and second and also of the last varieties has already been explained. That of the acute suppurative and of the acute interstitial nephritis is still a matter of dispute.

The theories which have been advanced to explain the conditions may be thus summarised:

Simple distension may give rise to irritation of the distended parts, but will hardly account alone for the extreme degree of inflammation occasionally shown in the consecutive nephritis. It has been thought also that the kidney might become inflamed by reflex conveyance of irritation through the nervous system, the primary source of irritation being

situated in the lower urinary tract. This view again would probably not suffice to explain the advent of suppuration, although it has been urged that repeated attacks of congestion produced through the agency of the nervous system, such as have been observed to occur in the kidney after catheterism and other operations on the urethra and bladder, would in time lead to chronic overgrowth of the interstitial tissue of the organ.

It seems now to be certain that the most typical form of "surgical kidney," the acute suppurative nephritis, is produced by the access to the kidney of septic matter proceeding from the bladder. Dr. George Johnson has suggested that by rupture of urinary tubules, there may arise extravasation of urine into the interstitial tissue. Dr. Dickinson holds that the septic urine retained in the pelvis and straight tubes of the kidney under some pressure, transudes into the blood-vessels. The poisonous matter is then carried by the veins to different parts of the organ and is here and there localized in septic thrombi of these vessels. Mr. Marcus Beck, on the other hand, asserts, that it is the lymphatics of the kidney which are mainly concerned in disseminating the poison; that they absorb it from the pelvis and straight tubes, whither it has come from the bladder. The irritating fluid causes desquamation of the epithelium of the tubules and so makes way for its ready absorption.

Dr. Lindsay Steven has shown that the abscesses which are found in the medullary portion of the kidney, are the result of septic poison which reaches the kidney by means of the tubules, but that the wedge-shaped abscesses which lie in the cortex, and between the cortex and the capsule, are caused by septic material absorbed by the lymphatics. He has proved that the lymphatics of the kidney can be injected from those of the ureter and that they pass in from the border into the cortex of the kidney in the direction of the wedge-shaped abscesses. He believes, therefore, that the inflammation of the kidney is due to septic poison absorbed from the bladder or the pelvis of the kidney and conveyed by the lymphatics. This view would appear to be that most consistent with the facts.

Symptoms.—Simple distension of the kidney and ureters causes no symptoms which can be distinguished among those of the cystitis or other trouble which is the primary cause of the condition.

Chronic interstitial nephritis, which usually to a greater or less extent accompanies simple distension, may also give rise to no recognizable symptoms. It may, however, cause the urine to be increased in quantity, and to be of low specific gravity. Any other signs which might have been expected are masked by the inflammatory products from other sources which are added to the urine.

Similarly the extension of inflammation from the bladder to the pelvis of the kidney is often accompanied by no increase in severity of the symptoms and no further alteration in the condition of the urine. The cells discharged from the pelvis of the kidney so closely resemble those of the mucous membrane of the bladder that no reliance can be placed upon their discovery as an indication of pyelitis. On the other hand, in typical cases, the presence of more fever and more severe constitutional symptoms than the bladder or urethral mischief will account for, would raise a suspicion of the affection of the higher portions of the tract. Other signs which may be present are a large discharge of pus in a but faintly ammoniacal urine, and tenderness in the loins. Further, it must be remembered that when these symptoms being present are nevertheless not well marked, the fact of the primary trouble having existed for some years renders it very probable that the kidneys are also affected. When the accumulation of pus has reached the stage of pyonephrosis (*q.v.*) the ordinary symptoms of that condition will be present.

Acute or sub-acute interstitial nephritis gives rise to a febrile temperature, sometimes only observed at night, and together with this there are emaciation, pallor or sallowness of the complexion and great and progressive weakness. Digestive troubles are marked. The tongue varies in its appearance; it may be clean or furred, dry or moist. Nausea and sometimes vomiting are noticed. Either obstinate constipation or diarrhoea may be found. The pulse is frequent and feeble. The urine gives no reliable indications, nor is there any acute pain or tenderness in the loins, although an aching or dragging sensation may be complained of.

When such symptoms come on acutely, with rigors or chills after the passage of an instrument or after some operation upon the bladder or urethra, little difficulty will be experienced in diagnosing the condition. On the other hand, as in

the chronic form, the disease may be insidious and incapable of recognition.

Acute suppurative nephritis gives rise to similar but more marked symptoms. Particularly it must be noticed that the temperature is much higher and subject to great variations. Rigors and sweatings are pronounced, and somnolence and torpor with muttering delirium may be observed in the later stages. The pupils may be either normal or contracted. Pain and tenderness in the region of the kidneys is often complained of.

Prognosis.—The prognosis of all the secondary forms of kidney disease is very grave. They increase greatly the danger of instrumental interference with the primary affection, and indeed no operation should be performed until an attempt has been made to alleviate the symptoms of interstitial nephritis, if these be present. At the same time, it must be stated that treatment adapted to allay irritation from the primary disease often leads to great diminution in severity of the secondary affection, and even to an apparent but temporary cure.

Treatment.—These secondary affections must be treated on the same lines as the same conditions when occurring primarily. The rules for such treatment will be found on reference to the articles on these various subjects. It will suffice here to say that the patient must be kept at complete rest, and on a light fluid diet, while quinine and opium are of use to allay the constitutional symptoms. Cystitis with decomposition and retention of the urine should be treated by washing out the bladder.

ROBERT MAGUIRE.

SWEAT GLANDS, DISEASES OF THE.—The diseases of the sweat glands are principally of functional origin, being due to an alteration either in the amount or in the nature of the fluid secreted. Anidrosis and hyperidrosis are the affections in which there is a quantitative change, bromidrosis, chromidrosis, and uridrosis those in which there is a qualitative change in the secretion.

Anidrosis.—A deficient excretion of sweat occurs in the early stage of febrile disorders, in diabetes and in Bright's disease; it is also found as a secondary phenomenon in various affections of the skin—*e.g.*, ichthyosis, scleroderma, anæsthetic leprosy, prurigo, eczema, and psoriasis. It may result from personal uncleanliness and the consequent accu-

mulation of effete epidermis blocking the sweat ducts. Occasionally also persons are found who never perspire, even after violent exertion on the hottest days, but who present no appreciable structural peculiarity of skin; such persons are usually of phlegmatic temperament, or in a high condition of "training," which appears to have a steady effect upon the peripheral circulation.

Treatment.—Turkish or vapour baths are generally useful, and the re-establishment of sweat secretion gives the greatest relief—*e.g.*, in chronic renal disease, scleroderma and ichthyosis. The undoubted utility of subcutaneous injections of pilocarpin (gr. $\frac{1}{10}$ – $\frac{1}{4}$) in severe prurigo with dense infiltrated patches of skin, is probably also the result of the gradual re-establishment of the sweat secretion.

Hyperidrosis.—A condition of excessive secretion from the sweat glands. It occurs in most diseases accompanied by pyrexia, especially in acute rheumatism and pyæmia; it is a striking feature in the third stage of ague and in the hectic of phthisis and rickets; it is also produced by the action of certain drugs especially pilocarpin, antipyrin, and the salicylates. In these cases the increased secretion is general all over the body and is purely a symptom, not a disease in itself. The sweat is usually normal in character or rather more watery than natural, and it is poured out freely on the surface of the skin. Sometimes, however, it does not escape so readily owing to blocking of the duct from swelling of the structures through which it passes; the sweat then accumulates under the superficial horny layers of the epidermis to form small, clear, transparent vesicles to which the names of *Sudamina vel Miliaria crystallina* have been applied.

Sudamina from their transparency have very much the appearance of drops of water on the skin, but, of course, cannot be wiped off. They are principally found on the neck, chest, back, and abdomen; they form rapidly, but when once formed do not increase in size, nor coalesce to form bullæ, but remain always discrete. In a few days the fluid is absorbed, the vesicle dries up, and there is slight desquamation of the epidermis over the part. In a certain number of cases the appearance of miliaria seems to be independent of excessive secretion of sweat. Sometimes the contents of the vesicles become cloudy, milky, or semi-puriform in character, a

condition to which the name *Miliaria alba* has been applied; it is especially likely to occur over regions to which poultices have been applied.

Inflammation may be set up in the tissues surrounding the sweat glands, secondary to the retention of sweat. This gives rise to some redness round the vesicles, accompanied by slight itching; the contents often become purulent; the eruption is very copious and thickly set so that the skin assumes a vivid red colour, hence the name of *Miliaria rubra* applied to the condition.

The Red Gum or *Strophulus* of infants is in reality a miliaria rubra, and generally results from too much wrapping up; it was previously described as a form of lichen and confused with lichen urticatus.

Prickly Heat (*Miliaria Papulosa* or *Lichen Tropicus*).—A disease which usually occurs among people in hot climates, but persons who have once been affected are liable to suffer from recurrences even in temperate climates, after long intervals and without the usual exciting cause. A condition of affairs exists opposite to that which obtains in miliaria rubra, in that the inflammation around the orifices of the ducts of the sweat glands is primary and gives rise to obstruction of these ducts and so to retention of their secretion, while in miliaria rubra the inflammation is secondary to the retention. The eruption appears suddenly on any portion of the body and usually over extensive areas, but affects especially the forehead and back; it is accompanied by violent itching and there is also profuse perspiration.

Local Hyperidrosis.—Besides the above general hyperidroses a state of excessive sweating sometimes occurs in which a limited portion of the body or certain definite, symmetrical areas are affected. This occurs under two conditions:—(1) as a symptomatic phenomenon associated with lesions or functional disturbances of the nervous system, and (2) as an apparently idiopathic condition. (a) The connection of the nervous system with the secretion of the sweat glands has been clearly demonstrated by physiological experiments. When the sympathetic is paralysed, or the sensory nerve is stimulated, or the vaso-motor nerves supplying a part are divided, profuse sweating occurs there, and it has been found that in certain cases of hemiplegia profuse sweating has occurred on the affected side, the determining factor of which has, however, not been ascer-

tained; the same has been observed in other cases—*e.g.*, a tumour of the meninges pressing on the spinal cord, division of nerves by injury, the sweating of one side of the face after parotid bubo pressing upon the facial nerve. Local hyperidrosis is an occasional sequela or concomitant of neuralgia affecting the fifth nerve or any of its branches. The writer has also observed a very interesting case in which violent sub-occipital neuralgia recurred every night for years, lasting about two hours, when a copious localized sweat broke out giving complete relief to the pain and allowing sleep. The patient had syphilitic disease of the bones of the base of the skull.

(b) In the other condition, without previous or concomitant symptoms, there is a constant or periodic hyperidrosis of certain definite parts of the body, the feet, hands, axillæ, groins, pubes and perinæum being the regions chiefly affected. The amount varies from a mere clammy moisture of the parts to a copious, continual dripping of sweat, and the subjects of the disease are often neurotic or alcoholic. The sweating produces soaking and maceration of the epidermis of the affected parts which becomes opaque and sodden, and soon peels off leaving a red, tender, weeping surface. A secondary eczematous condition often results especially when the hands, feet, and genital region are affected, and to this category belongs the disease described as Dysidrosis by Tilbury Fox. The affection is fairly common, especially among the lower classes, and is very chronic. It is said to be congenital and is sometimes hereditary, affecting various members of the same family.

Associated with this is the affection termed Bromidrosis; the connection between the two will be described later on.

Treatment.—For general hyperidrosis no special treatment is usually required. For the night sweats of phthisis, when excessive, atropine (gr. $\frac{1}{120}$ – $\frac{1}{60}$), picrotoxin (gr. $\frac{1}{60}$), arsenic, belladonna, strychnine and oxide of zinc, are specially useful drugs.

In the chronic local form of the disease great improvement can be effected by appropriate means. The clothing worn next to the skin ought to be made of flannel or wool, which absorbs the sweat. Various methods of medicinal treatment have been recommended—*e.g.*, belladonna, atropine, ergot, agaricin, bitter tonics with the mineral acids, &c., &c., while Crocker strongly recommends precipitated sulphur in drachm doses in

milk, twice daily. The parts may be washed with warm water and carefully dried, after which astringent lotions containing acetate of lead, alum, tannin or hazeline may be employed. More efficacious, however, is powdering the parts with finely divided boracic acid, which may, with advantage, be dusted over the feet and hands, and into the stockings, boots and gloves every day. Salicylic acid, 3 per cent., with starch and oxide of zinc or powdered talc is also most useful, but all these measures are merely temporary, and after discontinuing their use the condition is apt to recur. In such cases the following treatment recommended by Hebra is generally curative:—the feet are to be well washed and thoroughly dried; a dressing made of about equal parts of linseed oil and diachylon plaster melted together with 1 to 2 per cent. of salicylic acid and spread on linen, should be applied to the foot enveloping it entirely, pledgets being inserted between the toes. This dressing is to be removed after twelve hours, the foot rubbed with dry cloths and powdered with starch and the dressing re-applied. This must be repeated twice a day for a week or fortnight, when it will be found that the outer layer of epidermis will peel off, leaving a white surface, and the hyperidrosis will have permanently disappeared.

Preventive treatment is most important in persons liable to prickly heat; they ought to avoid excessive heat and chills, and should be careful to wear woollen clothes both night and day, instead of cotton or linen. The irritation can be relieved by lead, or lead and milk lotion, by calamine lotion (3j ad 5j), or by dusting powders of zinc oxide or salicylated starch.

Bromidrosis (Osmidrosis).—An affection in which the sweat has a disagreeable odour. The condition is generally, if not always, associated with chronic local hyperidrosis, especially of the feet; the subjects are very frequently female domestic servants, and the disease is peculiarly distressing as the odour is sickly, rancid and penetrating. In a few recorded cases, the odour has been considered agreeable, as of flowers—*e.g.*, roses, violets. A specific decomposition takes place in the sweat, due to the presence of demonstrable micrococci and bacteria (*bacterium fœtidum*) which, however, are always present in the macerated epidermis between the toes of uncleanly persons. The sweat, when first secreted, is inodorous, and prob-

ably a great part of the stench is due to the simultaneous decomposition of sebum and the formation of acids of the fatty series. The situations affected are those of hyperidrosis generally, and the treatment is similar, special value being attached to powdering with salicylic acid and starch. German soldiers, who appear to be very prone to the affection, are in the habit of rubbing suet containing 2 per cent. of salicylic acid into the feet night and morning. When the palms are affected, pure silicic acid (*terra silicea*) is even more effectual than salicylic acid.

Chromidrosis (*Coloured Sweat*) is of very rare occurrence, but authentic cases are on record of all the following:—

(a) *Black sweat* (*Seborrhœa vel Steatorrhœa nigricans*) occurs usually in hysterical girls, the part affected being the face, generally above the eyelids; the affection is usually symmetrical. It is certainly frequently associated with chronic constipation, which probably stands in causal connection to it, indican being excreted by the sweat and sebaceous glands, and becoming oxidized to give rise to the dark colour. The amount of pigmentation varies from day to day, and is generally worst before a menstrual period. It forms a deposit on the skin which is washed off with great difficulty, unless ether or chloroform be used. The condition is sometimes simulated by hysterical or designing women.

(b) *Blue or green sweat* is sometimes seen in copper workers; it has also been attributed to taking large doses of iron medicinally.

(c) *Red sweat or hæmatidrosis* may be due either to a micro-organism causing decomposition of the sweat after its secretion, in which case it occurs especially in the axillæ and genital region, or it may be due to an exudation of blood into the sweat gland. This latter condition sometimes occurs in hysterical persons.

Uridrosis, or the excretion of urea in large quantities in the sweat, is observed in cholera, atrophy of the kidneys and uræmia, when the renal functions are in abeyance. The sweat assumes a distinctly urinous odour, and the urea reactions in it are easily obtained.

J. J. PRINGLE.

SYCOSIS (*Folliculitis Barbæ*; *Sycosis Non-parasitica*).—An inflammation of the hair follicles and peri-follicular tissue, usually chronic, characterized by the presence of pustules, tu-

bercles, and occasionally dermic abscesses or fungating excrescences, accompanied by tenderness or burning sensations, and sometimes resulting in scarring and permanent loss of hair. The disease is almost exclusively confined to the male sex, and affects chiefly the hairs of the moustache, beard, and whiskers; it occurs between the ages of twenty and fifty, and, if not treated, may persist for years. An absolutely identical process, to which the name of *Folliculitis* is attached, may affect the hairs of the scalp, axillæ and pubes, either primarily or as a sequela of eczema in these situations.

Eruption.—The appearance presented by true non-parasitic sycosis is subject to great variation according to the duration, acuteness or chronicity of the affection, but pustules perforated at their apex by a hair are invariably present. The moustache is frequently the original site of the disease. The hairs in the earlier stages are firmly attached, and their extraction is painful, but afterwards they lie loosely in the disorganized and patulous follicles, and are easily extracted without pain. In either case they exhibit no fungus under the microscope, but are swollen down to the root from serous infiltration, and the inner root-sheath, which is often detached along with them, may be mistaken for a fungus. Serum, pus, or sanguineous fluid oozes out along the hair shafts or is poured out from the distended follicles after the hairs have fallen or been removed, and the discharges collecting among the neighbouring hairs dry up to form yellow crusts. The progress of the inflammatory process in the peri-follicular tissue (which appears generally to be primarily involved) leads to the formation of large, indurated, prominent tubercles, practically identical with the condition of the scalp known as *kerion*; these, however, are a more prominent feature of parasitic sycosis (*Tinea Barbæ*); from their inflammatory destruction fungoid excrescences or dermic abscesses are formed, the healing of which is accompanied by cicatrization. The scars are frequently the starting-point of cheloid formation. Relapses are common, and persistent treatment is indicated even after apparent recovery.

Ætiology.—The disease affects all classes, and persons who shave as well as those who do not; personal uncleanness is, nevertheless, undoubtedly a predisposing cause. A large proportion of its victims are in poor general health or

suffer from overwork. A specially severe form is sometimes communicated from cattle to man. The immediate causative agent is not known; some attribute the disease to the irritation produced by the growth of a young hair into a follicle before the old hair has fallen, or to excessive size of the hair-shaft; irritant cosmetic applications, blunt razors, &c., may produce it. There is good reason to believe that the exuded pus is infective, suggesting the possibility of a specific micro-organism. The use of the microscope is in all cases necessary to establish a certain diagnosis, especially to distinguish it from tinea barbæ. It may also be confounded with acne, eczema, lupus, and pustular syphiloderma.

Treatment.—Constitutional treatment is often beneficial, iron, quinine, strychnine, arsenic and cod-liver oil being the remedies most generally indicated. In some cases the perchloride of mercury appears to be very serviceable and Donovan's solution has been specially advocated.

(2) *Local.*—The hair must be cut short or very carefully shaved with a sharp razor every day or two. All crusts must be removed by poultices or oil; if the process be very acute and painful, soothing tepid lead lotions ought to be applied. If more chronic, epilation is certainly the best means of cure; the skin having been steamed or bathed in hot water, epilation of the loose hairs only ought to be effected with forceps, each hair being seized separately; a small area ought to be epilated daily, mild mercurial or sulphur ointments being smeared on afterwards, and applied on strips of lint during the night. In the latest stages Unna's zinc-ichthyol salve-muslin is very useful. After recovery, great personal cleanliness must be enjoined.

J. J. PRINGLE.

SYMPATHETIC SYSTEM, AFFECTIONS OF.—It is necessary to consider separately the affections of the sympathetic nerves and of the sympathetic ganglia.

SYMPATHETIC NERVES.—A. **Cervical Sympathetic Nerve.**—Many attempts have been made to stimulate this nerve in the human subject during life by placing one electrode over it, usually just beneath the lobule of the ear, and the other on some indifferent point. The nerve is so deep that by the time the current reaches it, it must have diffused through so many important structures

that it is impossible to be sure that the results which follow its passage are due to its influence upon the nerve. We are therefore, in our study of the cervical sympathetic nerve in man, confined to those cases in which it has been damaged by wounds, tumours, abscesses, or aneurysms. It will be convenient to take the functions attributed by physiologists to this nerve, and to see how each of them is affected in man by disease or injury of it.

(1) The cervical sympathetic nerve contains fibres whose section causes *dilatation of the vessels of the head and neck* on the same side, and whose stimulation causes them to contract. Many cases prove that when in man the sympathetic in the neck has been destroyed from any cause, the affected side of the head shows well-marked dilatation of the blood-vessels which derive their nerve-supply from the nerve above its point of destruction. No observations have yet been made in man which prove that the vessels of the brain are dilated. The retinal and conjunctival vessels, as a rule, are normal, although in some of the lower animals they are dilated after section of the cervical sympathetic. It must be remembered that there are many individual differences in different animals in the distribution of the sympathetic nerves, probably in some the whole of the intra-cranial contents receive their sympathetic supply from the nerves which accompany the vertebral arteries. In man, as in rabbits and cats, the vascular enlargement may last for years. If a tumour irritates the nerve the vessels contract.

(2) There has been a *rise of temperature* on the affected side after destruction of the sympathetic in the neck in all cases in which it has been carefully taken. For example, in one case it was 36.7° C. in the ear on the affected side, and 35.8° C. in the ear on the other side. In one patient in whom the nerve was supposed to be irritated the temperature was lower on the affected side.

(3) *The Pupil.*—All the recorded cases show that in man as in the lower animals if the sympathetic in the neck be destroyed the pupil on the same side contracts, if the nerve be irritated it dilates. The contracted pupil reacts to light, to accommodation, to atropine, and to eserine. Contraction of the pupil is the most constant symptom of destruction of the sympathetic nerve both in man and in the lower animals. It remains contracted for years. As the

sympathetic fibres for the pupil leave the spinal cord chiefly by the second thoracic nerve, affections of the roots of the spinal nerves in this region as, for example, occur in spinal pachymeningitis and in certain cases of aneurysm, cause contraction of the pupil, and as the pupillary sympathetic fibres pass down in the cord from the brain to the second thoracic nerve, it follows that disease of the cervical spinal cord will, if it destroy these fibres, cause contraction of the pupil. Irritation of the cervical sympathetic causes dilatation of the pupil.

(4) *Retraction of the Eyeball* is in the lower animals often observed to follow destruction of the sympathetic nerve, and it has also been seen in some cases in man. In the lower animals it is apparently due to paralysis of the orbitalis muscle of Müller, but in man this is so imperfectly developed that it is difficult to believe that it can have any functional activity. In one case of irritation of the cervical sympathetic the eyeball protruded.

(5) *Narrowing of the palpebral aperture* follows upon destruction of the cervical sympathetic in about 80 per cent. of the cases. It is almost always observed after experimental division in the lower animals. The narrowing is due to an affection of the smooth muscles of the lid, its striped muscles are unaffected. Irritation of the sympathetic in the neck has been known to cause a widening of the opening.

(6) *The Secretion of Sweat*.—In the lower animals a diminution of the secretion is observed on the same side of the head and neck as that on which the nerve was divided. In man the evidence on this point is conflicting. In the majority of cases the secretion is diminished on the side of destruction of the nerve, but in a few it is increased. At present we cannot explain these differences.

(7) *The Secretion of Saliva*.—In the lower animals there is usually a diminution on the side of destruction of the nerve, in man sometimes there is a diminution, sometimes an increase. The reason for these differences is unknown.

(8) *The Lachrymal Secretion*.—In the lower animals this secretion has been observed to be deficient on the side of section of the nerve, and the same result has been noticed in two cases in man.

(9) *Trophic Changes*.—In young animals, if the cervical sympathetic nerve be divided, there is often slight hypertrophy upon the affected side, and also

an increased growth of hair. In man, four cases are on record, in which, after injury of the nerve, there was slight facial hemiatrophy; the bones and hair were not affected. It will be observed that these changes are just the reverse of those which occur in the lower animals. The cause of this difference is not clear.

No other symptoms than these nine are known to be due to extrinsic lesions of the cervical sympathetic nerves in man, except that occasionally, if the nerve be destroyed, there is slight internal strabismus, because the external rectus is to a small extent supplied by the cervical sympathetic.

The order in which the commoner symptoms appear after destruction of the nerve is usually the following:—Contraction of the pupil, narrowing of the palpebral fissure, vascular dilatation, rise of temperature, and alteration in the secretion of sweat.

Wagner stimulated the cut sympathetic in the head of a decapitated criminal, and obtained dilatation of the pupil.

Migraine, exophthalmic goitre, angina pectoris and facial hemiatrophy have all been attributed to intrinsic disease of the cervical sympathetic nerve, but this nerve has never been shown to be diseased in these maladies, and there is no doubt that the theories which attribute them to disease of it are incorrect. We do not know of any intrinsic lesions of the cervical sympathetic.

B. Vaso-motor Nerves.—Many diseases, such as Raynaud's disease, have been speculatively attributed to disease of the sympathetic vaso-motor nerves in different parts of the body, but there is not sufficient evidence in any case for the theory to be worth discussion. In peripheral neuritis, however, the vascular and trophic changes sometimes observed are no doubt due to affection of vaso-motor fibres which form part of the nerve which happens to be inflamed (*see TROPHIC NERVES*). Fagge ("Medicine," vol. i. p. 1002, second edit.) has recorded a case in which a growth involving the nerve-roots at the upper part of the thorax caused vaso-motor changes in the fingers, due no doubt to implication of sympathetic vaso-motor fibres. Dr. Sharkey has recorded a case in which alcoholic neurosis of the vagus caused acceleration of the heart (*see also Splanchnics*).

C. Splanchnics.—There are very few cases on record in which these were diseased. In one published by Dr. Wilks

injury to them was followed by paralytic distension of the stomach, and the writer has recorded a case in the *Pathological Transactions* (vol. xxxvi. p. 67) in which diabetes was associated with neuritis of the splanchnics. This is possibly the explanation of some cases of diabetes, for the splanchnics are the vaso-motor nerves of the liver, and irritation of them will lead to dilatation of the hepatic vessels, a condition which in the lower animals at least is followed by glycosuria.

SYMPATHETIC GANGLIA.—Many authors have described as extrinsic lesions of these bodies œdema, hyperæmia, accumulation of fat and hypertrophy. There is, however, no doubt that these descriptions are based upon errors of observation. The only extrinsic lesions of the sympathetic ganglia that are known are their invasion by neighbouring malignant growths. The writer has examined two cases in which the semilunar ganglia were involved in cancer of the pancreas. In both of them it was interesting to see how the cancer cells grew along and replaced the nerve fibres in the ganglion, so that in section masses of cancer cells could be seen surrounded by the hard fibrous tissue of the ganglion. This mode of growth was probably due to the fact that the nerve fibres offered least resistance. We know of no symptoms which can with certainty be ascribed to destruction of sympathetic ganglia. No conclusions should be drawn from the size of the larger sympathetic ganglia, for even in healthy subjects they vary more in size than do any other organs in the body.

Many diseases have been attributed to intrinsic lesions of the sympathetic ganglia, but those authors who have done so have failed to remember that in the human adult it is normal for the cells of the superior cervical and semilunar ganglia to be small, granular and pigmented. It is probable that the larger sympathetic ganglia in man are functionless, being like the appendix cæci, remnants of organs which in the lower animals have some function. The reasons for this statement are that in human fœtuses and in animals lower in the scale than man the cells are well formed, typical nerve cells, not atrophic, as in man; that the size of the larger ganglia is in human fœtuses, and in most species of lower animals constant, but in adult man it is very inconstant; and, lastly, that in man destruction of the ganglia by disease produces no symptoms

which can be referred to the loss of the ganglion.

The following diseases have been attributed to lesions of the sympathetic ganglia:—

Diabetes.—The changes which have been described in the semilunar ganglia in this disease are pigmentary atrophy of the cells and an increase of the connective tissue; but both these conditions may frequently be met with in patients who have not had diabetes.

Addison's Disease.—The medullary part of the supra-renal capsules is derived from the sympathetic system. Probably it is, like the larger sympathetic ganglia, functionless in adult man, for it is often small in proportion to the size of the whole organ, and even shortly after death is frequently found broken down, while in fœtuses and the lower animals it is larger in proportion to the whole organ and is firm and hard. It is extremely likely that the change often found in the supra-renals in Addison's disease is not the cause, but only a very frequent symptom, of the malady. Congenital absence, cancer and lardaceous disease of the supra-renals in man, and their extirpation in the lower animals do not produce Addison's disease. Occasionally the characteristic change may be found in the capsules without any other symptoms of Addison's disease; and lastly, sometimes the other symptoms of Addison's disease are found, and the characteristic change in the capsules is wanting, for they are only atrophied. These considerations have led some pathologists to believe that disease of the semilunar ganglia is the cause of Addison's disease, but this view is probably incorrect, for extirpation and cancer of the semilunar ganglia does not give rise to Addison's disease. Many of the cases which have been urged in support of this view have been unaccompanied by any microscopical examination of the ganglia and their nerves. Those which have been examined microscopically have only shown changes common in many persons who have had no symptoms of Addison's disease, and lastly, it is probable that in adult man the semilunar ganglia are functionless. We are in fact completely in the dark as to the cause of Addison's disease.

Exophthalmic Goitre.—The view used to be held that this malady depended upon disease of the superior cervical ganglion, but it is now discarded because physiology gives no support to the supposition that the superior cervical

ganglion can influence the heart or thyroid, and because the changes in the ganglion observed in exophthalmic goitre can frequently be found in other diseases.

Myxœdema.—In this disease the connective tissue of the sympathetic ganglia shows the same sodden appearance that it presents elsewhere.

The sympathetic ganglia have been said to be diseased in chronic Bright's disease, epilepsy, acromegaly, progressive muscular atrophy, tabes dorsalis, general paralysis of the insane, lead-poisoning, and syphilis, but all these statements are based upon faulty observation.

Numbers of maladies have been ascribed to functional disease of the sympathetic ganglia and nerves, but in no case is there any sound justification for such an hypothesis.

We have no knowledge that the smaller sympathetic ganglia are ever diseased in man.

In the *Guy's Hospital Reports* (vol. xlv.) and the *Journal of Physiology* (vols. viii. and x.) will be found articles by the writer in which the views of the functions of the sympathetic nerves and ganglia here given are described at greater length.

W. HALE WHITE.

SYNCOPE (Faintness).—A sudden loss of consciousness and motor power due to cardiac failure.

Symptoms.—The onset is more or less sudden (where heart disease exists it may be very sudden), the person turns pale, becomes giddy, and, if not seated, staggers. The skin is pale and clammy; the pupils are dilated and the eyes closed; the pulse is weak, frequent and irregular; the heart sounds are very weak and the respiratory movements are imperceptible; there may be vomiting, then complete unconsciousness follows, and the patient falls to the ground. From this state after a variable time the patient gradually recovers, slight sighing or movements of the limbs being often the first sign; colour then returns to the lips and warmth to the hands. As a rule, an attack does not last more than a minute or even less; but in cases of organic disease the duration may be considerable. When due to loss of blood there are sometimes general convulsions. A relapse, when it occurs, suggests that hysterical tendencies are present.

Ætiology.—Syncope may be due to organic disease of the muscular substance of the heart, but on the whole, it more often occurs apart from that

condition. Either the nutrition of the ventricular walls, or the nervous mechanism of the heart may be at fault, or owing to hæmorrhage an insufficient quantity of blood may reach its cavities. Amongst the exciting causes, apart from organic disease, exhaustion plays a prominent part, induced it may be by hunger, by breathing a vitiated atmosphere, by exposure to excessive heat or by wearing tightly fitting clothes. Sudden emotion, especially fear, is often the cause, while an unpleasant sight or smell or even a sudden sound will cause syncope in some individuals.

Treatment.—If the person be seen at the commencement of the attack, and if there be no cardiac disease, loss of consciousness may generally be prevented by making him sit down and stoop forward with his head between his knees, the feeling of faintness will soon pass off, and fresh air and a glass of water will complete the cure. When actual fainting has occurred the patient should be placed flat on his back and the clothes about the neck, chest and abdomen loosened, the windows should be opened and every means taken to secure a free access of air. In most cases spontaneous recovery will take place, but this may be aided by the administration of a little alcohol or sal volatile in water, or by the use of smelling salts. Should these measures fail, 5 to 15 minims of ether in water may be injected subcutaneously. Artificial respiration, galvanization of the phrenic nerves, and, in desperate cases, transfusion, may be resorted to.

SYPHILIS.—Syphilis belongs to a group of diseases which has increased in interest and importance since the relation of micro-organisms to certain morbid process has been properly recognized. This group, termed infective granulomata, comprises, besides syphilis, such diseases as tuberculosis, glanders, leprosy, actinomycosis, and the like.

Syphilis, in its clinical and histological features, is a typical example of the group. It is due to the introduction into the body of a virus from another individual, all the diseases of this group being inoculable or infective. The place of inoculation in syphilis becomes the seat of tissue-change, and then the poison spreads throughout the body. After a period varying within certain well-known limits, the skin and mucous membrane exhibit characteristic lesions, and after a variable time, swellings, resembling in structure granulation-tissue, form in the

various organs of the body. It is usual to divide the course of syphilis into three stages, primary, secondary and tertiary.

Primary Stage.—This varies in duration from six weeks to three months: it dates from the appearance of the initial sore, or chancre, until the advent of the constitutional symptoms which indicate the commencement of the secondary stage.

The *primary sore* or *chancre* appears from three to five weeks after inoculation as an excoriation, pimple or vesicle. This may increase in size and remain as a hard spherical dusky red pimple, but in the majority of cases it gradually enlarges and the centre breaks down, leaving a circular ulcer, the base and sides of which are hard and gristly to the touch. Sometimes the ulcer is at first soft, the induration ensuing subsequently. Under the microscope these indurated sores appear as an infiltration of small cells into the connective tissue. Gradually larger cells make their appearance and occasionally giant cells are seen. The greater part of this tissue breaks down, a part resolves and the remainder becomes converted into cicatricial tissue which persists and indicates the situation of the original lesion. As syphilis is most commonly contracted during sexual congress, the most frequent place for chancres is on the external genitals of both sexes, but indurated chancres may occur in such situations as the lips, cheeks, tongue, nipple, eyelid and finger. These are known as *erratic chancres*, and they often remained unrecognized until the appearance of the secondary rash unmistakably discloses their true meaning.

Soon after the appearance of a chancre the adjacent lymph-glands enlarge. In the case of the genitals it will be the oblique inguinal set, often on both sides; for the hand, the epitrochlear gland; for the mamma, the axillary set; for the lips and tongue, the sub-maxillary; for the eyelid, the pre-auricular glands. This enlargement and induration of lymph-glands may subside as the chancre heals; often they persist much longer and even remain obdurate in spite of treatment.

Secondary Stage.—This may commence at a period varying from six to twelve weeks after the initial sore. It is ushered in by a roseolous rash in typical cases, accompanied by a slight rise of temperature and a sore throat. As the roseola fades a papular or pustular eruption appears which may mimic almost

every known form of skin eruption. The spots are fairly symmetrical, cause little local discomfort, tend to disappear in the course of a few weeks, generally exhibit a coppery hue, and leave a pigmented stain after the papule has disappeared. The eruption on the mucous membrane takes the form of smooth raised circumscribed patches, mucous plaques; these are best seen on the tongue, near the tip, the soft palate, tonsils and lips, the margins of the anus, and on the labia of women. These mucous plaques are due to inflammatory change and infiltration of the upper layer of the corium and epithelium. Often raised patches, resembling mucous plaques, are seen in the soft skin between the toes.

Some weeks after the skin rash has appeared more serious lesions may become manifest, such as iritis, periostitis, without the formation of nodes, and painful affections of joints and tendon sheaths, frequently mistaken for rheumatism. At this stage the hair may fall (alopecia) and inflammation may affect the margins of the nail (syphilitic onychia). Epididymitis is an occasional complication and coincident with such symptoms, the general health suffers and anæmia supervenes.

During the course of the next few years, that is between the manifestations of the early secondary symptoms and the more typical lesions peculiar to the third stage, a syphilitic patient may be troubled with such affections as inflammation of the skin of the palms and soles (palmar and plantar psoriasis), a peculiar form of choroiditis, inflammation of the internal coats of arteries (syphilitic endarteritis), especially those of the cerebrum, white patches upon the tongue (leucoplakia), gyrate unsymmetrical rashes on the skin, especially on the forehead (corona veneris), and occasionally an acute form of laryngitis. These are sometimes referred to as late secondaries, or the *intermediate* symptoms.

Tertiary Stage.—Although the lesions of the third stage are characteristic enough, they begin at no definite period like the secondaries; they may appear four or five years after the initial sore or be delayed for ten, fifteen, or even twenty years. This stage is characterized by the formation of circumscribed patches of morbid tissue like granulations, in the organs, and known as *gummata*. A gumma is a very unstable body, it is somewhat spherical in shape, and in the early stage soft and gummy, hence the name. Often it undergoes absorption

and gives rise to no trouble. As it is poorly supplied with blood-vessels the central parts break down or caseate. The cells may become converted into scar tissue, the gumma then contracts, and a cicatrix forms. When seated in or near the surface of skin or mucous membrane gummata exhibit a strong tendency to soften and ulcerate, especially if irritated. A gumma may occur in any organ; lung, liver, spleen, kidney, brain, heart, testes, muscles, supra-renal capsules, in periosteum, where it is often called a node, and in connection with the dura mater and skin. Often the formation of a gumma is determined by injury. In a case known to the writer a gumma formed beside a small hydatid cyst in the liver. A blow or crush of the testis may be followed by the formation of a gumma in the organ; a blow on bone, which, under ordinary circumstances, would be of no moment, produces a node; an irritant tooth induces a gumma in the tongue; a strain of the biceps or rectus may be followed by an intramuscular gumma.

Gummata vary considerably in size. Usually they are noticed when of the size of a ripe cherry. In viscera they attain the dimensions of walnuts or Tangerine oranges, but visceral gummata rarely break down. When of large size in connection with joints and periosteum there is little doubt that they are frequently confused with sarcomata, a mistake of obvious disadvantage to the patient.

Pathology.—As stated at the commencement of this article, the clinical and morbid anatomy of syphilis indicate emphatically that it is identical with those diseases known to be due to the entrance and multiplication in the system of pathogenic organisms. As yet no one has succeeded in isolating the syphilitic virus, and no positive facts are forthcoming as to whether it is due to a micro-organism or a chemical poison. Micro-organisms have been detected in syphilitic lesions, but they have not fulfilled the conditions necessary to establish the fact that they are the cause of this disease, that is, they should be constantly present in the lesions; secondly, they require to be cultivated in media apart from the body, and, lastly, when the products of pure cultivation are introduced into an animal they should produce the lesions peculiar to the disease. So far as syphilis is concerned, these conditions have not been fulfilled; this may in part be owing to the remarkable fact that syphilis, so far as our present

knowledge goes, is a disease peculiar to human beings. No one has detected syphilitic lesions in the lower animals, nor satisfactorily produced "complete" syphilis by direct inoculation even in monkeys.

Treatment.—Two drugs are specific for this disease, mercury and several of its salts, and iodide of potassium. It is impossible to give modes of treatment for every case that comes before the practitioner, but it is important to bear in mind that the primary stage requires mercury, and this is easily administered in the form of blue pill or grey powder. The induration of the chancre and glands rapidly disappear during its administration. When the secondary rashes appear iodide of potassium must be given as an *adjuvant* to the mercury. The latter drug should be exhibited for at least a year, the dose being varied according to the constitution of the patient and the practitioner's experience of the case. Even in the anæmia of syphilis mercury acts as a tonic, but in the tertiary stage its effects are often detrimental, then iodide of potassium is usually a most potent drug. In this stage it is well to begin with small doses gradually increased, for patients rapidly acquire a toleration of iodide of potassium.

Minor, but distressing, troubles arising in the course of the disease, such as the sores on the lips, mouth, throat, anus, &c., require special applications and modes of treatment apart from the general therapeutics of syphilis and are considered elsewhere (*see* SYPHILITIC AFFECTIONS OF THE SKIN; *also* SYPHILIS, CONGENITAL).

J. BLAND SUTTON.

SYPHILIS, CONGENITAL.—The variations in the clinical characters of inherited syphilis are very numerous and may be of every possible kind. In practice certain combinations of symptoms are of frequent occurrence and others are rare. No proposition is more true than that inherited syphilis may exert an influence on the nutrition and function of every tissue in the body; at the same time some tissues are much more prone to be affected than others. To draw hard-and-fast distinctions between hereditary and acquired syphilis is warranted neither by clinical nor pathological observations. It is unnecessary here to discuss Colles's law, which states that the mother never having shown signs of syphilization may yet suckle her syphilitic child without herself being tainted.

Syphilitic semen appears to be the commonest source of a syphilitic child, the ovum of the mother being tainted but the rest of her organism frequently escaping.

Hereditary syphilis, rickets, and improper feeding are the most potent causes of disease during the first months of life, and there is often adequate proof of the influence of each of them having been in operation in the same infant. This very mixture of causes is a fruitful source of difficulty in diagnosis. Syphilis may cause lesions and death of the fœtus and of the newly born as well as of infants of all ages. Miscarriages, premature births and still-births are its familiar consequences.

Early Manifestations of Congenital Syphilis.—The commonest manifestations after birth are inflammatory changes and their consequences about the junctions of the mucous membrane with the skin. The eruption about the nates in syphilitic infants differs from that produced by the napkin, in its coppery tint and in not being strictly limited to the region covered by the napkin, but spreading down the calves and legs. Some believe that syphilis may cause an eruption indistinguishable from one due to indigestion or other form of irritation, except in that it disappears when mercury is administered. The nature of the syphilitic lesion varies widely. There may be redness and infiltration with slight desquamation of the skin, or a weeping surface, or a more squamous area; tubercular infiltrations, coppery maculæ and roseola are also met with.

An inflammation of the nose, rhinitis, is commonly present, and may proceed to ulceration and caries, with the result of bringing down the bridge of the nose to a varying extent. In the early stages the coryza of rhinitis causes the familiar "snuffles."

Pemphigus neonatorum is rare, and generally appears during the first days of life; large bullæ arise on the buttocks, palms, soles, and even elsewhere; they are generally flaccid, and contain a seropurulent fluid; the disease is frequently fatal; some cases are probably not syphilitic; in two fatal cases the writer found no syphilitic or other internal lesions.

Other early manifestations are—Infiltration, redness and desquamation of the soles, and sometimes of the palms; pigmented areas on which blebs or bullæ may arise; crusts and scabs resulting from bullæ, and red raised scaly patches

spreading in rings, differing very little from ringworm in external appearance. There may be a very general infiltration of the skin, which may feel tough and suggest scleroma, or tough and dry, reminding one of parchment or wash-leather. The finger- and toe-nails are sometimes cylindrical and stained as if with picric acid; the palms and soles may show a similar staining; there may be hard swellings of the testicles with or without hydrocele; the tongue may present "wash-leathery" looking patches, serpiginous ulcerations and gummata; the so-called superficial migrating glossitis (mapped or geographical tongue) is not always syphilitic; ulcers may appear in the mouth, with diffuse stomatitis and gingivitis, leading rarely to alveolar necrosis. Subcutaneous tubercles, differing from scrofulous indurations in being more numerous, more prone to suppuration and to bleed freely when opened; condylomata, more often found after the seventh month than before, and not accompanied by other cutaneous lesions and craniotabes of the occipital and postero-parietal region, constitute other evidences of the condition. A hoarse cry from laryngeal disease, diffuse catarrh, mucous tubercles, or general hyperplasia and ulceration may appear.

Syphilitic pseudo-paralysis of the limbs, due to inflammatory disease at the junction of the shaft and epiphysis in the most growing area, is characterized by immobility, tenderness, and symmetry. The faradic irritability of the nerves is not impaired, the knee- and elbow-jerks are not lost; indeed the faradic, galvanic, and mechanical irritability of the nerve-muscle seem rather increased. The knee-jerk is not lost even when the epiphysis is separated from the shaft. The affection is very common about the knee-joints, elbow, and wrist, and is most frequently observed before the age of ten months; it may be mistaken for infantile scurvy, but the cachexia and tenderness are more marked—as a rule—in the latter affections, and the induration involves the shaft more than in the syphilitic disease. Cases of mixed scurvy, rickets, and syphilis are occasionally seen.

The Later Manifestations of Congenital Syphilis may occur at any period after two years of age; they are apt to appear at the beginning of the period of second dentition and at puberty.

The rhinitis may smoulder for a long time, and may appear to have died out and then may light up again. From this

may result bloody discharges and pharyngeal secretions, ulceration, sloughing, and, finally, scarring; the soft palate getting united more or less extensively to the back and sides of the throat. To distinguish this from scrofula is sometimes difficult. The soft palate and nasal septum may be perforated by ulceration. Ear disease of almost any kind may arise in connection with the disease of the nose and throat. Deafness may result from changes in the true internal ear, exudation taking place into the cochlea and semicircular canals. But the commonest signs of past congenital syphilis are to be looked for in the bones, teeth, cornea, and in radiating linear scars about the mouth, nose, and anus, involving the mucous and cutaneous surfaces. Occasionally within the oral and nasal circles a vein-like marking recalling that of leaves may be seen; this is really a furrowing, but the cuticle has not been thrown off; beneath the cuticle there has been syphilitic tissue which has been absorbed.

The protuberant frontal eminence may be the expression of a past syphilis, but true bossing is found around the site of the anterior fontanelle. It is doubtful whether pure syphilis delays or quickens the closure of the anterior fontanelle. A want of clearness in the complexion is often present; opacity of the cornea is very common; the cornea may be simply foggy or the opacity may equal that of white porcelain. The keratitis is of the well-known interstitial type, it is most frequent during second dentition, but may be seen as late as thirty years of age; females suffer more than males; the rate of its appearance and disappearance varies much, but one eye is usually affected before the other. Iritis without keratitis is a rare symptom. Diffuse disseminated choroiditis, resulting in irregular pigmentation and atrophy, is also due to inherited syphilis; the colour of the pigment may be rusty or coppery or black. The ulnæ, lower ends of humeri, clavicles, tibiæ and the calvaria should be examined for diffuse or nodose enlargement; in the tibiæ pains may be complained of but rarely in the other bones, unless, which is unlikely, the headaches are to be attributed to Parrot's bossing. Dome-shaped molars and notched and pegged upper central incisions of the second set are the most characteristic dental changes in syphilis; stunted teeth and wide spacing of the teeth are also observed. The bones, teeth and cornea are apt to be

affected at much the same time in the same patient but any variety and any combination may be noted.

Morbid Anatomy.—Bone changes in syphilitic fetuses are most manifest in the area of junction of the shaft and epiphysis, where growth is most active. Contrasted and compared with rickets the changes are of great interest. The calcified lamina on the shaft side of the proliferating cartilage is much thicker and more irregular than in health; the marrow itself is more fluid and vascular; a considerable formation of soft bony material appears beneath the periosteum: excessive calcification, periostitis, and endostitis of the fungating kind being, briefly, the most marked changes. The process may lead to the separation of the shaft from the epiphysis, with or without the formation of pus. Sometimes a thin shell of periosteal bone can be separated from the endosteal bone, much as a pea can be removed from its pod. The changes are the same or very like those which cause syphilitic pseudo-paralysis.

The lungs may present white hepatisation in the new-born—large tracts or even a whole lobe of a lung having a pale, smooth aspect, the section not being granular, the consistence generally increased and the microscope revealing a fibrous interstitial overgrowth with atrophy of the pulmonary vesicles; the same condition as results from atelectasis. Probably this hepatisation is always a sub-acute process, at any rate it is rare to find a markedly cellular non-fibrous specimen. Nodules resembling gummata occur in the liver, with or without perihepatitis and adhesion to the abdominal parietes. The spleen may be enlarged, its section being uniform in appearance, of a dark-red colour, its consistence firm, and its borders unusually notched or lobulated, as the result of inflammation of the capsule. The capsule is thickened and puckered, and sometimes adherent to the abdominal parietes; the colour of the thickened tissue may be opaque white or buff coloured. The heart muscle may be the seat of diffused syphilitic tissue—the colour of the affected areas being milky white—and rarely of caseous gummata. Interstitial nephritis has also been described. Typical arteritis, choroiditis, meningitis, gummata in the substance and on the membranes of the brain and cranial nerves and enlargement of lymphatic glands, have been found in post-mortem examinations of syphilitic

children. The brain may be atrophied and sclerosed, with or without meningitis, and arteritis. Lepto-meningitis infantum—posterior meningitis—is sometimes syphilitic (see paper by writer in *Path. Trans.* 1889 and *Brain*, 1883).

The thymus may be the seat of supuration, the pus being laudable or cheesy. Even lardaceous disease of the liver, kidneys, spleen, and intestines may arise.

Treatment.—Attention to the dietary and to other matters on which the general health depends may suffice to enable the child to overcome its syphilitic taint. The syphilitic child may be nursed by its mother. A cotton wool dress should be ordered if the infant is shrivelled and has the “old man” look. As such children are specially susceptible to the influence of bad air, bad food, and cold and damp, great attention must be given to all these particulars. Ulcers and fissures may heal without the aid of mercury, by simply keeping the parts clean and protected from every kind of irritation, including the atmosphere; but mercury promotes the soundness and increases the rate of the cure.

Hydrargyrum c. creta is the best mercurial preparation; it should be given in grain doses, three times a day. Should it appear to derange the intestines or stomach, which is seldom the case, bismuth or bicarbonate of soda may be given with it. In bad cases, rubbing blue ointment into the thin skin of the belly or armpits is the only mode which should be practised. The skin should be cleansed freely with soap and water before each inunction. Syphilitic meningitis, laryngitis and hepatitis (with or without ascites) should each be treated by local inunction of blue ointment. The head and neck should be shaved in the first-mentioned disease and the ointment freely rubbed into the skin of the back of the neck and into the shorn scalp. The enlarged spleen does not diminish to any appreciable extent under the use of mercury; probably the repeated and prolonged congestion has led to the overgrowth of fibrous tissue, and this form of fibroid overgrowth is not so easily removable as that which is the product of syphilis alone. Any antiseptic preparation is useful for skin and mucous lesions—*e.g.*, iodoform, calomel, boric acid; but rest, cleanliness and avoidance of irritation are of equal importance. Ozæna is best treated by sea air, local medication and good living. Cod-liver oil and syrup of the iodide of

iron are as useful in syphilis as in scrofula. If the chalk preparation cannot be borne the liquor hydrargyri perchloridi in half-drachm doses may be used.

ANGEL MONEY.

SYPHILITIC AFFECTIONS OF THE SKIN (Dermatosyphilis, Syphiloderma).—It is still usual to describe syphilodermata as “secondary,” “late secondary,” and “tertiary,” although there is no clinical or pathological justification for drawing so artificial a distinction. Certain characteristics are usually ascribed to early or “secondary” rashes, and although no single one among them is peculiar to syphilitic lesions—which differ in no sense morphologically from non-syphilitic—their *ensemble* constitutes, nevertheless, a striking picture which may with advantage be retained in the mind.

Characters of Early Syphilitic Eruptions.—(1) They are of reddish brown, coppery or raw ham-like colour, and leave pigment-stains; the transudation of blood-pigment upon which this depends is common to all rashes where there is blood stasis, especially in dependent parts.

(2) They exhibit marked symmetry—like the erythemata and many other groups.

(3) They frequently affect the forehead (corona veneris), the sides of the mouth and nose, the soles and palms, the flexor aspects of the limbs and the nape.

(4) They are polymorphous—*i.e.*, various types of eruption, or various grades or stages of evolution of the same type, are frequently present at the same time. Although not an exclusive appanage of syphilides the character is an important one: hence the necessity for the fullest possible exposure and examination of doubtful cases.

(5) They show a tendency to circular grouping—a minor point.

(6) They seldom itch or cause subjective symptoms except when markedly desquamative, or when irritating applications have produced secondary eczema.

(7) They develop slowly as compared with certain exanthematous rashes which most closely resemble them.

The so-called “tertiary” rashes are always ulcerative and result from the breaking down of gummata in the skin or subcutaneous tissue. Their general characteristics are:—

(1) They occur on any part of the body—as contrasted with simple ulcers—

which almost invariably are situated on the legs.

(2) They are unsymmetrically distributed, although not usually confined to one side of the body.

(3) They extend centrifugally by a raised, infiltrated edge while healing in the centre; horseshoe-shaped, kidney-shaped and serpiginous ulcers being thus formed.

(4) They affect the palms, soles and roots of the nails with great frequency.

(5) They form rapidly, and the pain accompanying them is usually less than that caused by the disease in the same situation which most closely resembles them (lupus).

(6) They leave flat white scars.

Kaposi points out that all syphilides possess these essential characteristics which serve to distinguish them from all other eruptions—viz., (a) they are always sharply defined, uniform, cellular infiltrations of the papillæ and corium, varying only in size; (b) these cells never organize forming permanent tissue, but are either absorbed or break down and pustulate; (c) the lesions always extend centrifugally, the oldest—i.e., central portion disappearing first.

For descriptive purposes the classification of Baümler may be adopted with slight modification.

Group I.—Circumscribed Hyperæmia of the Papillæ with slight Infiltration.—The macular or roseolous syphilide is usually the first symptom of syphilis which succeeds the primary sore and adenopathy, both of which it may occasionally precede. It generally occurs from six to twelve weeks after inoculation, or as a symptom of relapse within the first twelve months; in the former case its appearance is often heralded by a few days malaise and evening pyrexia, often considerable (103° F.), and is accompanied by symmetrical congestion and superficial ulceration of the tonsils. The rash consists of discrete, erythematous spots varying in size from a lentil to a finger-nail, the edges not well defined, at first of a bright pink colour obliterated by pressure, afterwards dull and pigmented, causing a "marbled" appearance, brought out well by exposure to cold. They last from a few days to two months, and do not desquamate. Generally they occur on the abdomen and flanks, then on the fronts of the arms, the back and sides of the neck; they are rare on the face and backs of the hands. Occasionally an undue amount of effusion may cause them to resemble

urticaria. Up to the end of the third year a form of erythematous rash, consisting of large, persistent ringed spots occasionally shows itself (roseola syphilitica annulata).

The disease must be differentiated from measles, rōtheln, urticaria, tinea versicolor, seborrhœa corporis, pityriasis maculata, and many medicinal rashes.

Group II.—Marked Infiltration of the Papillæ.—The large or lenticulo-papular syphilide is perhaps the commonest and most important syphiloderm. Smooth, shining, dusky red papules the size of a lentil, or larger, and at first circumscribed, develop in the flexures, on the front of the arms, forehead, back of the neck, borders of the scalp, in the groins, between the mammæ, round the mucous orifices, and in receding angles of the skin (e.g., alæ nasi). They do not suppurate, but after absorption leave atrophic depressions, at first pigmented, but afterwards brilliant white. Often one of the earliest syphilodermata, they may occur along with the macular syphilide and constitute the commonest relapse form during the first five or ten years. Their abundance is usually proportional to the earliness of the period at which they appear. In late relapses they tend to affect the angles of the mouth and the "web" of the toes, where they may cause painful and obstinate rhagades.

They may become (a) squamous, (b) moist, (c) circinate.

(a) The large papulo-squamous syphilide is characterized by the presence of scanty, thin, dirty-looking scales on a dull red papular base. The scale is the result of the shrinkage of the formerly tense epidermis after the absorption of the central portion of the papule. Its distribution has already been described. The condition frequently mis-called psoriasis palmaris et plantaris is the result of the development of this syphiloderm on the palms and soles, modified by the anatomical peculiarities of the parts, especially by the thickness and resistance of the epidermic layers. The papules are scarcely at all raised, and appear as dusky blotches over the centre of which fine scales may form; more frequently the epidermis splits and becomes opaque; sometimes minute perforations may occur, or the central portion, may be shed, leaving an irregular breach of surface with frayed, ragged edges and dusky red base. The condition affects the centre of the palm and ball of the thumb, and may extend to the wrist, where its raised spreading

edge is speedily recognizable, but it never affects the dorsum of the hands, and is not accompanied by pain, burning or itching. If it occur as a late manifestation, it is often one-sided and obstinate to treatment. It must be carefully differentiated from palmar eczema and psoriasis.

(b) *The moist papular syphilide, flat condyloma or mucous patch* is the result of the maceration and removal of epidermis from papules where subject to contact, friction, warmth, moisture and dirt; thus they occur about the anus, perineum, genitals, navel, armpits and in the flexures; their surface is covered with greyish detritus, and their secretion is very infective, usually producing condylomata rather than hard sores.

Mucous patches are the commonest starting-point of the condition known as syphilis eutanea vegetans vel frambesiformis, which consists in the rapid outgrowth of red, warty, cauliflower excrescences; these, although formidable in appearance, are very amenable to local treatment. They sometimes also originate from gummatous lesions.

(c) *The early circinate syphilide* is a very rare form, chiefly affecting the forehead, nose and chin; it probably begins as a papule, the centre of which is rapidly absorbed, leaving healthy looking skin, whilst the edge only persists as a delicate, thread-like ring. Several of these generally coalesce to form elaborate gyrate figures; they may be mistaken for tinea circinata.

Group III.—Marked Infiltration especially implicating the immediate vicinity of the Hair Follicles.—*The miliary, lichenoid, or small papular syphilide* is of comparatively infrequent occurrence. The papules vary from the size of a poppy-seed to that of a pin's head, are closely packed in groups or circles and each is pierced by a hair. They occasionally develop as an early relapse rash in cachectic individuals, when they affect the shoulders, arms, trunk and thighs; they are extremely obstinate to treatment. More frequently a few papules appear in late relapses about the mouth and eyes, and in the flexures.

(a) *The miliary papular syphilide* is the typical form just described; it often itches and heals, leaving deep atrophic scars, after copious desquamation; or it may develop into the two following forms. It closely resembles lichen ruber, lichen scrofulosorum, keratosis pilaris, or even psoriasis guttata.

(b) *The miliary vesicular or herpeticiform*

syphilide is a very rare syphiloderm, which occurs usually in successive crops on regions where the skin is thin, especially the face and genitals, in the first six months of the disease along with other manifestations. The vesicles may or may not be umbilicated, the fluid in them remains clear for many days and after its absorption, light grey crusts and minute umbilicated depressions are left.

(c) *The miliary acuminated pustular syphilide* is also derived from the miliary papular syphilide, and is commoner than the herpeticiform variety; a bead of pus forms at the apex of each papule, and after separation of the resulting crust, a minute, deeply pigmented scar is left.

(d) *The large acuminated pustular, or acneiform syphilide* is closely allied to the last form, but its base is more extensive, and deeper suppuration occurs; it follows closely upon inoculation, in association with other syphilodermata and tends to affect especially the scalp, face and trunk. It is commoner in negro than in white races, and its course is usually rapid and benign; it may closely resemble bromide or iodide rash. *The varicelliform or varioloid syphilide* is the highest grade of this syphiloderm. The vesicles are sometimes umbilicated, the pustules may be as large as a pea, the dusky halo round the base of each is marked, the pyrexia attending their development is high, the scars following their subsidence are deep and honeycombed.

Group IV.—Deep Infiltration with sub-epithelial Suppuration and superficial Ulceration.

(a) *The superficial ecthymatous syphilide* which begins as a flat papule soon forms a flat pustule and desiccates, forming a brown scab, which, when separated, leaves a flat cicatrix. It occurs most commonly on the back, shoulders and limbs from the sixth to the eighth month after inoculation.

(b) *The deep ecthymatous syphilide* is distinguished by the increase of suppuration and the deeper extension of the ulcerative process. It forms the basis of the form of syphiloderm known as *Rupia*, and characterized by the limpet shape, lamination and imbrication of its crusts, due to continuous formation from beneath. The condition is a somewhat rare one and occurs in cachectic individuals, either within the first twelve months of the disease or later; it requires special tonic treatment.

(c) *The bullous or pemphigoid syphilide* exhibits larger blebs and a less marked areola than the last form; it is seldom

present in other than congenital cases.

Group V.—*Gummatous Infiltration with Ulceration* may be either cutaneous or subcutaneous.

(a) *The tubercular or lupoid syphilide* is the result of infiltration of the papillæ and corium; the nodules are deep red, brownish or yellowish in colour, vary from the size of a pea to that of a bean, and are commonest on the face and back, usually grouped in circles or corymbose clusters. They never occur until at least two years after inoculation; they are very chronic and usually painless. They leave serpiginous scars; their differentiation from lupus is frequently a matter of extreme difficulty. The age of the patient, the duration of the disease, the rapidity of its extension, the characters of the scars, the presence of other syphilitic manifestations and the result of treatment will usually guide to a correct diagnosis.

(b) *Subcutaneous gummata* form the basis of the so-called "tertiary" ulcers already partially described. They are at first deeply situated, hard, elastic and frequently painful; they occur in small numbers and generally in regions where the tissues are lax,—e.g., flexor surfaces of limbs, abdomen, thorax; the resulting ulcers are sharply cut, "punched out" with undermined edges and uneven base covered with dirty-looking gummy deposit; they often cause necrosis of subjacent bones or cartilages.

Pigmentation in Syphilis is usually the result of antecedent roseolous, papular, pustular, or ulcerative lesions, but a special and independent form of pigmentary syphilide is comparatively common in young women and weakly lymphatic men with thin skins. This shows itself as brown spots or patches on otherwise healthy skin, from six to twelve months after inoculation; usually first on the back of the neck, to which it gives a "dappled" appearance, or on other exposed parts, from which it may gradually spread over the whole body. If slight it may only cause some "muddiness" of complexion; if severe the pigment is irregularly distributed, and the condition exactly resembles on the one hand leucoderma, on the other those diffuse forms of chloasma which accompany many cachectic diseases. It probably does not depend directly upon the syphilitic virus, and this view is borne out by the complete futility of anti-syphilitic treatment directed towards its removal. Leucodermatous patches independent of

antecedent pigmentary rashes have been occasionally observed, although their existence has been disputed, especially by German writers.

Alopecia in Syphilis.—Baldness frequently accompanies the various stages of syphilis. In the first three to six months it usually results from the development of erythematous or papular rashes on the scalp; the hair falls uniformly all over the scalp, and frequently also from the eyebrows and genitals; permanent baldness from this cause is very rare. Seborrhœa causing partial baldness is also common. Occasionally baldness appears to result from disordered innervation or cachexia, the scalp presenting a normal appearance. Late ulcerative lesions cause permanent baldness. Syphilitic infants are frequently quite bald.

Treatment.—Most English authorities approve the internal administration of mercurials as soon as the diagnosis of syphilis seems fairly established, without waiting for its confirmation by the appearance of roseola. The Vienna school condemns such treatment, and considers that although the "secondary" efflorescence may be thereby delayed, it is usually aggravated in intensity, and so altered in type as to become confusing to the medical attendant. No such difference of opinion exists as to the value of mercury after the appearance of rash. It may be administered by the mouth, by inunction, by fumigation, or by hypodermic injection. Grey powder and blue pill are the preparations usually given in the earlier stages internally, and preferably in small, oft-repeated doses. The liquor hydrargyri perchloridi, often advantageously combined with bark, and the green proto-iodide of mercury, are those most frequently used at a later period. It is necessary in every case to watch the effects of the drug with care, not only because individual susceptibility varies greatly, and even minute doses are occasionally not tolerated, but also because in non-susceptible individuals the dose ought to be cautiously increased up to a point just short of the establishment of its physiological effects. Meanwhile, any tendency to diarrhœa must be counteracted by combining the mercurial with opium or hyoscyamus. Quinine, iron, cod-liver oil, and other tonics are often imperatively indicated, and general hygiene is of the greatest importance. The diet ought to be simple, and alcoholic excess is specially harmful. Flannel clothing ought to be worn to guard

against chills. Particular attention must be paid to the condition of the mouth and gums; tartar ought to be removed, carious teeth extracted, a soft toothbrush used several times daily and astringent gargles and mouth-washes sedulously employed. Smoking ought to be prohibited. It is well to continue mild mercurial treatment for one year after the initial lesion, even if the skin lesions have been slight. Some think that the use of mercury in any form is contra-indicated by albuminuria, and it appears occasionally to cause phagedæna, when its discontinuance in favour of opium is desirable.

For inunction twenty grains of blue ointment or of a 5 per cent. oleate of mercury ointment with lanolin may be rubbed into the groins, axillæ, or popliteal spaces every night, the site being varied to avoid local irritation. This method is invaluable for children. For fumigation calomel is usually employed, twenty or thirty grains being evaporated over a spirit lamp, beneath a wicker-work chair on which the patient is seated naked, and covered with a blanket. Both inunction and fumigation sometimes suddenly produce severe salivation.

The subcutaneous injection of mercurials has hitherto not found much favour in England, although its action is rapid and effectual, and it does not interfere with the digestive functions. One-third of a grain of the perchloride dissolved in twenty minims of distilled water may be injected once, or at most twice, a week deeply into the gluteus maximus muscle. The tannate, albuminate, formate, and peptonate are also employed, their efficacy being apparently proportional to the slowness with which they are eliminated from the system.

The iodides of potassium and sodium have little or no influence on the earlier stages of the disease, but act with remarkable certainty and rapidity on

gummatous infiltrations and ulcers. They are frequently prescribed at first in combination with the perchloride of mercury, the compound decoction of sarsaparilla being a favourite vehicle. As individual susceptibility to their effects varies greatly, and small doses are often very efficacious, it is generally advisable to begin with such, and gradually increase the dose. In the earlier secondary stages the iodides have probably little curative influence, but they remove the insoluble albuminate of mercury from the tissues, and may then aggravate salivation and other symptoms of mercurialism. Occasionally iodides directly aggravate the severity, and modify the characters, of syphilitic eruptions; the simultaneous administration of arsenic frequently prevents this puzzling complication. Some obstinate old syphilides are much benefited by the vigorous eliminative treatment carried out at many spas—*e.g.*, Aix-le-Chapelle. The local treatment of syphilodermata, although of secondary importance to the constitutional, is often a very useful adjunct. Diluted white precipitate ointment is good for papulo-squamous lesions, especially about the face; condylomata ought to be frequently dressed with black wash or mild perchloride lotion, and subsequently dusted with some drying powder. Mercurial plaster and ointment are especially useful for localized patches of papules and tubercles; obstinate "lupoid" lesions are sometimes advantageously destroyed with the acid nitrate of mercury solution, while iodoform or iodol is invaluable for serpiginous ulcers. Congenital syphilodermata are best treated by grey powder internally, and the inunction of mercurial ointment into the palms, soles, and abdomen, or by dusting powders containing calomel— $\frac{5}{8}$ ad $\frac{5}{8}$ of starch powder.

J. J. PRINGLE.

T

TABES MESENTERICA (*Tabes, a wasting disease*).—An old-fashioned term for chronic wasting disease characterized by enlargement of the lymphatic glands of the mesentery. The majority of such cases are instances of tubercular disease of these glands (*see* LYMPHATIC SYSTEM, DISEASES OF); others of chronic adenitis, with perhaps caseous degeneration secondary to intestinal catarrh;

others of malignant disease, especially lymphadenoma. Strümpell defines it to be general tuberculosis of the abdominal organs. Hensch uses the term "*atrophia meseriaca*," by which he understands a more or less general tuberculosis chiefly concentrated in the abdomen, the mesenteric glands having been affected secondarily to the peritoneum or intestinal mucous membrane.

TÂCHE CÉRÉBRALE is the name given to the pink streak which, under certain circumstances, appears when the nail or any pointed instrument is drawn across the skin. It has but little clinical value except as an evidence of an irritable condition of the vaso-dilators throughout the body. It is frequently present in tubercular meningitis, but may be seen quite apart from any cerebral affection; for example, in Graves' disease and in enteric fever.

Another form of tâche, called the "white tâche," in which the vessels of the area irritated by the nail undergo contraction and remain empty, can be occasionally produced in the same manner, especially in typhoid fever.

TAPE-WORMS (Tænia).—The cestodes or tapeworms have an exceedingly small head and neck and a long flat white body, which widens out gradually. The body is divided transversely into a number of segments, called *proglottides*, joints or links. The head is provided with suckers, by means of which it is able to fasten itself on to the mucous membrane of the intestine. From the slender neck the segments are gradually produced, becoming more and more distinct as they get further from the head. Each develops a bi-sexual generative apparatus, with a uterus in the form of a central passage traversing its entire length, and giving off numerous branches at right angles. After impregnation, the uterus becomes filled with ova, and eventually the segment, when it is ripe, separates from the rest of the worm, and is expelled with the fæces. Each segment is capable, under favourable conditions of moisture and warmth, of maintaining a separate existence for a short period. It has been calculated that the segments require for their full development a period of about three months, and as fast as they are thrown off others are ripening to take their place, so that the worm, when it has once reached a state of maturity, probably remains much the same length. The proglottides may rupture and discharge their ova whilst still in the intestines, but they are usually passed entire, and spontaneous movements of contraction and extension may be observed in them whilst still alive. If the segments and their contained ova be swallowed by their proper intermediate host, the gastric juice dissolves the covering of the ova, and the embryos are set free. Each embryo is armed with minute spicules, by the aid of which it passes

through the coats of the stomach. It is then probably carried away by the blood, ultimately reaching the liver, or muscles or some other part of the body, where it establishes itself permanently. It then loses its spicules and becomes the *scolex*, having a head exactly like that of the mature worm with a neck terminating in a cyst, within which the head and neck are inverted. In this situation the scolex may die and be converted into a calcareous mass, but if not, and if the portion of the animal containing the living scolex be eaten, it will be liberated in the stomach, its sac will atrophy, and the scolex passing into the intestine will affix itself to the mucous membrane and develop into the complete tapeworm.

VARIETIES OF TAPE-WORMS.—Several species of tape-worm have been found in the human body, but only three need be mentioned here, viz.—(1) *Tænia Medio-canellata*; (2) *Tænia Solium*; (3) *Bothriocephalus Latus*, of these only the two former occur with sufficient frequency to merit description.

(1) *Tænia Medio-canellata*, the beef tape-worm. This worm is the one by far the most commonly met with, and may attain a length of twenty feet. The head has four hemispherical suckers, but no hooklets. The segments, which are very numerous, are at first wider than they are long, then almost square, and subsequently of greater length than width, the fully developed ones being sometimes an inch long and a quarter of an inch wide. The branches from the uterus are very numerous, and terminate in club-shaped extremities. The *tænia medio-canellata* inhabits the small intestine. In beef the scolices appear as minute whitish oval bodies about the size of a mustard seed; such beef is called "measly."

(2) *Tænia Solium*, the pork tape-worm. Specimens of this variety are extremely rare in museums in this country, although many are so labelled. The mature worm is not so long as the one just described; the head is smaller, with four hemispherical suckers, and presents at the summit a blunt papilla or proboscis with a double circle of about twenty-five hooks. The segments differ from those of *tænia medio-canellata* in that the uterus gives off fewer branches, which terminate in flat pouches. The hog is the host; the scolices appear in its flesh (measly pork) as oval, hard, whitish bodies about the size of a hemp-seed, and possess already the double circlet of hooks. This worm is also

occasionally met with in the human subject in its larval form, the *cysticercus celluloseæ*, affecting chiefly the eye and the brain (see BRAIN, TUMOURS OF).

SYMPTOMS.—The symptoms usually described as resulting from the presence of a tape-worm rarely form a sufficiently distinct clinical group to allow of the diagnosis being made until some of the segments are passed. Amongst the most common symptoms are itching about the mouth and anus, uncomfortable sensations in the abdomen, disordered appetite, colicky pains, pallor, a furred tongue, foul breath, headache, and tinnitus aurium. Various reflex neuroses may be due to this cause, and in some undoubted cases insanity has owed its origin to the presence of a tape-worm. Sometimes the worm gets rolled up, giving rise to constipation, and may even produce intestinal obstruction. The symptoms are relieved when the worm is expelled.

TREATMENT.—The treatment of a case of tape-worm requires considerable care and attention to details to ensure a successful result. This is proved by the fact that it is by no means uncommon to meet with cases in which five or six separate attempts to dislodge the worm have ended in failure. The patient should go to bed and remain there until the treatment is over, for, if allowed to take exercise, he will be unable to undergo the prolonged fast which is an essential preliminary to the administration of the vermicide. The period of fasting usually recommended—viz., twenty-four hours—is quite inadequate to clear the intestines of their fecal contents. For three or, preferably, five days before attacking the worm the patient should take only food sufficient to sustain life, and this must be such as will be almost entirely absorbed by the stomach. Two pints and a half of beef tea or an equivalent quantity of Brand's essence may be given, with, if necessary, a glass or two of port wine, but no solid food or milk should be allowed. The period of starvation must be regulated by the strength of the patient; its duration should never be less than three days, and is preferably five days, or even a whole week. Every morning a small dose of some laxative, such as cascara sagrada in capsules, should be administered. Castor oil should not be given during this stage of the treatment, as it is believed to protect the worm from the action of the anthelmintic to be subsequently administered.

When the period of fasting is over the anthelmintic drug must be given. The oil of male fern is the most efficacious remedy against tape-worms. It is best prescribed in capsules each containing 15 minims, at intervals of a quarter of an hour, until four capsules have been taken. Administered in this way it is more efficacious, less nauseous, and less likely to cause vomiting than if given in a single dose of a drachm, in an emulsion, as is usually recommended. The last capsule should be followed in half an hour by $\frac{1}{2}$ ounce of castor oil. When the bowels act the motion should be passed into an utensil loosely covered with muslin. Water should be gently poured over it, and the practitioner must himself examine the worm before its removal and search carefully for the head, as if this be not passed the animal is certain to grow again. In addition, by placing the fragments end to end, he must determine whether all belong to the same worm, as two or more may be present. When the examination is finished, the worm should be burnt.

If the head be missing, the male fern should be given again in four doses as before, to be followed by a dose of castor oil. If the head be not found at the second attempt, unless the patient be too weak to bear it, the male fern and castor oil should be administered again after an interval of an hour. In a case under the care of the writer the head was not found until the third attempt, although all but about an inch of the worm was passed after the first dose of the male fern. If the head be found and the examination of the portions of worm passed show that only one is present, the patient is cured; but if the head be missing at the conclusion of the treatment, it is still possible that it may have been passed but overlooked.

As the period of maturation is almost invariably three months, or it may be exactly thirteen weeks, it follows that should no segments appear in the motions after an interval of four months, this has probably happened, and the case may be regarded as cured. If large portions of tape-worm, including part of the neck, be passed, and segments spontaneously appear in the motions after an interval of less than two months, it may be certainly concluded that two worms were originally present in the intestine. The only prophylactic measure against tapeworms is to avoid eating raw or imperfectly cooked meat. Children have been known to acquire them from

raw meat taken under medical advice.

Oil of turpentine is also used, in doses of from 1 to 2 ounces, emulsified with white of egg and sugar. Pomegranate root, 3 ounces macerated in water for twelve hours and then concentrated to one-half, is also recommended, but it is apt to produce digestive disturbances. Kousoo, kamala, and areca nut are other remedies sometimes prescribed.

TASTE, DISORDERS OF.—The sense of taste may be impaired or lost from a variety of causes which may be thus classified:—

1. Morbid conditions of the mucous membrane of the tongue and palate.
2. Lesions of the nerves concerned in the conduction of the sensory impressions.
3. Certain cerebral conditions.

Many of the sensations ordinarily spoken of as sensations of taste are really due to the perception of flavours by the olfactory nerve. As stated under *ANOSMIA* (*q.v.*) loss of smell implies the loss of all these sensations, the true taste impressions being limited to such as are either bitter, sweet, sour, or salt.

1. Morbid conditions of the mucous membrane of the tongue and palate are more often concerned in causing an impairment of the sense of taste than in its total loss. The parts of the mouth capable of receiving taste impressions are the tongue, the palate, and the palatine arches. A dry condition of the tongue and a very thick coating of fur on its surface are sufficient to cause a dulling of the sense of taste, and it may be completely lost over limited areas of disease, although owing to the large surface over which the impression may be received, such a loss will probably be unnoticed by the patient.

2. The nerve chiefly concerned in the conduction of impressions of taste is the fifth. It is stated in the article on the glosso-pharyngeal nerve that it is the nerve of taste for the posterior part of the tongue and the soft palate, a view which is perhaps the one most generally accepted, but as no case is on record in which taste has been lost over these parts from a lesion limited to the glosso-pharyngeal nerve, and as disease of the root of the fifth nerve has been known to cause complete loss of taste in these parts, and also in front of the tongue, it is more probable that the fifth nerve subserves this function; and that if

fibres apparently distributed with the glosso-pharyngeal nerve are concerned in conveying taste impressions they subsequently leave that nerve and pass to the brain by the fifth. When paralysis of the fifth nerve occurs without loss of taste it is probable that the taste fibres escape owing to the lesion being partial only or to its being situated within the pons, where these fibres are probably separated from the fibres conveying common sensibility.

The impressions from the tip and sides of the tongue are almost certainly conveyed by those fibres of the lingual or gustatory nerve which it obtains from its communication with the chorda tympani, and it is also almost certain that the latter is the nerve of special sense for these parts of the tongue, a view which accounts for the loss of taste in the front of the tongue so often observed in disease of the middle ear, through which the chorda runs, and also in cases of facial paralysis of rheumatic origin. But as in disease of the facial nerve within the skull there is no affection of taste, it follows that the fibres of the chorda leave the facial again. It is believed that they pass from the geniculate ganglion of the facial, through the Vidian nerve, to the sphenopalatine ganglion, and thence ascend, in the superior maxillary division of the fifth nerve, to its root and to the brain. In caries of the middle ear there may be loss of taste on both the back and the front of the tongue.

3. In certain lesions of the hemispheres, in general hemianæsthesia, and also in hysteria, there may be complete loss of taste on one or on both sides.

Tests.—The condition of the sense of taste may be tested by placing various substances on the protruded tongue, the patient's eyes being closed. The quantity of the substance must be small, so that it may not be diffused over the surface, and the taste must be perceived before the tongue is withdrawn. The best substances for the four varieties of taste are for bitter, quinine; for sweet, honey; for sour, vinegar; for salt, common table salt. On applying a feeble electrical current to the tongue a metallic taste is perceived; this constitutes one of the best tests.

Treatment.—When the sense of taste is lost, the treatment depends upon the causal condition.

TENESMUS is the name given to a group of symptoms referable to the large intestine, of which the most constant and

important is straining during defæcation. There may also be a sense of weight and fulness about the rectum and a frequent inclination to stool. The motions are usually slimy and may contain blood. Tenesmus is a marked feature of dysentery.

TETANUS, IDIOPATHIC.—An acute affection characterized by a more or less continuous tonic spasm of the voluntary muscles with paroxysmal exacerbations of great severity, during which the head, trunk and lower extremities are maintained in an arched position, owing to the predominance of the action of the extensor over the flexor muscles (Ross).

The idiopathic form is that in which no evidence of any wound or external injury can be discovered, the malady being, it is supposed, due to cold or wet, though sometimes there is no evidence of such exposure. It differs in no respect from the traumatic form except that the disease, as a rule, runs a less acute course and is less fatal.

Symptoms.—The onset is marked by chilliness or actual rigors, followed by difficulty in articulation, in swallowing, or in yawning, or by some stiffness of certain muscles of the face and neck. The masseters and other muscles of mastication are usually the first to be attacked, giving rise to the well-known and dreaded "lock-jaw" or "*trismus*." As the other muscles of the face are affected the features become drawn, all the lines of the face being so much exaggerated that the patient presents an aged appearance; the angles of the mouth are drawn apart so that the lips are pressed against the teeth producing a grin—the "*risus sardonicus*." The spasm spreads to the trunk and limbs and the body is arched backwards, the legs extended, and the head thrown back, the patient when in the supine position resting only on his head and heels, a condition known as *opisthotonos*. When, as happens in rare instances, the trunk is arched forwards or laterally, there is said to be *emprosthotonos* or *pleurosthotonos*. The eyes are staring or half closed, the pupils contracted, the chest is fixed, the abdomen flat or sunken, and the abdominal walls exceedingly hard. The larger joints of the extremities are generally rigid, but the smaller sometimes escape, though the hands are often clenched. Pain at the epigastrium, of a very severe character, extending through to the back,

is so common that it has been regarded by some as almost pathognomonic.

The spasm undergoes paroxysmal increase, but in the intervals there is never complete relaxation; occasionally the spasm is continuous. Each paroxysm may last from a few seconds to some minutes, and including slight remissions, even for some hours; as the disease progresses they tend to become more frequent and more severe. Generally there is a little fever, occasionally hyperpyrexia; the pulse is at first unaffected, but towards the end becomes rapid. The mind is usually clear, unless delirium supervene at the close. There is often profuse perspiration with the development of sudamina. The tongue is coated and the mouth clogged with viscid saliva; the bowels are generally obstinately confined, the urine is scanty and of high specific gravity.

Death may occur at any time after the third day, and, as has been already stated, the duration of the disease is generally shorter in the traumatic form. In the early stages death generally takes place during a paroxysm, and is then due to suffocation from the fixation of the chest. At a later stage death may be due to heart failure or fever; sometimes it may occur from mere exhaustion as late as the third week, when all danger seems almost at an end.

The *diagnosis* does not, as a rule, present much difficulty, but the possibility of hysteria must always be borne in mind. Strychnine poisoning has many features in common with tetanus, but there are two cardinal points which should serve at once to distinguish between them; in strychnine poisoning the muscles of the jaw are never affected till late, and in the intervals between the paroxysms the patient is quite free from any spasm.

The *prognosis* must always be grave, but not so grave as in the traumatic form.

Pathology.—Very little is known as to the exact nature of the disease; that there is some affection of the centres in the medulla and spinal cord cannot be doubted, but no constant changes have as yet been recognized. In many cases microscopical examination of these parts has revealed infiltration with leucocytes, multiplication of connective-tissue corpuscles, and various alterations in the multipolar nerve cells.

Treatment.—The patient should be kept quiet in a darkened room, and his

food, which must be nutritious, should be given in a fluid form; if, owing to the spasm of the muscles of the face, he can neither take it by the mouth nor bear to be fed by means of a catheter passed through the nose, nutrient enemata and suppositories must be used, or chloroform may be administered and then a tube passed down the œsophagus. Opium, chloral hydrate, Calabar bean, and curare are the remedies which have proved most successful in overcoming the spasm, but it is by no means an easy task to bring the patient fully under the influence of any of these drugs. The hypodermic injection of morphine presents advantages over all other methods of treatment. When the paroxysms are very severe relief can only be obtained by keeping the patient more or less continuously under the influence of chloroform, and until more is known of the essential nature of the disease this is perhaps all that can be expected from treatment. JOHN ABERCROMBIE.

TETANY.—A tonic spasm of the extremities occurring chiefly in rickety infants and lasting a variable time.

Symptoms.—The attack commences more or less suddenly with numbness and tingling in the fingers. This is soon followed by stiffness and drawing of the hands into the typical position, with the thumb adducted to the palm but not flexed, and all the fingers adducted to the middle line of the hand, so that this is a little arched. The fingers are only slightly flexed at the metacarpophalangeal joints, but the wrists, elbows and knees are usually somewhat flexed. The fingers may be separated when the attack is passing off. The feet are also arched and the toes adducted, the dorsum of the foot being tense and swollen; the hands and feet are usually very painful and tender; the back of the hand is swollen and tense, but does not pit. If the stiffness be overcome by force, the hand immediately resumes its position when the force is removed. In rare cases the muscles of the face about the jaw may also be in a state of contraction.

The spasm may last only a few minutes, though its duration is usually from a few hours to some days or even weeks; it does not disappear during sleep, and is unaltered during chloroform anaesthesia. The attack passes off gradually, and as it does so there is a feeling of numbness and tingling; relapses occasionally occur. Facial irritability and

laryngismus (*q.v.*) are constant accompaniments of tetany in children. Fever is not always present. The peripheral nerves may show an increased irritability to both the induced and constant currents. Convulsions when present are probably due to some independent cause, they do not appear to have any connection with, or any influence over, the tetany, which may persist through them unaltered. Recovery is the rule, but the patient may die from suffocation during an attack of laryngismus.

Prognosis.—Except in the most severe cases there is a tendency to spontaneous recovery in the course of a few days.

Pathology.—No central changes have yet been discovered, the symptoms would point to reflex irritation of the spinal cord as the determining cause; the persistence of the spasm during sleep, chloroform anaesthesia and convulsions shows that the brain has no share in the causation.

Ætiology.—This disease is seldom met with except in rickety infants during the first three years of life, but it occasionally occurs in older children and even in young adults of both sexes, and has been specially described by Trousseau as occurring in young nursing women. In the case of older children and adults it is always difficult to determine what share hysteria may have had in its production. The exciting cause in these cases is often a definite chill. In children usually some source of reflex irritation can be found, intestinal derangement being present in a considerable proportion of the cases. Teething, apart from rickets, does not seem to be a cause. Often other children in the family have suffered from it, and frequently one or other parent is neurotic or has neurotic antecedents.

Treatment.—Wrapping cold water bandages round the affected limbs always relieves the spasm pain and tenderness and should never be omitted. The bandages should be renewed every three hours until the spasm is completely relaxed and the limbs can be manipulated without any pain. In all cases careful attention to the diet and to the hygienic surroundings is of the first importance in the treatment; any source of reflex irritation such as diarrhoea, worms, or eczema, should be sought for and obviated. Where nothing of the kind can be discovered nervine sedatives may be tried, Calabar bean ($\frac{3}{8}$ grain thrice daily for a child aged two years) being probably the best. Bromide of potassium, chloral and morphine have

also been given with success in some cases. In adults the possibility of hysteria should be borne in mind in directing the treatment. In children the administration of cod-liver oil and steel wine is always useful.

JOHN ABERCROMBIE.

THIRD NERVE, DISEASES OF.—This nerve, the motor nerve of the eyeball, arises from its nucleus of large cells in the floor of the aqueduct of Sylvius on either side of the middle line, in the neighbourhood of the corpora quadrigemina. The nerve runs forwards through the crus, and emerges at the interpeduncular space, courses along the outer wall of the cavernous sinus, and enters the orbit through the sphenoidal fissure dividing into two branches; the superior supplies the superior rectus and the levator palpebræ superioris, while the inferior supplies the internal rectus, the inferior rectus and the inferior oblique muscles. Besides these the nerve also supplies the ciliary muscle and the constrictor muscles of the iris. According to Hensen and Voelcker, these different functions are arranged in the nucleus of the nerve in the following order from before back. Most anteriorly is the centre for accommodation, then for the reflex action of the iris, next for the muscles, the internal rectus, the superior rectus, levator palpebræ and inferior rectus, while below them is the fourth nucleus, for the superior oblique. Muscular paralysis and spasm are the affections which result from lesions of the third nerve.

Paralysis.—This will differ in its distribution accordingly as the nucleus or the nerve trunk is involved; when the former is affected, the symptoms will vary according to whether the whole nucleus is paralysed, or different parts of it, as described above. When the whole nucleus is affected, the lesion is frequently associated with disease of the nuclei of the other ocular nerves, and the ophthalmoplegia externa and interna of Hutchinson is the result, all movements of both eyes being lost together with the reaction of the pupils to light, and the power of accommodation (*see* OPHTHALMOPLÉGIA). The loss of the pupil reflex (Argyll-Robertson pupil) is a well-known symptom of locomotor ataxia, and occurs without any other part of the nucleus being affected. The trunk of the nerve is affected by hæmorrhage or softening in the crus cerebri, by meningitis or growths, or aneurysm in the interpeduncular space; by

rheumatic disease of the nerve in the wall of the cavernous sinus; by syphilitic disease of the membranes there, or aneurysm of the internal carotid artery. The nerve may also be affected in diphtheritic paralysis, and in tabes dorsalis. In the orbit the nerve or its individual branches may be compressed by growths. When the whole trunk is affected, the eye cannot be turned in any direction except outwards and outwards and downwards; there is external strabismus, with diplopia, ptosis, and loss of accommodation. The pupil is of medium size, but does not contract to light or on accommodation. When the different branches of the nerve in the orbit are involved, the individual muscles supplied are paralysed. Thus, when the right *superior rectus* is paralysed, the eye cannot be turned upwards, and in trying to do so the eyeball is rotated on its antero-posterior axis out and down by the inferior oblique; secondary deviation—*i.e.*, the overaction which the sound eye executes when the paralysed eye tries to fix an object above it and which the sound eye is prevented from seeing, is by the left superior rectus; there is diplopia for objects seen in the upper half of the field of vision, the images being side by side and one above the other; they are crossed—*i.e.*, when the right eye is covered up, the left image, which is also the higher of the two disappears; the further the object is removed from the horizontal line, the greater the separation of the images.

In paralysis of the right *inferior rectus*, the symptoms are similar, though the direction is reversed; movement is defective downwards, the eyeball being rotated on its antero-posterior axis out and up by the superior oblique; secondary deviation is by the left inferior rectus; there is diplopia for the lower half of the field of vision, the images are side by side and are below the other, they are crossed, the left and lower image disappearing when the right eye is covered up; the separation increases downwards from the horizontal line.

When the right *internal rectus* is paralysed, there is a divergent squint, and the eye cannot be turned inwards; secondary deviation is by the left external rectus. Diplopia occurs in looking at objects to the left of the middle line, the images are side by side, and become further separated as the object is moved to the left; they are crossed—*i.e.*, the left image disappears when the right eye is closed.

With paralysis of the right *inferior oblique*, there is defective movement upwards, for the muscle works with the superior rectus; secondary deviation takes place by the left inferior oblique and superior rectus. Diplopia is for objects in the upper field, and is simple, —i.e., the false image is to the right, the images are side by side, the false one being the higher, and the distance between them is increased by looking to the left, whilst on looking to the right the false image becomes oblique, converging towards the horizontal line.

Spasm occurs in some of the muscles supplied by the third nerve, and especially the internal rectus and levator palpebre; the former condition is met with in hysteria, meningitis and hypermetropia. Clonic spasm of the muscles occurs in nystagmus, especially in the form affecting miners.

Diagnosis of paralysis, when the whole trunk is involved, is not difficult, but when single muscles are affected, and strabismus is not a marked symptom, the position and behaviour of the double image will assist the diagnosis.

Prognosis.—When the paralysis is due to organic growths or an affection of the nucleus, as in ophthalmoplegia externa, the prognosis is unfavourable, but favourable when caused by rheumatic or recent syphilitic disease, or after diphtheria. In *tabes dorsalis*, in the early stages, the prognosis is favourable, but in the latter the paralysis is usually permanent.

Treatment.—If the paralysis be due to organic disease, the treatment is that suitable for the disease. When due to cold, hot fomentations may be applied and be followed by a blister on the temple just outside the orbit, and tonics may be given. Iodide of potassium in increasing doses should be administered if syphilis be the cause of the lesion. After diphtheria, the paralysis usually recovers with tonic treatment. The constant current may be employed (very weak), the negative pole being applied to the closed eye, and the positive pole placed at the back of the neck. In cases of spasm the best results are obtained by counter-irritation to the temple.

C. E. BEEVOR.

THOMSEN'S DISEASE (Myotonia Congenita).—An hereditary disease occurring in several members of the same family. Upon the attempt to use any of the voluntary muscles the patient finds that contraction is slow, and relaxation is still slower because the muscles

remain tonically contracted for some seconds. Much the same result is noticed upon the application of any form of stimulus to the muscles. There are certain characteristic electrical reactions. Under the microscope the muscular fibres are found to be hypertrophied.

It is usually said that Sir Charles Bell first described this disorder, but it is doubtful whether his cases were really examples of Thomsen's disease. Two cases were mentioned by Benedikt in 1864, and Leyden referred to it about the same time, but it was the publication in 1876, by J. Thomsen, of a description of the disorder as it existed in himself and members of his family which first directed attention to it. Erb, in 1886, published a monograph on the subject, and he has recently issued an article bringing his previous account up to date. In England four cases have been exhibited at the societies. Dr. Buzzard described two cases in the *Lancet* in 1887, and a full account of the disease appeared in the *Guy's Hospital Reports* for 1889. Cases have occurred in Germany, France, England, Russia, Italy, Sweden and America. Up to the present date about 50 cases have been put on record.

Symptoms.—The chief of these is a peculiar stiffness, as the patient calls it, which accompanies voluntary movements. Involuntary movements are never affected. The peculiarity of movement consists in the fact that the contraction of the muscle the patient wills to move, is slower than normal, that it persists, and then relaxes gradually and very slowly, consequently the muscle remains contracted for some seconds and this contraction is so strong that the antagonistic muscles cannot overcome it. If a series of similar voluntary movements be made one after another, the patient begins to execute the second movement before the first contraction has completely relaxed, and his difficulty as regards stiffness gradually becomes less and less in each movement. For example, if he be standing still and set out to walk he puts forward one leg rather slowly, it then remains stiff for a few seconds; the next time it is moved the stiffness is less, and soon he walks quite comfortably even for miles, but if he trips against a stone this brings into play some new movement, and the muscles performing it become stiff and he may fall down. The acts of respiration, micturition, defecation and parturition have never been observed to

be implicated, but with these exceptions the stiffness may be noticed in any movements executed by voluntary muscles. The muscles of the extremities are most commonly implicated, some of the rarest to be affected are the muscles of deglutition, those of speech, those of the eye, and the interossei. The muscles are well formed, sometimes they are a little increased in bulk; there is slight diminution in power. Erb gives the following points as characterizing the "Myotonic Reaction" (MyR.). (1) The contraction of the muscles upon mechanical stimulation of the motor nerves is normal. (2) Mechanical stimulation of the muscles, as by repeatedly hitting them with a percussion hammer, easily produces contractions lasting from 5 to 30 seconds. (3) The motor nerves are quantitatively normal to the faradic current, but strong closing currents induce long lasting contractions. (4) The motor nerves are quantitatively normal to the galvanic current, but strong closing currents produce long lasting contractions. (5) The effect of the faradic current applied to the muscles is the same as when it is applied to the nerves. (6) The galvanic current applied to the muscle shows that opening contractions are very difficult to obtain, that the closing contractions are of very long duration; that anodal closing contractions (ACC) are as easy or more easy to obtain than kathodal closing contractions (KCC), and that upon stable application, well formed, wave-like contractions may be seen to pass from the kathode to the anode. Almost all observers have obtained all these features of MyR, except that very few have found the wave-like contractions, and there is some doubt as to the response of the muscles to mechanical stimuli to the nerves. Pain upon contraction of the muscles is excessively rare. The latent period is probably normal, although there are some differences of opinion on this point. Myographic tracings bring out the features of the movement very well. The difficulty of movement is usually, but not always, increased by mental excitement or cold. It is often said to be diminished by alcohol, digestion and warmth. The reflexes are normal; there are no sensory symptoms. The muscular fibres excised during life are wider (from two to four times) than normal, the transverse striation is indistinct, the border of the fibre is irregularly curved, the muscle nuclei are increased in number and sometimes there is a slight excess of interstitial tissue.

Course of the Disease.—It is usually first observed during childhood, most often at about the age of eight or nine the child notices that it cannot take part in games. The difficulty of movement, as a rule, becomes worse at puberty. It is doubtful whether recovery ever takes place, usually the trouble is slowly progressive. It usually incapacitates from almost all occupations.

Diagnosis.—This is not difficult if the salient points are remembered, but all sorts of obscure cases of muscular spasm are incorrectly described as Thomsen's disease.

Prognosis.—This is bad. No certain case of recovery has been recorded. Thomsen found he was better the more active his life. One woman is said to have improved when she married.

Pathology.—The only pathological basis for the disease is in the muscular fibres. That these are its seat is supported by the following facts: (1) The histological changes in them; (2) Thomsen-like contractions can be produced upon direct stimulation of the muscles of the frog, even when the end plates have been paralyzed by curare, if the animal has been brought under the influence of sodium phosphate; (3) some animals possess in each muscle two sorts of fibres, white, which contract quickly, and red, which contract slowly; (4) the muscles of new-born animals also contract very slowly. Bernhardt has suggested that the disease is an hereditary defect of muscular development. Some have supposed that the nervous system is also at fault, but of this there is no evidence.

Etiology.—Rarely it has been ascribed to fright, but it is uncertain whether this ever has any causative relation, probably not. It is strongly hereditary, occurs in many members of the same family, and is directly transmitted by fathers and mothers to both sons and daughters.

Treatment.—None has been of any avail. Tonics, electricity, electric baths and massage have all been tried.

W. HALE WHITE.

THREAD-WORMS (*Oxyuris Vermicularis*).—The thread-worm is a minute filiform nematode, of which the female is the longer, though less than half an inch in length; the female is full of ova, the eggs being oval in shape. It is supposed that the eggs are swallowed with fruit or vegetables, and that the embryos are liberated in the stomach.

Re-infection afterwards takes place without any external source of infection, the child (for the affection is much more common during childhood than subsequently) scratches the anus, and so gets some of the ova under his nails, when they find their way into his mouth at meal times. According to Cobbold, the cæcum is the habitat of the thread-worm.

Symptoms.— Unless the worms are actually seen either about the anus, in the bed, or in the motions, it should not be taken for granted that a child is suffering from thread-worms. They are apt to produce heat and irritation about the anus, as also about the vagina and prepuce, whither possibly they are transferred by the hands of the child rather than by spontaneous migration. Children suffering from worms are often restless and irritable; they pick at their noses, have twitchings of the face and limbs, and sometimes even convulsive movements. Leucorrhœa may be set up in little girls, and thread-worms have been regarded as one of the causes of masturbation. There may also be diarrhœa and slimy motions, with a tendency to prolapsus ani.

Treatment.— Popular superstition attaches much importance to so-called worm powders, and a dose of three grains of powdered rhubarb with half that quantity of carbonate of soda may be given to an infant under one year to bring away the worms; such a powder often does expel large quantities of thread-worms. Its administration should be followed up by a small enema (not more than three ounces) of salt and water, or a similar quantity of infusion of quassia may be used, and except in inveterate cases, the repetition of the enema on two or three successive evenings is usually sufficient to rid the patient of his trouble. In the more chronic cases cod-liver oil and steel wine may be given internally with benefit, whilst calomel and jalap may be substituted for the rhubarb and soda, and small doses of perchloride of iron may be added to the enemata. In adults the same treatment should be adopted, but the cases are often more rebellious. Saline mineral waters, such as Friedrichshall and Hunyadi Janos, are of service in these cases. The strictest cleanliness should be adopted, and the child's hands should be muffled and tied up at night so as to avoid the possibility of re-infection taking place as above described.

THROMBOSIS.— The process of coagulation of the blood within the heart and vessels during life.

The resulting product of coagulation is termed a *thrombus*. The essential cause of coagulation is the formation of *fibrin*, which, according to Hammarsteon, is derived from the action of a *ferment* upon fibrinogen contained in the plasma. Formerly it was believed that fibrinoplastin was also necessary (Schmidt theory). According to Wooldridge, lecitin is the essential agent in the production of fibrin by its action upon B fibrinogen, one of three fibrinogens which he asserts exist in the blood.

The disintegration of the white corpuscles continually produces this ferment, but not in sufficient amount to cause coagulation in health. It is more abundant in venous blood than arterial. Recent observations have shown that this ferment is derived not only from leucocytes, but also from the blood plates, or from microcytes, and the formation of thrombi has been especially ascribed to their agency. If a foreign body such as a thread be introduced into the circulating blood, it will be covered, after a short time, with leucocytes and microcytes, which serve as a starting-point for coagulation.

The blood, in order to remain in a fluid state, must be in contact with the healthy endothelium, which forms the wall of the capillaries and the internal lining of the remainder of the cardiovascular system. Should this be damaged, coagulation will occur at the point of injury. The vessel, denuded of epithelium, acts like a foreign body, the leucocytes and microcytes adhere to it, the result is the formation first of ferment, and then of fibrin. Retardation of the circulation is not, of itself, a direct cause of thrombosis, but it is a very important factor in its production, firstly by favouring the accumulation of leucocytes, and secondly by causing impaired nutrition of the vessel wall.

Thrombosis may arise from two causes, which generally co-exist:

1. INJURY AND DESTRUCTION OF THE CARDIO-VASCULAR ENDOTHELIUM.—

- (1) The process of obliteration of a vessel by ligature, torsion and cautery, is an example of simple injury without any abnormal condition of the blood.
- (2) Inflammatory conditions of the cardio-vascular system, such as *endarteritis*, *endocarditis* and *phlebitis*, whether originating primarily in the intima, or extending from inflamed circumjacent tissues

are the commonest causes of thrombosis. (3) Foreign bodies and newgrowths may cause thrombosis of the veins by piercing the walls of the vessels. (4) Imperfect nutrition of the vessel walls, due to slowing of the circulation and poverty of the blood, is another important factor in such cases; leucocytes are frequently in excess in the blood. The affection occurs with especial frequency in the veins of the lower extremities, also in the auricular appendices, the apices of the ventricles and between the trabeculae of the heart.

II. ABNORMAL CONDITIONS OF THE BLOOD.—In septic fevers, typhus, septicaemia, erysipelas and pyæmia, the amount of fibrin ferment is greatly increased, owing to the breaking up of leucocytes, possibly by the agency of micro-organisms. This condition of the blood is usually associated with a failing heart and loss of vascular tone. The circulation is thus retarded, and the endothelium is liable to be damaged.

There is a tendency to thrombosis in the later months of pregnancy and after profuse hæmorrhage, also in certain diseases, as typhoid fever, diabetes, Bright's disease, gout, phthisis, and cancer. After parturition, thrombosis of the iliac veins is liable to occur, causing phlegmasia dolens (*q.v.*)

Varieties of Thrombi.—Red thrombi are uniform red clots, soft in the early stages. They form from the blood by coagulation when the circulation through a vessel has ceased—*e.g.*, after ligature or embolism.

White or Mixed Thrombi are found in the circulating blood; the foreign body or damaged vessel serves as a surface of attraction for the sticky leucocyte and microcyte. These adhere and form ferment, which causes a deposition of fibrin from the blood. The deposit is frequently stratified, and the strata may present different colours owing to the varying numbers of red corpuscles in the coagulum, this being dependent upon the degree of slowing of the circulation. Thrombi may be further divided into *obliterating*, or those which completely fill the vessel, and *parietal*, or those which adhere to some portion of the wall. The former are generally red, the latter colourless.

When a thrombus extends, whether in an artery or vein, it is always towards the heart; hence thrombosis of the iliac veins may extend to the inferior vena cava and give rise to symptoms of obstruction of that vessel.

Cardiac Thrombi.—The distinction of *ante-mortem* from *post-mortem* clots in the heart is of importance. The former are found especially in the auricular appendices and at the apices of the ventricles, they have a smooth or ribbed surface, buff or variegated colour, and usually vary in size from a pea to a large filbert; they often occur in groups which are continuous with one another. They may be of uniform consistence on section, but more frequently their centre is broken down from degenerative changes into a thick reddish-yellow pus-like fluid consisting of cholesteroline, fat granules and degenerated blood corpuscles. They cannot be removed, being firmly adherent.

Post-mortem clots are often like black-currant jelly, the portions prolonged into the arteries being usually fibrinous, while those of the veins and pulmonary arteries are soft and black. They are readily removed, and in no case adherent. Often during the death agony clots are forming in the heart for some hours. These consist almost entirely of fibrin; they are opaque, buff-coloured, it may be even slightly laminated, but they are only entangled and never really adherent; they are moister and tougher than *ante-mortem* clots, and never show the yellow hue of degeneration.

The changes which may occur in thrombi are *decolorization* from changes in the hæmoglobin and absorption of the pigment, *softening, organization* or conversion into fibrous tissue, *canalization* or channeling of the thrombus, and lastly *calcification*, giving rise to a phlebolith.

The softening may be *simple*, the degenerative changes taking place in the centre; or *puriform*, as in cases of *infective thrombosis*. The latter occurs when germs gain admission to the thrombus, or when the process which excites thrombosis is a septic one. As an example, infective thrombosis of the lateral sinus occurring in purulent otitis media may be mentioned.

In connection with the obstruction of vessels by blood-clots it is well to bear in mind, first, that thrombosis is the cause of obstruction when it exists in the pulmonary, hepatic, and systemic veins; secondly, that arteries and the portal vein may be obstructed either by thrombosis or embolism; and, thirdly, that when obstruction occurs in the pulmonary arteries associated with pre-existing venous thrombosis, it is due to embolism.

The results of thrombosis are (1) those due to mechanical obstruction of the circulation, and (2) the dislodgement of simple or infective particles into the circulation with the production of embolism.

The results of venous thrombosis depend in great measure upon the possibility of collateral circulation being established; the conditions are the same as those produced by the obstruction of veins from whatever cause—namely, swelling and œdema of the part, with compensatory enlargement of anastomatic vessels. If the obstruction lasts for some time, the tissues become indurated as the result of mechanical congestion.

The organ which is specially liable to be affected by arterial thrombosis is the brain, but the changes which result are much the same whether the obstruction be by thrombosis or embolism. For this reason, the results of arterial thrombosis are more conveniently discussed together with those produced by embolism, and will be found in the article on the latter subject.

F. W. MOTT.

THRUSH.—A form of stomatitis due to the presence of a vegetable parasite termed the *Oidium Albicans*.

Symptoms.—The disease commences with the formation of circular spots about the size of a pin's head, slightly elevated, and of a white colour, on the tongue, gums, buccal mucous membrane, or pharynx. It does not extend into the larynx, nor has the white membrane, which is characteristic of the disease, been found beyond the œsophagus. If the course of the disease be unchecked, the spots gradually coalesce until in some cases the mucous membrane of the mouth is covered with patches of a whitish colour. The membrane is at first slightly adherent, so that a little oozing of blood follows attempts to remove it. Thrush is usually ushered in with some febrile disturbance and gastrointestinal irritation, such as sickness, diarrhœa, and abdominal pain and tenderness. In cases running a fatal course the patient becomes drowsy, there is profuse diarrhœa with foul smelling stools, and the nates and anus become red and excoriated.

Diagnosis.—The only condition with which thrush is at all likely to be confounded is simple aphthous ulceration; its differentiation from the latter will be found under APHTHÆ.

Prognosis.—In children who are under favourable conditions, and who can be

kept clean, the disease generally yields readily to treatment; but in adults, on the other hand, it usually indicates the commencement of the end, though cases of recovery do occur even when patches of membrane of a considerable size have formed.

Pathology.—As already stated, the essence of the disease consists in the presence of a vegetable parasite, the *oidium albicans*, and it is now generally admitted that this is identical with the *oidium lactis*, the ferment fungus on the presence of which depends the acid fermentation of milk. When the white membrane of thrush is examined microscopically, it is found to be composed of spores and filaments with a granular basis.

Ætiology.—Thrush is for the most part a disease of infancy, occurring almost exclusively in children brought up by hand, but it may be met with in old people and in persons exhausted by some wasting disease, such as cancer or phthisis.

Treatment.—The important indication is the observance of the most scrupulous cleanliness in everything used for the child, especial attention being paid to the state of the bottle. The mouth should be carefully swabbed out two or three times daily with a weak solution of carbolic acid, permanganate of potassium, or sulphurous acid. In the interval a spray composed of 20 grains of borax and 20 minims of glycerin in an ounce of water may be used. If, in children brought up by hand, the disease does not yield to the treatment just recommended, a wet nurse should be engaged, and recovery may then be expected even in cases apparently hopeless. In a very severe case occurring in an adult observed by the writer the administration of a lozenge containing $\frac{1}{4}$ grain of cocaine and 5 grains of chlorate of potassium every three or four hours speedily effected a marked improvement in the local condition, and enabled the patient to take food without pain.

F. DE HAVILLAND HALL.

TINEA VERSICOLOR (Pityriasis Versicolor).—A disease of the skin due to the presence of a vegetable parasite—*microsporon furfur*—and characterized by the existence of fawn-coloured or brown, slightly scaly patches, usually confined to the trunk.

Tinea versicolor is common, but its discovery is frequently accidental, as it seldom causes subjective symptoms of sufficient intensity to prompt application

for relief, but a severe form is said to exist in the East. It is essentially a disease of middle life, being rare below fifteen and above forty-five years of age. It runs a chronic course, and is subject to considerable exacerbations and remissions according to the amount and condition of the sweat secretion. The affection is, therefore, generally worst in warm weather and its relative frequency in phthisical subjects who perspire freely is thus explained.

Eruption.—The favourite seats of the disease are the front of the chest, the abdomen and the interscapular region. The lesions consist, at first, of small, cir-

“complexion” of the patient—*i.e.*, the amount of pigment normally present in the skin. Their surface is finely scaly, their edge sharply defined although only slightly elevated. Scraping with the nail or with a knife removes the scale and discoloration. Occasionally, especially after violent exertion and in summer, the patches inflame, become eczematous and itchy, some difficulty in diagnosis being thereby produced. The fungus, which lies in the most superficial horny layers of the epidermis, can be easily demonstrated by microscopic examination of scrapings after their treatment with ether and liquor potassæ

Mycelium and Spores of *Microsporon furfur*.

cular, discrete spots which soon coalesce to cover extensive, irregular areas and may finally cover, almost uninterruptedly, the whole trunk. Generally, however, the distribution is more patchy, and round the main tract of disease there are outlying islets, roughly circular in outline. Extension to the upper arms and thighs is common, and the disease may spread occasionally as far as the wrists and ankles, but its occurrence on exposed parts (*e.g.*, face and hands) is extremely rare. The fungus has, however, been found in a case of apparently simple seborrhœa of the scalp. The colour of the patches is yellowish, fawn or some deeper tint of brown, according to the

or acetic acid. It consists of closely interlacing, fine mycelial threads or tubes, and of triangular or pyramidal heaps of small, brightly refracting, circular, nucleated spores which often lie at points of intersection of the mycelial threads. Some experiments made in France tending to show some relationship to the bacillus tuberculosis, or, at all events, the power of *microsporon furfur* to produce tuberculosis when injected into animals, have received neither credence nor confirmation elsewhere. Although undoubtedly contagious, *T. versicolor* is so to a very limited degree only.

Diagnosis.—The affection can only be mistaken for lichen circinatus (eczema

seborrhœicum corporis), pityriasis rosea, erythrasma, pigmentary syphiloderma, or other disorders of pigmentation, but in doubtful cases the microscope will at once clear up the diagnosis.

Treatment.—Repeated and vigorous washings with hot water, soft soap and a flesh brush, or a piece of flannel, are necessary to remove greasiness and scales previous to the application of the parasiticide lotion or ointment. Ointments of sulphur or chrysophanic acid are efficacious but disagreeable remedies. A lotion of hyposulphite of soda (5j ad 5j) is that most usually employed, and probably the previous dabbing on of vinegar, which causes the decomposition of the hyposulphite and the production of sulphurous acid in an active state, is an improvement. It is generally advisable to continue treatment after apparent cure has resulted, as little islets of disease, where the parasite is perhaps unusually deep in the epidermis, are apt to pass unperceived. It is also a wise precaution to destroy all clothing worn next the skin; silk is a preferable material to flannel for the underclothing of persons liable to the disease.

Erythrasma.—A rare disease of the skin to which certain authors are inclined to assign no place as a morbid entity, but to consider it as a phase of *Tinea versicolor* or *Tinea cruris* (*eczema marginatum*), or even as an intermediate condition between the two.

Erythrasma always attacks the axillæ or inguinal regions, nates and immediately neighbouring regions. It forms reddish or brownish, sharply defined, slightly raised, desquamating patches, which cause no itching or inconvenience, and may thus pass for years unperceived. In the one indubitable case seen by the writer, in a man, it occupied the entire gluteal region. The micro-organism—*microsporon minutissimum*—consists of densely packed, very fine, interlacing threads, none of which branch or segment. Observers differ with regard to the presence of spores, the majority, however, have not observed them.

The condition is readily curable by the same means as *Tinea versicolor*.

J. J. PRINGLE.

TINNITUS.—A singing, ringing, or other kind of noise in the head; a frequent accompaniment of deafness. It may be present in almost every form of disease of the middle or internal ear, in obstruction to the Eustachian tube, and in accumulation of wax in the ex-

ternal auditory meatus. It is also met with in nervous and other forms of deafness where the ear is quite normal, and in such cases it is usually incurable. When disease of the ear is present the treatment must be directed to its removal.

TOBACCO, POISONING BY.—

Whether taken in the form of infusion or smoked or chewed, the *symptoms* of poisoning by tobacco are much the same, and consist of vertigo, nausea, vomiting, and colic. These are accompanied by a clammy state of skin, or the latter may be bathed in perspiration; diarrhœa, pallor, faintness, and trembling are also usually present, and the pulse becomes very small and weak, and the patient much collapsed. There may be tetanic cramps. The pupils become dilated and insensible, and, in fatal cases, stupor and convulsions precede death.

Post-mortem Appearances.—The odour of tobacco, if present, would be easily recognized, otherwise there would be nothing characteristic.

Treatment.—This would consist in aiding the rejection of the poison, by vomiting, &c., and in combating the collapse by the use of stimulants and strychnine, either by the mouth or by hypodermic injection (gr. $\frac{1}{2}$).

Chronic Effects.—The most important is atrophy of the optic disc producing the so-called tobacco amaurosis, but the excessive use of strong tobaccos may lead to other disorders. Epileptic fits have sometimes been clearly traced to this cause, and many cases of dyspepsia and palpitation are largely due to it. In amaurosis total abstinence from tobacco generally suffices to effect a cure, but sometimes a partial atrophy of the optic nerve remains (see OPTIC NERVE, DISEASES OF, section, Tobacco Amblyopia).

TONGUE, DISEASES OF.—The following morbid conditions of the tongue are briefly described in this article:—

1. Fur.
2. Acute Inflammation (*Glossitis*; *Hemiglossitis*).
3. Leucoma (*Leukoplakes*; *Ichthyosis*; *Psoriasis*).
4. Wandering Rash.
5. Syphilis.
6. Tubercular Ulcer.
7. Epithelioma.

For fuller information the reader is referred to works on surgery, and especially to Mr. Butlin's work on the diseases of the tongue, to which the writer is

indebted for much of the information herein contained.

1. **Fur on the Tongue.**—The condition of the tongue has always been considered of great importance as an index of the general health, particularly of the state of the digestive organs, and, although the more accurate methods of modern medicine have tended somewhat to displace it from its pre-eminence as a signal of disease, it still shares the chief place jointly with the pulse and the temperature.

The white or yellowish-white coating of fur so commonly present on the dorsum has been shown to consist chiefly of masses of minute living organisms—viz., micrococci and the bacillus subtilis; epithelial scales and the débris of food are also present, but their minor importance is proved by the fact that where the fur is thickest they are found in the smallest quantity. The fungus is attached to the filiform papillæ, the fungiform and circumvallate papillæ and the intervening spaces being seldom covered. The appearance known as “strawberry tongue” is produced by the turgid state of the vessels of the fungiform papillæ, causing them to stand out as red points, in marked contrast with the thick coating of fur on the filiform papillæ.

When the processes of the filiform papillæ over any area are temporarily destroyed, fur ceases to form there, and if the loss be permanent, as in the condition known as leucoma (*q.v.*), the surface remains afterwards free from fur.

The presence of fur, even a layer of considerable thickness, is quite consistent with health; in fact, in most individuals, the dorsum of the tongue in front of the circumvallate papillæ is furred on rising in the morning. The tongue is generally covered with fur in patients who take little or no solid food, as the movement of the tongue during mastication plays an important part in the cleansing of its surface. Any condition of debility, by lessening movement, tends to produce the same effect. In febrile disorders accompanied by prostration, in addition to the above factors, the mouth is often kept open, and this, with the increased temperature, tends to produce dryness of the surface of the mucous membrane.

To recapitulate, the essential factor in the production of fur is: (1) a growth of micro-organisms on the surface of the filiform papillæ; this is aided by (2) diminished movement of the tongue, (3) the absence of solid food from the diet, (4) any condition of debility, (5) the

febrile state, and (6) an open mouth, whereby evaporation is favoured.

Unilateral Furring.—The tongue is occasionally found to be furred on one side and clean on the other. This condition is probably in every case due to some cause tending to restrict the movements of the affected side, which consequently fails to get properly cleansed, and not to a loss of nervous influence. Among such conditions are the presence of an ulcer or a sharp jagged edge of a decayed tooth, and loss of power of movement, as in hemiplegia.

For the appearance of the tongue in disease, which it may be observed is in very few cases sufficiently distinctive to warrant much reliance being placed upon it in forming a diagnosis, the reader is referred to the separate articles, in each of which it is described.

2. **Acute Inflammation (*Glossitis*).**—Inflammation may affect the whole of the tongue or one-half only (*Hemiglossitis*). Either form of the disease is extremely rare, but the latter especially so.

Symptoms.—The onset of glossitis is sudden; pain on movement of the tongue, followed by its complete fixation, gradually increasing swelling of the organ and profuse salivation, constituting the most prominent signs of the affection. The tongue in severe cases may attain such a size that the mouth is unable to contain it, and it protrudes. In such a condition the acts of swallowing and speech are naturally either difficult or impossible, and there may also be urgent dyspnoea. The surface of the organ becomes thickly coated with fur, and the protruded part may be dusky, dry and brown. Fever is present, but is usually moderate in degree.

Course.—The duration of the affection is, as a rule, from three to five days, when the swelling subsides, but death may occur from suppuration or gangrene of the tongue or septic pneumonia.

Pathology.—The idiopathic form, above described, is believed to be a catarrhal affection, the inflammation following on a cold. Acute inflammation may also be due to an injury, the sting of a wasp, or the effect of mercury.

Treatment.—The patient should be freely purged without delay; leeches are sometimes of service; ice to suck is useful, but the act of sucking is difficult, from the fixation of the tongue. If the swelling be extreme and there be dyspnoea or other urgent symptom, an incision about a third of an inch deep

should be made on either side of the median line. A moderate degree of bleeding is beneficial.

Hemiglossitis is a less severe affection than the foregoing, and differs from it in that a definite nodule or lump may be present in the substance of the tongue.

Treatment should be conducted on the same lines as in glossitis. Incision is rarely necessary.

3. Leucoma (*Ichthyosis; Leukoplakes; Chronic Superficial Glossitis*).—This affection is characterized by the presence of a pearly-white or bluish-white patch on the surface of the tongue.

The affection may be limited to a small area, or the whole of the dorsum may be involved. The patches present a smooth surface and an irregular outline. The papillæ are absent, and, consequently, the affected part is devoid of fur. The tissue constituting the plaques may be of almost any degree of thickness and density.

So few are the subjective sensations, that a leucoma may be present for a long time without attracting the patient's attention. When once formed, it is probably in all cases permanent. The chief importance of the condition arises from the fact that it very often precedes the appearance of epithelioma.

A leucoma is often associated with an ulcer of the mucous membrane. In the variety known as "ichthyosis" the surface of the patch is warty and the papillæ are hypertrophied.

Ætiology.—It is probable that any irritant, by setting up a chronic inflammation, may, in an individual with some predisposition the nature of which is not understood, be sufficient to produce a leucoma. The most commonly assigned causes are—smoking a pipe, some local syphilitic affection, the taking of undiluted alcoholic drinks, and the wearing of tooth-plates. The affection is rare under the age of twenty; women are but seldom affected.

Treatment has but little effect upon the condition. Alkaline solutions (pot. bicarb. gr. xx ad ʒj) may be used as a gargle or wash, or a weak solution of chromic acid (gr. v to x) may be painted on the patch. All sources of local irritation should be removed, and smoking forbidden. The diet should be such as gives rise to the least possible irritation of the tongue whilst the food is in the mouth.

4. Wandering Rash (*Geographical Tongue*).—This is a rare affection, usually met with in children below the age of

six years, and characterized by the presence on the dorsum of the tongue, generally near the tip, of smooth red patches, at first of small size, but which gradually enlarge, and form rings with yellowish, raised, sharply defined borders, but smooth and red within. Adjacent rings may intersect, and small rings may form within larger ones. Itching and salivation are the only subjective symptoms which have been noticed, and these in a very few cases only, none being present as a rule.

The affection may remain uncured for years, but fluctuates much, eventually undergoing spontaneous cure. Its nature is obscure; the only microscopical examination made appears to show that it is "a sub-acute inflammation of the derma of the mucous membrane," probably due to some nervous influence.

No *treatment* appears to be of much avail, but tonics, such as iron and cod-liver oil, may be of some service in improving the general health.

5. Syphilis.—*Primary syphilis* is very rarely seen; it appears as a hard, circumscribed, projecting sore situated on or near the tip of the tongue. It is usually small, equal in size to a pea or larger, and painless. The lymphatic glands below the angle of the jaw may be enlarged.

Secondary syphilis affects the tongue in the form of cracks, furrows, fissures and mucous patches,—or tubercles may break down and form ulcers. Mucous tubercles are generally multiple, and, when most typical, appear as rounded or oval, raised, and well-defined patches, with irregular border, and are of a greyish-white colour.

The surface may be either smooth, or warty, or ulcerated and hollowed out. Mucous tubercles are generally painful, and may persist for long periods.

Treatment must be constitutional and local. The latter only need be referred to here. The sore places should be painted three or four times daily with a solution of chromic acid (gr. x ad ʒj). Under this combined treatment, as a rule, they rapidly heal. Smoking should be given up, and alcohol taken in moderation only. Pain may be relieved by the application of a solution of cocaine (10 per cent.).

Tertiary syphilis causes ulcers which are much more serious than those which accompany the secondary manifestations of the disease. They are usually due to the softening of *gummata*. These latter may occur on the surface or as nodules

in the substance of the organ, and may be either single or multiple. When they break down they form fissures and deep furrows, and eventually cause much puckering and scarring. Gummata are more common in men than in women, and are rare in early life, although they have been met with in congenital syphilis.

Treatment.—If the gumma has not broken down, only constitutional treatment is required; but if there be an ulcer or any one of the various sores already described, it should be treated by painting four times daily with a solution of chromic acid (gr. x ad ʒj).

6. Tubercular Ulcers.—The statement that ulcers of tubercular origin are sometimes primary on the tongue appears to be made on the ground that in some cases no physical signs could be detected on examination of the lungs—a most fallacious test. There is, however, no reason why primary tuberculosis of the tongue should not occasionally occur, although it is undoubtedly in most cases secondary to similar disease of the lungs or larynx.

The affection was first described in 1858 by Sir James Paget, and fresh attention has of late been drawn to the occurrence in phthisis of these ulcers on the tongue and in the mouth.

The ulcers present a pale, yellowish-grey, granular surface, often covered with mucus; the edges are either bevelled or sharp cut, but are rarely undermined. Induration of the surrounding tissue is slight or absent, but, as a rule, there is some swelling. The ulcer is at first superficial, but subsequently increases in depth, and may lay bare the muscle. The tubercle bacillus has been found in the discharge from such ulcers and post-mortem in sections through the base. The ulcers are in the greater number of cases due to the passage over the tongue of the discharges from pulmonary cavities or laryngeal ulcers.

The *prognosis* is, as a rule, very unfavourable, but healing occasionally occurs.

Treatment.—The ulcers which appear to be primary and are still of small size may be excised, but in the majority of cases no operation is advisable, and, if there be severe pain, the surface of the ulcer may be gently brushed over with a solution of cocaine (10 per cent.). If this be done shortly before a meal, the patient is often able to take food without pain. All sources of irritation should be removed, and a powder composed of

iodoform in fine powder (gr. j), morphine (gr. $\frac{1}{2}$ – $\frac{1}{4}$), and borax (gr. iij) may be blown upon the surface of the ulcer.

7. Epithelioma.—This is practically the only form of cancer met with in the tongue. The disease is of very rare occurrence in females at all ages, and in males up to twenty-nine or thirty years.

Any part of the organ may be attacked, but the anterior half is more often affected than the posterior, and the edge than the dorsum. The disease is often preceded by other lesions occupying the same site; of these, ulcers, either syphilitic or non-syphilitic, ichtylosis and leucoma are amongst the most common. The constant irritation of the tongue by a pipe or the jagged edge of a tooth often acts as the exciting cause of the disease, and patients with teeth in such a condition should be warned of the danger they are incurring.

Local Signs.—The appearances vary with the nature of the exciting cause and the previous condition of the affected part. Thus the disease may commence as a fissure, an ulcer, or a tubercle or warty growth, or as a nodule within the substance of the tongue. Ulceration is an early and constant feature. The growth is raised above the surrounding parts, and these, with the base, invariably present induration, the latter being one of the most important diagnostic features of the disease. Pain and salivation are generally present; the former may be severe. The cervical glands are usually enlarged.

Diagnosis.—Syphilitic lesions and warty growths may closely simulate a carcinoma, but the latter is distinguished by a greater degree of firmness, its gradual increase in size, ulcerated surface, and the progressive induration of the base.

Course.—If the growth is not excised it gradually extends to the neighbouring parts; the floor of the mouth, the gum, the lower jaw, the root of the tongue, the epiglottis, larynx and palate may be in turn attacked and destroyed. Death occurs, as a rule, within eighteen months of the first appearance of the disease, from exhaustion, septic pneumonia or hæmorrhage. The affection may remain local to the end, and, on the whole, general dissemination of this form of cancer is rare.

Prognosis.—This is very unfavourable; if the case be seen in the early stage and operated on the disease is very likely to recur *in loco* or elsewhere, and it then invariably proves fatal. It is estimated

that about 10 per cent. of the cases remain free from a recurrence for some years at least, and of these some are undoubtedly cured, but a rather larger proportion appear to succumb from the immediate effects of the operation.

Treatment.—So soon as the condition is diagnosed, presuming that this occurs before there is any extensive glandular infiltration, the affected portion of the tongue should be immediately removed, wide of the disease. For the details of the operation, and the various modes of effecting removal of the tongue, the reader is referred to works on surgery. When the diagnosis remains doubtful, it is very important not to apply caustics to the sore or to irritate it in any way.

J. K. FOWLER.

TONICS are substances which improve the tone of a part or of the whole of the body. They brace up, so to speak, the relaxed tissues. They are divided into nervine, vascular, cardiac, blood and gastric tonics according to the organ upon which they are supposed chiefly to act, but the distinctions must not be adhered to too rigidly, as it is evident that anything which improves the quality of the blood, will through it have an immediate effect on every organ and tissue throughout the body. Cod-liver oil and iron salts are the chief blood tonics, the mineral acids and alkalies the chief gastric tonics, nux vomica, strychnine and arsenic the chief nervine tonics. None of these, however, act on one part of the system only, but in varying degrees on all parts.

TONSILLITIS (Quinsy).—Inflammation of the tonsils.

The disease may involve the whole substance of the gland (*parenchymatous tonsillitis* or *quinsy*), or be chiefly confined to the lacunæ on the surface of the tonsil (*follicular tonsillitis*).

Symptoms.—Clinically the two forms are so interwoven that it will be convenient to describe them together. The attack usually comes on with febrile disturbance, malaise and aching in the limbs. Stiffness in the neck and pain in the throat soon supervene; the pain shoots up into the ears and is increased on opening the mouth or attempting to swallow. There is a constant desire to swallow, but the difficulty in doing this is so great that the secretions dribble out of the mouth, and if fluids are taken they frequently return by the nose. The tongue is coated and the breath is offen-

sive. The voice is thick and nasal, there is often deafness, the patient snores when asleep and the breathing is sometimes noisy even when he is awake. In quinsy the above symptoms attain their maximum just before the pus is evacuated, and the patient may suffer excruciating pain. On examining the throat in a case of parenchymatous tonsillitis, the tonsil (usually only one is affected) and adjacent parts will be found greatly swollen, of a deep purple-red colour, and often coated with viscid mucus. In the follicular variety, which is usually bilateral, the tonsils will be found enlarged and the surface dotted over with yellowish creamy spots, due to retention of secretion in the lacunæ.

The following complications have been met with, though fortunately only rarely, in connection with an attack of tonsillitis, viz., otitis media, cardiac disease (either endo- or peri-cardial), acute rheumatism and bronchitis. Occasionally a trace of albumen is present in the urine, but only in cases where there is considerable elevation of temperature (Haig-Brown).

Diagnosis.—This is easily made as regards quinsy; but there is sometimes a difficulty in distinguishing between follicular tonsillitis and diphtheria; in fact, there are transition forms in which differentiation is impossible. In diphtheria the patches are of an ashy-grey colour, cover a larger area, and are not dotted about as in follicular tonsillitis, and leave a bleeding surface on attempt at removal. Moreover, the onset of diphtheria is more insidious, the temperature as a rule is not so high, and albuminuria is generally present.

Prognosis.—Recovery is the termination which may be confidently looked for in quinsy; death has, however, occurred in a few cases from the bursting of the abscess, and the entrance of the pus into the larynx causing suffocation.

Pathology.—In parenchymatous tonsillitis there is an inflammation of the substance of the gland, which may go on to suppuration. In the follicular form the inflammation is more superficial, and chiefly affects the little lacunæ or crypts due to the involution of the mucous membrane. The creamy exudation seen in the lacunæ consists of fibrinous lymph, epithelial cells, and *débris*.

Etiology.—Tonsillitis is essentially a disease of adolescence and early adult life, being rare before fifteen or after thirty. Great stress has recently been laid on the connection between rheuma-

tism and tonsillitis, and there can be no doubt that the same causes are operative in the production of these diseases, exposure to cold and damp being the most common exciting causes of both, while heredity also plays a part in both. Follicular tonsillitis should always suggest the possibility of septic poisoning, and there is distinct evidence in favour of the contagiousness of sore throats, even where there is no suspicion of diphtheria.

Treatment.—The treatment is the same as for acute pharyngitis (*q.v.*). The writer has recorded some cases in which the application of a 20 per cent. solution of cocaine appeared to prevent suppuration, and, even in those cases in which an abscess formed, the application added much to the comfort of the patients by diminishing pain and enabling them to swallow. Should there be signs of suppuration, the bursting of the abscess is to be encouraged by poultices externally and the inhalation of steam, but the patient should not be left in pain when it is clear that suppuration has occurred, as immediate relief may generally be effected by puncturing the tonsil, using for this purpose a bistoury protected by strapping except for an inch at the end, and taking care to cut upwards and inwards. The previous application of cocaine will diminish the pain of the incision and facilitate the operation. Bleeding is to be encouraged by washing the mouth out with hot water.

F. DE HAVILLAND HALL.

TONSILS, HYPERTROPHY OF.

—Chronic enlargement of the tonsils.

Symptoms.—The child—for it is in children that the symptoms are most marked—breathes with the mouth open and has consequently a vacant expression, which is increased if, as is often the case, deafness be also present. The deafness is usually due to catarrhal thickening of the mucous membrane of the Eustachian tube. The breathing is laboured, and when asleep the child snores. The face is long and the nose narrow and contracted. The mouth is generally open and the lower lip everted, there is as a rule some fulness of the neck about the angle of the jaw. The patient has an unhealthy aspect and is often listless, and has a thick and nasal voice. Owing to the difficulty in breathing the chest is pigeon-breasted; this is especially apt to be the case if, as often happens, the child be rickety. The cervical glands are almost invariably enlarged.

It is unnecessary to describe the appearance of the tonsils on making an oral examination.

Diagnosis.—One glance at the throat will suffice for this purpose.

Prognosis.—In advising the removal of the tonsils it is well not to give too certain a prognosis as to the effect of the operation, on account of the possibility of the co-existence of adenoid vegetations in the naso-pharynx; if this be the case the removal of the tonsils will not suffice to cure the patient of his symptoms, as the naso-pharynx will require to be cleared ere the patient can breathe freely. With this proviso there is, in the writer's experience, hardly any operation which yields more certain and satisfactory results than the removal of greatly enlarged tonsils, and all ideas as to possible injury of the voice or interference with the sexual function may be dismissed as groundless. Moreover, in recommending the removal of tonsils it should be clearly pointed out to parents the risk children suffering from enlarged tonsils run in the event of their being attacked by scarlet fever or diphtheria.

Pathology.—There is a true hypertrophy of all the tissues of the tonsils, but the proportion varies in different cases.

Etiology.—Nothing can be definitely said on this point except that there is a strong hereditary tendency to this condition; by some writers enlargement of the tonsils is attributed to struma; not unfrequently it seems to follow upon repeated slight attacks of tonsillitis.

Treatment.—If the tonsils are sufficiently enlarged to interfere with the breathing, especially if the chest is becoming affected, they should be removed, and for this purpose Morell Mackenzie's modification of Physick's guillotine is recommended. It is advisable not to remove them when they are inflamed. The only remedy, short of excision, which promises any success is the use of the galvano-cautery, the tonsil being made to contract through the cicatrization brought about by puncturing it with a fine galvano-caustic point. In less-marked cases painting the tonsils nightly for some months with an application composed of equal parts of tincture of iodine, tincture of catechu and glycerine, together with the internal administration of cod-liver oil, syrup of the iodide of iron, and residence at the seaside may succeed in preventing further enlargement and may even cause some diminution in the size of the tonsils.

F. DE HAVILLAND HALL.

TORTICOLLIS (Wry-neck and Spasmodic Wry-neck).—A spasmodic affection of one or more muscles of the neck, and mainly of those supplied by the external branch of the spinal accessory nerve.

The affection may be unilateral or bilateral, and the spasm tonic or clonic.

Symptoms.—It is convenient to describe the two varieties of wry-neck separately.

(1) *Tonic Spasm, usually limited to one Sterno-mastoid Muscle.*—In this case the occiput is drawn towards the shoulder of the affected side, the face rotated towards the opposite shoulder, the chin raised, and the head thrown forwards. The trapezius is sometimes the seat of spasm. When the clavicular part is involved, the head is drawn to the affected side, the occiput approximated to the shoulder, the face rotated to the opposite side. The other portions of the trapezius may be implicated, and hence the shoulder is raised, and the scapula drawn slightly inwards. The sterno-mastoid and trapezius may be involved separately or simultaneously. The affected muscles become rigid and prominent, and after the lapse of time the deformity cannot be rectified either by passive efforts or voluntary action. In old-standing cases the cervical part of the spinal column becomes curved, the convexity being towards the sound side. Tonic spasm of both sterno-mastoid muscles is very exceptional. When it occurs, the head is drawn forwards, and the chin depressed.

(2) *The Clonic or Spasmodic Variety of Torticollis.*—This form of the disease is often preceded by uneasiness or pain about the neck. Jerking of the head soon follows, which at first may be restrained or rectified by voluntary effort. During sleep, and when the head and neck are mechanically fixed, the spasms are arrested. On the other hand, mental excitement, fatigue and ill-health exaggerate the movements. The clonic spasms come on at variable intervals. At an early stage the intermissions are comparatively long; but later on they are of shorter and shorter duration, until the spasms are almost continuous. The head and neck now become permanently distorted, the clonic movements, though of less amplitude, still persisting. As in the tonic form of wry-neck, the sterno-mastoid is frequently affected, with coincident or alternating spasm of the trapezius. The movements resulting from the contraction of these muscles have already been

described. Very often there is associated clonic spasm of the splenius and obliquus capitis, which are innervated by the superior cervical nerve. In some cases movements of the face, of the jaw, and of the various segments of the upper limb, supervene. The muscles of the neck are usually involved unilaterally, but sometimes the movements are bilateral, and then the spasm may be either alternating or simultaneous.

In *eclampsia nutans* (nodding spasm or salaam convulsion) of young children, the head and upper part of the body are bowed forwards several times in succession. The attacks tend to occur in paroxysms, during which the child may suffer temporarily from disordered consciousness. With this variety may be mentioned the unilateral head-jerking, from movement of the sterno-mastoid and of the rotating muscles of the head, which is also occasionally observed in children at the time of the first dentition. The movements are intermittent, often recur on attempts at fixation of an object, and are very commonly accompanied by lateral or oscillatory nystagmus. Momentary loss of consciousness is sometimes present in these cases.

In the ordinary adult form of spasmodic wry-neck the irritability of the affected muscles to the faradic current is said to be increased. Sometimes the movements are arrested by pressure on the muscles or on the supplying nerves.

Diagnosis.—Tonic spasm of the muscles of the neck may accompany spinal caries, but in such cases spinal tenderness is often found, and sometimes angular curvature. In the early stage of caries, however, muscular rigidity may be the only appreciable symptom. The common stiff neck, resulting from exposure to cold, is usually associated with local pain, and its duration is short. Spasm of the muscles on one side of the neck may occur when their antagonists are paralysed, but in this affection passive movements may be freely executed.

Prognosis.—Though sometimes amenable to treatment, spasmodic wry-neck has a marked tendency to recur. The general health may become impaired in severe cases. The nodding and lateral spasm in children often disappears, but relapses are frequent. Sometimes, however, convulsions and mental deterioration ensue.

Morbid Anatomy and Pathology.—It is highly probable that torticollis belongs to the so-called "functional" class of

disease. At any rate, no gross lesion has yet been discovered. Reflex irritation, especially in children, is occasionally present.

Etiology.—The causes of the disease are obscure. Both sexes are liable to be attacked, and the ordinary form of spasmodic torticollis occurs mainly in early or middle adult life. Emotional disturbance sometimes precedes the disease, and in some instances the individuals attacked are of hysterical stock or disposition. Over-exertion, exposure, and excesses have been looked upon as exciting agents.

Treatment.—In the tonic form division of the muscle or tendons is often effectual. Subsequently the head must be maintained in the normal position, by some form of mechanical apparatus. In spasmodic torticollis, various remedies have been suggested, such as bromide of potassium, belladonna, cannabis indica, antipyrin, sulphate of zinc, and morphine. The last named drug should, on obvious grounds, be used with great caution. The dose of many of the remedies above mentioned ought to be increased gradually, and it is often desirable to push the drug until the physiological effect is produced. The cold shower-bath is sometimes of service. Blisters to the affected muscles or in the course of the nerve are sometimes followed by temporary relief. The continuous current locally applied, and the use of the faradic current to the antagonistic muscles, have been recommended. Dr. Ross records a case in which marked benefit followed the use of an apparatus which caused permanent pressure on the "point of arrest." Stretching and division of the nerve, excision of a portion of nerve, and myotomy have been employed with a varying degree of success. Such operative measures should only be resorted to when the case is of long-standing, and has resisted other means. Surgical interference is also contra-indicated when there are movements of other parts, such as the face and arms. Mechanical means to restrain the movements of the head have been used, but they are of doubtful advantage.

W. B. HADDEN.

TOUCH, DISORDERS OF (including **MUSCULAR SENSE**).—Under this heading are included all the varieties of sensibility other than the special senses—viz., tactile sensibility, sensibility to pain, sensibility to temperature, and muscular sensibility.

Tactile Sensibility.—This may be

either altered in character (paræsthesia) or lost (anæsthesia). The tactile sensibility is rarely, if ever, excessive (hyperæsthesia), but, if the sensory nerves be in a condition of irritability, a slight touch may give rise to pain, and to this condition the term "hyperæsthesia" is commonly applied in preference to the term "hyperalgesia." When the time which elapses before a stimulus, applied over a certain area is perceived is longer than on the corresponding part, sensibility is said to be delayed. Tactile sensibility may be tested by touching the part lightly with a pen, the patient's eyes being closed, or by the use of the "æsthesiometer," an instrument for ascertaining at how short a distance apart two points can be differentiated. As a rule, the simple method first mentioned gives satisfactory results.

Sensibility to Pain.—This form of sensibility may be affected together with or independently of the last-named variety. When lost, the condition is properly termed "analgesia," but the term "anæsthesia" is more often employed. As already stated, the same remark applies to the terms used to denote an increased sensibility to pain. Sensibility to pain, like tactile sensibility, may be delayed. The condition of sensibility with regard to pain may be tested by pricking or pinching the part, or a faradic current may be used.

Sensibility to Temperature.—The appreciation of differences of temperature may be affected with the varieties of sensibility already mentioned or independently, and it is also believed that the sensations of heat and cold are conveyed by different nerves. The impairment of this sense may vary from a difficulty in recognizing slight differences in temperature up to a point where such stimuli pass quite unperceived.

The usual method of testing sensibility to temperature is by the use of sponges from hot and cold water or heated and cold metal spoons.

These various forms of sensibility may be either impaired, lost, over-active or disordered owing to lesions situated in (a) the peripheral nerve, including its terminal organ, (b) the spinal cord, or (c) the brain.

(a) *Peripheral Lesions.*—The fact that after complete division of a nerve there is in some rare cases no loss of tactile sensibility is generally explained by assuming that in such individuals an unusually free nervous anastomosis exists. In cases of injury or disease the peripheral nerves remain capable of conduct-

ing sensory impressions long after motor impulses have ceased to pass, a very few healthy fibres being apparently sufficient to convey sensory stimuli. Loss of tactile sensibility is a marked symptom in all forms of peripheral neuritis (*q.v.*) and also in the anæsthetic variety of leprosy (*q.v.*), and under various circumstances from pressure upon nerves. Irritative lesions of nerves may produce hyperæsthesia and pain in the area of distribution of the affected nerve.

Spinal Lesions.—For the effect of partial and total transverse lesions of the spinal cord, the reader is referred to the article SPINAL CORD, ANATOMY AND PHYSIOLOGY OF.

Loss of sensibility in spinal lesions is usually bilateral, but is always situated on the side of the body opposite to the lesion of the cord.

The posterior median and the anterior portion of the lateral white columns, or antero-lateral ascending tract, are probably the chief conducting strands for sensory impressions, and it is believed that the former are mainly concerned in the transmission of tactile impressions and the latter of sensations of pain.

The path by which impressions of temperature are conveyed through the cord is unknown, but it is probably situated in the lateral columns with that conducting sensibility to pain.

Increased sensitiveness is more often found in association with lesions of the spinal meninges than of the cord itself, whilst sensation may be abolished by lesions involving the posterior roots.

There are a great number of diseases in which, owing to lesions of the spinal cord, these various senses are affected, the most important being compression of the cord, as from tumours or hæmorrhage, or in any other way; and in the various forms of myelitis and spinal sclerosis, especially locomotor ataxia.

The mere enumeration of these affections is here sufficient, as the condition of the sensory perceptions is described in the separate articles, which will be found under the appropriate headings.

(c) *Cerebral Lesions.*—In cerebral lesions, owing to the decussation of the sensory fibres in the cord, the side of the body affected is opposite to that of the lesion. As a rule, in cerebral lesions the loss of sensibility, although affecting a larger area, often exactly one-half of the body, is less complete than in spinal and peripheral lesions. Sensory impressions are probably conveyed through the upper part, or tegmentum, of the pons and cura,

thence through the posterior third of the hinder limb of the internal capsule and the corona radiata, to the cortex in the central and parietal regions.

Hemianæsthesia may be produced by a lesion situated anywhere in the sensory path. In the case of a tumour situated in the pons, the loss of sensibility may affect both sides of the body. Hemianæsthesia rarely occurs from disease of the cortex, but there is often some impairment of sensibility in such cases. As a rule, the loss of tactile sensibility is most marked in the extremities of the affected limbs.

In typical cases of hemianæsthesia the loss of sensibility affects the head, trunk, extremities and mucous membranes on the side opposite to the cerebral lesion, sensibility to pain and touch being lost either separately or in association. In such cases the special senses are often affected also (*see* BRAIN, FUNCTIONS OF).

A condition somewhat similar to the above is met with in neurotic subjects—hysterical hemianæsthesia; in this the muscular sense is also lost, and, as a rule, ovarian pain is present (*see* HYSTERIA).

Irritant cerebral lesions may give rise to various paræsthesiæ.

MUSCULAR SENSE.—This may be defined as the knowledge of the degree of muscular contraction, *i.e.*, of how much force a given muscle is exerting. It also includes the ordinary sensibility of the muscles to pain and pressure, but it is commonly used in connection with the first-mentioned and more striking form of sensibility. The power of estimating differences in weight and the knowledge of the position of a limb are intimately bound up with the sense of degree of muscular contraction, and are lost when that sense is in abeyance.

This sense may be tested in various ways. The patient's eyes being closed, his arm is placed in a certain position, which he is asked to describe or imitate; two glasses, one full of water, the other empty, may be allowed to rest upon the end of corresponding fingers of the two hands, or balls of equal size but of different weight may be placed in the hands, or bags containing different weights may be hung on to the fingers, and the patient be asked to state which is the heavier.

The fibres conveying the muscular sense do not decussate in the cord, consequently, the muscular sense is lost on the same side as the lesion. The path of these fibres is possibly in the posterior median columns, and it is also

considered possible that the posterior vesicular tract and the direct cerebellar tract may convey sensory impressions from the muscles of the lower part of the trunk.

As already stated, the muscular sense may be lost in hysterical hemianæsthesia, whilst anæsthesia of the muscles may be present in locomotor ataxia and in hysteria. If the loss be sudden, the affection is probably spinal in origin. The treatment depends entirely upon the nature of the underlying cause.

J. K. FOWLER.

TRACHEA, FOREIGN BODIES IN.—A foreign body may enter the trachea and cause sudden death from obstruction if sufficiently large to occlude the air tube, if of smaller size it may cause dyspnoea and symptoms of irritation.

Treatment.—Tracheotomy should be performed at once, and not unfrequently the foreign body is speedily expelled either through the glottis or through the opening, if this does not happen inversion may be tried or forceps may be cautiously used.

F. DE HAVILLAND HALL.

TRACHEA, INFLAMMATION OF.—Inflammation of the trachea may be either acute or chronic.

ACUTE TRACHEITIS.—Acute catarrhal inflammation of the trachea is almost always the result of extension from the larynx or bronchi, it may, however, be the primary affection. In such a case the voice will not be affected, tenderness may be felt along the course of the trachea, with pain on coughing, and the patient may experience pain on swallowing, as the bolus of food passes down the œsophagus. By the aid of the laryngoscope the congested condition of the mucous membrane may be recognized in a certain proportion of the cases, but a tolerant patient and an excellent light are required to make a satisfactory tracheoscopic examination.

Prognosis.—If the inflammation be limited to the trachea no danger need be apprehended.

The *etiology* and *treatment* of acute tracheitis are practically the same as for acute laryngitis.

CHRONIC TRACHEITIS may be the sequel of an acute attack; it generally occurs as a result of chronic laryngitis or chronic bronchitis. The *treatment* is the same as for the bronchitic affection.

F. DE HAVILLAND HALL.

TRACHEA, STENOSIS OF.—Narrowing of the trachea.

Symptoms.—There is dyspnoea, but it is unaccompanied by the up and down movements of the larynx which are observed when the obstruction is seated at the glottis. The breathing is attended by stridor and the respiratory sounds are masked by the tracheal sound. The voice is usually weak though clear. Semon has recorded a remarkable case of stenosis of the trachea of syphilitic origin in which there was inspiratory dyspnoea, free expiration and normal voice, a combination suggestive of bilateral paralysis of the abductors, but distinguished from it by the absence of the respiratory excursions of the larynx.

Diagnosis.—Laryngoscopic examination will usually suffice to distinguish tracheal from laryngeal obstruction, but unless the cause of the mischief can be seen in the trachea, it is often extremely difficult to say whether the obstruction is situated within or without the trachea.

Prognosis.—In all cases this is grave; the stenosis being so frequently of a cicatricial character has a tendency to increase, and if seated low down, mechanical treatment may be difficult or even impossible.

Pathology.—The stenosis may be brought about by (1) pressure from without; (2) disease of the tracheal wall; (3) the implication of the trachea in disease of neighbouring parts. Enlargement of the thyroid, aneurysm and mediastinal tumours are the chief causes of the first group. In the second class cicatricial contraction due to syphilis plays the most important part, in fact the great majority of cases of stenosis are of this nature. Granulation tumours due to the irritation of the cannula after tracheotomy, new growths—*e.g.*, cancer, occasionally lead to stenosis. In the third class cancer of the œsophagus may in its onward growth implicate the trachea and cause a diminution in its lumen.

Treatment.—Unless syphilis can be absolutely excluded the patient should be placed on an anti-syphilitic treatment immediately upon the supervention of symptoms of tracheal stenosis—*i.e.*, half a drachm of blue ointment must be rubbed in daily, and ten to twenty grains of the iodide of potassium given every six hours. In chronic cases attempts may be made to dilate the trachea either through the larynx, or after the operation of tracheotomy.

F. DE HAVILLAND HALL.

TRACHEA, TUMOURS OF.—

A. NON-MALIGNANT.—New growths are not nearly so frequently met with in the trachea as in the larynx, in fact they are of rare occurrence.

Symptoms.—Dyspnœa is the chief symptom, the degree depending on the size of the tumour. As in other instances of tracheal obstruction dyspnœa is unaccompanied by respiratory excursions of the larynx. In some cases the tumours may be seen by tracheoscopy.

Treatment.—In a few instances the tumours have been removed *per vias naturales*; if this cannot be effected the trachea must be opened in a vertical direction so as to gain access to the tumour.

B. MALIGNANT.—Primary carcinoma of the trachea is exceedingly rare. Up to the end of 1887 only thirteen cases had been placed on record.

Dyspnœa is the chief symptom, but a diagnosis can only be made if the growth can be seen by the aid of the laryngoscope.

Tracheotomy will prolong life unless the growth extend too low down to admit of its being performed.

F. DE HAVILLAND HALL.

TRACHELORRAPHY (Emmet's Operation).—An operation devised by Dr. T. A. Emmet, of New York, for the repair of the lacerations of the cervix, which occur in most women who have had children. When this operation was first introduced, it was asserted that almost every disease to which women are subject was produced by these lacerations, and that therefore their repair was a necessary step to successful treatment. No proof has ever been adduced either of the effects on health which these lacerations have been stated to produce or of the benefits stated to result from the operation; but there is a good deal of testimony that in some cases not benefited by other means relief has followed repair of the cervix, and therefore it may be proper in cases of chronic inflammation of the cervix with laceration, if other treatment fail, to repair the cervix. But at present we have no criteria by which to identify these cases beyond the failure of other treatment. It is quite certain that the enormous majority of cervical lacerations interfere in no way with convalescence after labour or with subsequent health, comfort, and fertility, and that, if the operation of trachelorrhaphy be done in every case in

which laceration co-exists with illness, in the vast majority of cases it will fail to improve health. G. E. HERMAN.

TRANCE.—Trance in its ordinary sense is a term of somewhat vague limits, but had best perhaps, in strict medical language, be confined to a prolonged and rare condition of abnormal sleep which is produced by no known external agency, is generally entirely passive, in which the vital functions are reduced to an abnormally low minimum, and from which the entranced patients cannot be aroused by such ordinary excitants as would be more than sufficient to wake them from normal sleep. They can assimilate food artificially given, and may remain in this trance condition for as long as twenty-three weeks (Gairdner) or even for a year (P. Richer). Braid made a careful collection of Indian cases in which the fakirs induced in themselves a trance condition of extreme lethargy in which they were able to remain ten days or more without either food or drink (Sir Claude Wade, Sir C. Trevelyan). This tends to show a certain power of the will in the matter, and a greater adaptability of the Oriental mind and body to the conditions.

The onset of such a condition is usually sudden, and the awakening from it also rapid, though not to such an extent as to startle the person who has been in trance.

The symptoms are almost entirely negative. There is an absence, complete or incomplete, of sensation, and in a less degree of motion and of deep and superficial muscular reflexes. The breathing becomes nearly imperceptible; it may even be impossible to see any cloud on a clear mirror held before the mouth; the respiratory movements may be imperceptible, or at least as infrequent as three in two minutes; the pulse and action of the heart may be impalpable, though the condition of the retina will show that very slow circulation is still being kept up. The temperature is low, but has not been observed below 97° F. There is sometimes pallor, but very rarely that cadaveric appearance which once led Vesalius to mistake trance for death. Any such question of diagnosis can be settled by the electrical reactions of the muscles.

The condition in its physical signs is as a rule very like that of a hibernating animal. But the physical signs are variable; in fact, there are few cases in which they are all present at the same time. There may be, for instance, nearly

normal pulse and respiration and normal sensation or even hyperæsthesia.

The condition in itself is not one of any danger under careful supervision and treatment by food and warmth, but it may be almost indistinguishable, except by its history, from one of so-called spontaneous somnambulism arising in a hysterical subject, which generally implies an obstinate type of hysteria.

With the *psychical conditions and relationships* of trance we are at present very imperfectly acquainted. It needs careful study in company with a large group of cognate mental abnormalities. As a rule, the mental state is passive, and no memory of it persists; but there are insensible grades between this and ecstasy in which there is mental concentration on perceptions, sometimes supernormal, with outward expression of this, and more or less subsequent recollection. On the other hand, though the mental state in trance is generally quite unaffected by its surroundings, there are intermediate states between this and self-induced hypnotism, or auto-hypnotism, in which, with almost the same physical signs, there may be a very remarkable *rapprochement* with other people and notable receptivity to slight external stimuli.

A. T. MYERS.

TRANSFUSION (and INFUSION).—By these terms are meant the operations by which blood or some saline solution is injected into the blood-vessels of a living animal by artificial means. In medicine transfusion has been performed in various kinds of cases, such as (1) where there has been great loss of blood after operation or parturition, (2) where there has been excessive drain of the fluid constituents of the blood, as in cholera, (3) in diabetes, (4) where there has been profound alteration in the blood itself from various causes, such as occurs in leukæmia, anæmia, pyæmia, or the acute specific fevers.

Of recent years the opinion has been gaining ground that the value of "blood," as such to the person into whose vessels it is injected is less than was originally supposed and that much, if not all, the benefit claimed for it can equally be claimed for some simple saline solution. This latter acts by increasing the quantity of fluid in the vascular system and by enabling the circulation to be maintained when, for some cause or other, it had practically come to a standstill.

It has been ascertained by experiment that even after syncope has occurred, suffi-

cient corpuscular elements are left in the vascular system to carry on the function of the blood if only some harmless fluid be poured into the circulation. Various substitutes for human blood have been suggested, such as milk, or the defibrinated blood of some mammal whose corpuscles are smaller than man, such as the sheep. Not only have these no superiority to simple saline solution, but they are in some cases positively harmful.

Two methods only will here be considered. First, the injection of blood, either mediately or intermediately; and secondly, the injection of normal salt solution (0.75 per cent. solution of chloride of sodium in distilled water at 98° F).

Many ingenious forms of apparatus have been invented, but they are not here described, as those who possess them should know how to use them, and none of them have any superiority in skilled hands over the simplest apparatus which is in the possession of every surgeon. The best known forms of apparatus are those of Aveling (*Obst. Trans.*, 1873) and Roussell ("Transfusion of Human Blood," London, J. & A. Churchill, 1877). The former is practically a Higginson syringe with stop-cocks instead of valves at either end. The latter is an attempt to provide a mechanical substitute for surgical skill, and does not seem to be in any way necessary for the safe and easy performance of the operation.

The whole question of transfusion from a pathological, physiological, and practical point of view is discussed ably and at length in Dr. W. Hunter's lectures on Transfusion, reported in the *British Medical Journal* (vol. ii. 1889). His experiments show that in the great majority of cases the infusion of normal saline solution is attended with equally satisfactory results, and accompanied by far less danger than the injection of blood, whether defibrinated or not. The nutritive value of blood when injected into the circulation is very small; any advantage from its use seeming to depend more upon its physical than its physiological character, and considering the difficulty of keeping in order any particular form of apparatus for the mediate or intermediate transfusion of blood, the injection of saline solution should receive the preference in cases of emergency, such as hæmorrhage after confinement, diabetic coma, or choleraic collapse.

In order to perform the operation it is only necessary to open some moderate-sized vein, to insert a small cannula and attach to it a few inches of india-rubber

tubing filled with the saline solution. To the end of this tube a small glass funnel is attached, so that the requisite amount of fluid can be allowed to pour into the vessel by the force of gravitation. The quantity injected must of necessity vary very much according to the size of the patient, the extent of the loss of blood, and the effect produced by the injection. Probably not more than a pint would in any case be required.

Professor Schäfer (*Trans. Obstetrical Society*, vol. xxi., 1879) has published a series of experiments on the direct transfusion of blood from vein to vein or artery to artery.

In order to perform the former of these operations it is only necessary to insert one cannula into the vein in the arm of the donor and another into the vein in the arm of the recipient, connecting the two by a small tube of india-rubber which has been filled with bicarbonate of soda solution to prevent the coagulation of the blood.

In direct transfusion from artery to artery, it is suggested that the dorsal artery of the foot in the donor should be opened, and that during the operation he should stand, by which means the highest pressure of blood is made available. If the dorsal artery of the foot in the recipient cannot be found, owing to its not being filled with blood, it is desirable that the left radial should be opened, the cannula in any case being made to point towards the heart. It is in some cases easier to practise the intermediate operation, that is to say, to receive the blood of the donor in a glass vessel, to mix it with solution of phosphate of soda to prevent coagulation, and then to inject it into some vein of the recipient.

Dr. J. Duncan has discussed this question in the *Transactions of the Edinburgh Medico-Chirurgical Society*, 1885-86, and he recommends that a solution of 5 per cent. of phosphate of soda should be added in the proportion of 1 part to every 2 of blood.

In performing this operation the most scrupulous precautions must be taken to render the apparatus aseptic. If this be done, it is almost as simple as the injection of the saline solution.

The blood from the donor to the amount of from 8-15 oz. should be received in a small glass beaker containing the required amount of phosphate of soda solution, which must be kept at the normal temperature of the body by being immersed in hot water. A small cannula of glass with 2 inches of india-rubber

tubing attached, after being filled with phosphate of soda solution, should be inserted into the selected vein of the recipient. The blood may then easily be injected with a simple glass syringe, whose nozzle fits into the india-rubber tube. Care should be taken to avoid the entrance of any bubbles of air, though this source of danger has been very much exaggerated. The whole apparatus may be kept warm with flannel wrung out in some hot antiseptic solution. It is necessary to perform the injection very slowly. As much as 16 oz. have been injected in this manner with very satisfactory results. If excess of phosphate of soda be used, violent pain, chiefly in the back, may be induced; and if the operation be performed too rapidly over-action of the heart may make it necessary to desist, but if the details are attended to there is little fear of either of these complications. In all cases it is desirable before attempting to insert the cannula that the vessel should be carefully dissected out, as it is often not easy to find owing to its being empty or only partially filled with blood.

Dr. Roussell has published fifty cases of transfusion, twenty-seven of which were successful, and, entirely on practical grounds, he urges the use of some such apparatus as his, and the use of human blood passed directly from giver to the recipient.

Against the use of any such form of apparatus it may be urged that the operation of transfusion is only likely to be necessary in cases of extreme emergency and that any apparatus however simple is liable to get out of order unless constantly attended to: that no form of apparatus will supply want of skill on the part of the operator, and that on clinical, experimental and physiological grounds it is unnecessary to incur the risks and complications of using blood when so simple a fluid as a normal salt solution will supply all that is necessary to carry on the circulation of those cases which are not already hopeless.

The transfusion of blood in cases of anæmia and other blood disorders has not justified the hopes which were at first formed as to its value.

T. D. ACLAND.

TRANSPPOSITION OF VISCERA.—Man, in common with mammals, is distinguished from other vertebrates by the fact that the aorta arches over the root of the left lung, and passes

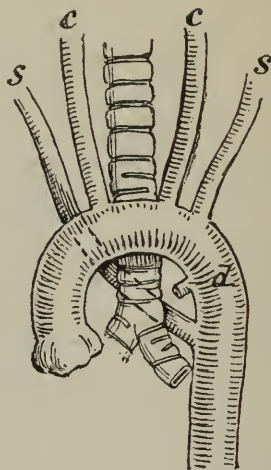

downwards on the left side of the vertebral column. Certain anatomical conditions in man are closely associated with this position of the aorta—viz., the apex of the heart is directed obliquely to the left side of the thorax, the right lung is three-lobed, the thoracic duct terminates at the junction of the left subclavian and internal jugular vein. Turning to the abdomen we find the liver occupying the right hypochondrium, its right lobe greatly exceeding in size the left; the *cul-de-sac* of the stomach lies in the left hypochondrium, and is closely related to the spleen. The transverse duodenum is directed from right to left across the body of the second lumbar vertebra, and the pancreas has its head on the right side of the abdomen and its tail in relation with the spleen. The cæcum occupies the right iliac fossa, and the vena azygos major lies on the right side of the column and terminates in the vena cava superior after arching over the root of the right lung.

It occasionally happens that the aorta arches over the root of the right lung and runs along the right side of the spine. This variation is often accompanied by a transposition of the viscera—that is to say, those organs, normally found on the right side of the thorax and abdomen respectively, take up a position on the left side, and *vice versa*. This alteration is of a most complete character, and is not merely an alteration in position, but an actual transposition, and, in order to appreciate it, the organs implicated may be separately considered.

Aorta.—The direction of this vessel is not merely the reverse of that which is normal, but the order of the vessels arising from it is reversed also: thus the left subclavian and common carotid arise from an innominate trunk, whilst the right common carotid and subclavian arteries spring directly from the arch. Among the numerous anomalies to which the trunks arising from the arch are liable, perhaps the most interesting is when the right subclavian, instead of arising from the innominate as usual, is the last vessel given off. Under such conditions it passes behind the trachea and œsophagus to gain its usual position on the first rib. So common is this that many anatomists adopt the following rule,—when the right subclavian frees itself from the innominate, it usually arises as the last vessel from the arch, and passes behind the œsophagus (Fig. 1).

When this arrangement obtains, the

FIG. 1.

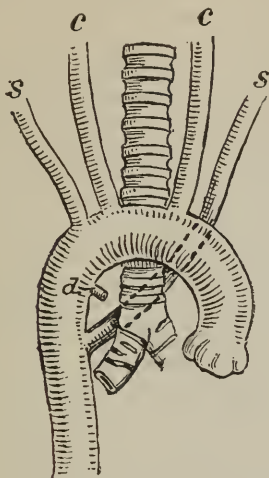

The right subclavian artery arising as the fourth branch of the aortic arch.

right inferior laryngeal nerve has often a direct instead of a recurrent course, and the thoracic duct has a dextral termination. In one carefully described case of right aortic arch the left subclavian artery, instead of coming from a left innominate, was the last vessel to arise from the arch, and then followed the course usual to this mode of origin—that is, it passed behind the œsophagus. The relation of the inferior laryngeal nerve and thoracic duct is, unfortunately, not stated. An aberrant subclavian artery of this character associated with a right aortic arch is represented in Fig. 2.

A right aortic arch with transposition of viscera must not be confounded with "transposition of the aorta." This term is used when the aorta arises from the right ventricle of a normally placed heart.

Heart.—The transposition of this organ consists, not merely in the deflection of its apex to the right instead of the left, but in an actual reversal of its cavities, the right ventricle becoming systemic and the left pulmonic. The superior and inferior venæ cavae open into the left auricle, and the major azygos vein arches over the root of the left lung to gain the superior vena cava. This displacement of the heart is frequently accompanied by imperfect development of the ventricular septum, often so extreme as to be incompatible with life.

FIG. 2.

A right aortic arch, with aberrant subclavian artery.

Lungs.—Even in cases of incomplete transposition, the left lung is furnished with three lobes and the right two; it is remarkable that a three-lobed left lung unassociated with transposition, complete or incomplete, has yet to be recorded.

Liver.—This organ is completely reversed; it not merely lies in the left instead of the right hypochondrium, but its left lobe is the larger, and is the part which accommodates the gall-bladder.

Stomach.—This is not altered in position so frequently as the preceding viscera. In typical cases the great *cul-de-sac* or fundus is directed to the right and the pylorus to the left. In individuals with the liver occupying the left hypochondrium and the stomach not transposed, it must naturally follow that this viscus cannot occupy its natural position but is pushed lower in the abdominal cavity than usual. When the stomach is transposed the direction of the duodenum is reversed also and the head of the pancreas, instead of lying on the right side of the spine, is directed to the left. Under such conditions the jejunum commences on the right side of the spine. The disposition of the various part of the duodenum is liable to considerable variation when the viscera are transposed.

Spleen.—The position of the spleen is influenced by the stomach;

when the latter organ is transposed the spleen, connected as usual with its great *cul-de-sac*, occupies the right hypochondrium. When the liver is in the left hypochondrium and the cardiac end of the stomach maintains a sinistral, though displaced position, the spleen maintains the natural relation to this viscus. When the stomach and spleen are completely transposed the latter is liable to be malformed. Even under ordinary conditions the spleen is extremely liable to be accompanied by one or more satellite spleens or spleniculi; but when it occupies the right hypochondrium it is usual to find numerous satellite spleens, and in some cases the spleen has been represented by a number of spleniculi instead of a single organ. In one case (Hickman's) nine spleniculi were counted. In another (Matthew Baillie's) five satellites were present. M'Whinnie found the spleen represented by three separate equal-sized portions in the right hypochondrium, and Curling in a similar case of transposition found the spleen on the right side "with four supernumerary spleens near the principal one." Thurnam, in reporting a case in which all the viscera except the stomach and spleen were transposed, writes:—"Behind the stomach was a round spleen, the size of a small apple, and accompanying it, were five supernumerary spleens, the size of walnuts and filberts, which grew, as it were, from the branches of the splenic artery something like a bunch of grapes."

The Cæcum and Colon.—In many of the cases in which the thoracic viscera with the liver, stomach, and spleen were transposed, the cæcum occupied the left instead of the right iliac fossa; the ascending, transverse, and descending colon took the reverse of the usual course and the rectum was on the right side of the pelvis. In others the cæcum was situated as usual in the right iliac fossa; under these conditions the ascending and descending portions of the colon were parallel to each other on the right side of the abdomen. In a few cases the cæcum was in the left iliac fossa, and the colon passed obliquely across the abdomen to the right hypochondrium and then descended to the pelvis. So vagarious is the colon when the viscera are transposed, that no positive statement can be made in regard to it, and even in cases where the stomach, duodenum, spleen, and pancreas are completely reversed, the cæcum and colon may retain a

normal position. Transposition of the cæcum and colon, independently of the remaining viscera, is by no means an unusual event. The intra-abdominal portion of the vitello-intestinal duct is unusually persistent in cases of visceral transposition.

Veins.—Many anomalies of veins, especially in regard to their terminations, have been recorded in connection with the transposition of viscera. These cannot all be considered; it is clear that if the aorta runs along the right side of the spine and the inferior cava on the left, certain alterations in the venous system are unavoidable. The chief of these are the following:—the right renal vein is longer than the left, and receives the corresponding spermatic or ovarian vein, as the case may be. It has been noticed in two cases that the right testis was lower than the left. The right iliac vein is longer than the left and the portal vein is directed to the left instead of the right side. In the thorax the right innominate vein is the longer; the dextral thoracic duct has already been mentioned. In a few carefully dissected cases the major azygos vein was situated on the left side of the spine.

The bronchial veins are liable under these conditions to vary in their mode of termination. The most remarkable variation is that recorded by Hickman, in which the pulmonary veins from the right lung entered the left auricle, and those from the left lung entered the right auricle. No symptoms which could in any way be attributed to this anomaly were observable during life.

Individuals with transposed viscera, unassociated with developmental defects of the heart, seem to be little influenced thereby. In several cases defects of the ventricular septum and anomalous terminations of the bronchial and systemic veins with concomitant cyanosis have been reported, but as these defects occur independently of transposition, they cannot in justice be attributed to it. In order to give some notion of the expectancy of life with transposed viscera the following ages of individuals with the name of the observer may be useful. Female, 28 years (Hickman); male, 40 years (Matthew Baillie); male, 48 years (Allen Thomson); male, 48 years (William Moxon; female, 25 years (M'Whinnie); female, 37 years (Thurnam); male, 40 years (Curling); and a female 85 years (Ed. Parker Young). A perusal of the history of the cases does not show that the position of the viscera had any evil

effect, in some of the cases death was due to lung trouble, and in several the heart was described as diseased and there was general dropsy.

It has often been stated that individuals with reversed viscera are left-handed, but an examination of the reports of many cases observed during life, and in a few in which this matter was inquired into after death, does not lend the least support to such a conclusion.

The cause of transposition of viscera is as unknown as the reason why the liver normally occupies the right hypochondrium and the spleen the left. Speculations as to the cause have been advanced but with little confirmatory evidence. Von Baer attempted to explain it in the following way:—In the early stages of the avian embryo, and certainly in a few mammals, the ventral aspect of the embryo lies on the yolk, but soon the left side is turned towards the yolk; occasionally embryos are found with the right side in the direction of the yolk. Von Baer believed this alteration in the position of the embryo determined the deviation in question. To say the least this suggestion is very ingenious, but when taken in consideration with such facts as the disappearance of the right omphalo-mesenteric vein and the left superior cava in man, the right oviduct in all, and the right carotid in a few species of birds, and other kindred facts, the view ceases to carry that conviction which it does when considered in relation to man alone.

Allen Thomson and others have pointed out that in double embryos produced by dichotomy of a single germ, the viscera of one or other embryo should be transposed, one should be, as it were, the reflection of the other, *velut in speculo*. The writer of this article has tested this matter, and in many instances such is indeed the case, but in the majority of specimens the heart, liver and other organs are so displaced or agglomerated, that it is impossible to decide not merely to which half of the body, but often to which foetus, they belong. This is particularly the case with the heart. The writer, too, is fully of opinion that when twins occur of the same sex, with a common amnion and single placenta, they are the product of a single ovum. This of course suggests that an individual with transposed viscera should be one of twins. Unfortunately no facts are forthcoming whereby this view may be tested, but it is one that would repay investigation. It must be carefully borne in mind,

that it does not follow that because only one child was recognized at birth, therefore only one was present. Many cases of twin-births have been recorded in which the second child was flattened out, and formed merely a small lump in the membrane, or presented itself in the form of an *acardiacus*, and the writer has known such masses to be cast aside even by obstetric physicians (who ought to have recognized them) as "mere adventitious lumps." Perhaps, now that many workers look upon teratology as something more than a science of curious deformities, in which the varieties are distinguished by sesquipedalian names, a solution to the question of visceral transposition may soon be forthcoming.

As models of careful description, as well as types of the condition to which this article is dedicated, the writer would particularly advise the perusal of the five under-mentioned and easily accessible papers:—

Matthew Baillie, *Philosophical Transactions*, 1788, vol. lxxviii. part 2; Allen Thomson, *Glasgow Medical Journal*, July 1853; Hickman, *Trans. Path. Soc.*, vol. xx. p. 93 (this writer had the rare opportunity of dissecting two individuals with transposition of viscera within a few weeks); Thurnam, *London Medical Gazette*, 1839, vol. xxvi. p. 181, and M'Whinnie, *ibid.*, p. 31.

J. BLAND SUTTON.

TREMOR.—A form of clonic spasm consisting of rhythmical movements of one or more groups of muscles. It may be coarse or fine according to the muscles affected.

Tremor constitutes an important symptom of many diseases, most of which are treated under their appropriate headings (*see DISSEMINATED SCLEROSIS*).

The tremor constantly met with in alcoholism and delirium tremens is described in the article on **ALCOHOL**; in paralysis agitans (*q.v.*) tremor is almost invariably present, but cases are on record in which the symptom was absent; and in poisoning by lead, mercury and arsenic, tremor is an important symptom, and it is generally also observed in chronic poisoning by chloral and opium. It is often met with in hysterical subjects, where it occurs in association with both paralysis and contracture.

Senile tremor, as its name implies, attacks the aged. The arms and head are the parts chiefly affected. When tremor occurs without association with nervous disease in persons who have not

passed middle life it is generally termed "simple" tremor. A coarse tremor occurring only on movement is often met with in exophthalmic goitre. Tremor is often present in conditions of debility—for example, during convalescence from acute disease—and passes off as strength is regained.

Diagnosis.—In disseminated sclerosis the tremor is irregular, and the movements are sudden and jerky, and are much increased by any voluntary effort of the patient to restrain them; they occur only on movement, and cease during rest. In paralysis agitans the tremor is regular and rhythmical, and occurs during both rest and movement, except in an early stage of the disease, when it may cease during rest.

Senile tremor occurs at first only on movement, and ceases, or almost so, during rest, but when severe it may be present during both rest and movement; it is more influenced by the latter than is the tremor of paralysis agitans, and in this form the head is more often affected than in paralysis agitans. Alcoholic tremor occurs only during movement, and affects chiefly the arm, face and tongue.

Treatment.—This will depend upon the nature of the causal condition. In simple and senile tremor but little is to be expected from treatment; a trial may be given to nervine tonics and sedatives.

TRICHINOSIS.—A disease produced by the ingestion of meat containing a minute helminth, the trichina spiralis. The male worm, when found free, measures $\frac{1}{16}$ th inch in length. The female is larger, measuring nearly $\frac{1}{4}$ th inch in length.

In the muscles the worm is found coiled up in a lemon-shaped capsule, at either end of which is a small collection of fat globules. The long axis of the capsule lies parallel with the muscular fibres. The worm may be found in the fæces.

After the trichinous meat (pork or sausages) has been eaten, the course of events is as follows:—In two days the larvæ become mature, in about six days the embryos are born, and in the course of the next week they proceed to migrate to all parts of the body, establishing themselves finally in the voluntary muscles, where they become enclosed in a thin, but subsequently laminated, lemon-shaped capsule. When this stage has been reached, the trichinæ are absolutely quiescent, and no symptoms may betray

their presence. Ultimately the enclosing sac becomes calcareous. Prior to encapsulation, nausea, vertigo and fever are the earliest symptoms noticeable. These are followed by diarrhoea, prostration, and a stiff and painful condition of the extremities. At the end of a week the fever increases, the face becomes cedematous, and the voluntary muscles throughout the body swollen and painful. There may be aphonia and pain on moving the eyes, whilst perspiration, insomnia and delirium are among the graver symptoms of this period. The helplessness of the patient is extreme. In a month or so improvement may set in, a gradual amelioration of all the symptoms being observed, and desquamation usually takes place. The patient however, may die from exhaustion with high fever before the end of the month, or from pneumonia or other complication.

Treatment.—As regards treatment, not much can be done except to try and relieve the pain and allay the fever by general measures. If seen within a day or so of taking the trichinous food, it might be well to empty the alimentary canal with a calomel purge. The trichinæ are destroyed by cooking, therefore only those who eat uncooked meat can become the victims of this disease.

TRIFACIAL NERVE, DISEASES OF (Fifth Nerve; Trigeminal).—This nerve, arises from the side of the pons Varolii by two roots, motor and sensory. The former, the smaller, comes from a nucleus lying rather deeply below the lateral angle of the fourth ventricle, and above the facial nucleus; the sensory nucleus is larger and lies to the outer side of the motor, and it also receives fibres from the so-called ascending root of the trigeminal.

The fifth is the largest of the cranial nerves and consists of three parts, or divisions as they are termed, the ophthalmic, the superior maxillary, and the inferior maxillary; of these the two former are connected with the Gasserian ganglion, and are purely sensory.

The *Ophthalmic* supplies the integument of the nose, upper eyelid, and forehead, and the upper part of the hairy scalp, the mucous membrane of the nose and eyelids, the ball of the eye, and the lachrymal gland.

The *Superior Maxillary* gives sensation to the skin above the zygoma, the lower eyelid, the side of nose, the upper

teeth, and the mucous membrane of the roof of mouth, nose, and upper part of pharynx.

The *Inferior Maxillary*.—The third division contains all the motor fibres, which do not pass through the Gasserian ganglion, and gives motor fibres to all the muscles of mastication as well as to the mylo-hyoid and digastric muscles, whilst the sensory part passing through the ganglion, supplies the skin of the lower lip and lower part of face, the lower teeth, the mouth, tongue, the side of the head and the ear, and the salivary gland.

The *Gustatory Nerve*, from this division, supplies the function of taste to the anterior two-thirds of the tongue.

The nerve is liable to be affected by local disease within the pons Varolii, as softening, hæmorrhage or tumour; outside the pons by meningitis, growths, or carious bone; and the individual branches are apt to be involved in growths in the orbital or speno-maxillary fissures. In locomotor ataxia, the fifth nerve is liable to be paralysed along with other cranial nerves. Paralysis is the most important affection, and may involve either the whole nerve or one or more of its divisions; other affections are neuralgia of the sensory part and trismus of the muscles supplied by the motor fibres.

Paralysis.—When the whole nerve is paralysed, the symptoms may be described under the head of (1) *Sensory*, (2) *Motor*.

(1) *Sensory.*—There is loss of sensibility to tactile and painful impressions in the parts supplied, the anæsthesia being often preceded by tingling or pain. The anæsthesia will include the corresponding half of the face and adjacent side of the head, as well as the conjunctiva, and mucous membrane of the half of the nose, lips, tongue, hard palate, anterior pillar of fauces, and the soft palate of the same side. As a consequence of this the conjunctiva can be touched, the nostril may be irritated by ammonia, and the fauces of one side can be tickled without any reflex actions being evoked. The patient bites on the other side as he cannot feel the food, and as a result fur collects on the affected side of the tongue. Smell is lost owing to the dryness of the nasal mucous membrane. Taste may be completely lost from disease of the root of the trigeminal (Gowers), but disease of the gustatory nerve, after it has been joined by the chorda tympani, causes loss of taste in the anterior two-thirds of the tongue; no effect is, however, produced when the

lesion in the gustatory is above this junction.

Besides the above symptoms there are certain trophic changes of importance. The secretions, including those of the lachrymal and salivary glands, are diminished; herpes zoster of the face and inflammation of the cornea are considered to be especially due to irritation and disease of the Gasserian ganglion; in the latter case the cornea becomes cloudy, opaque, ulcerates, and the whole eye may become disorganized and destroyed.

(2) *Motor*.—The chief motor symptom is an inability to use the muscles of mastication of the affected side; the patient cannot bite hard, and the temporal and masseter muscles can be felt to contract feebly or not at all. Owing to paralysis of the external pterygoid the lower jaw cannot be carried over to the opposite side in grinding the food, and in opening the mouth the lower jaw drops over towards the paralysed side, being drawn there by the healthy external pterygoid of the other side.

Diagnosis.—This is not difficult when the symptoms are well marked; in the early stages the pain produced by irritation of the nerve may simulate simple neuralgia, but in the former case the pain is more persistent and passes on to anæsthesia and motor paralysis of the parts supplied by the nerve, which is a certain proof of organic disease. Loss of sensation of the face and mucous membranes is met with in hemi-anæsthesia of organic or functional origin, but in these cases the anæsthesia extends beyond the anatomical distribution of the trigeminus, to the head, nerve, limbs, or the whole of one side may be affected, and this is also associated with hemiplegia and affection of all the special senses of the same side. The seat of the disease will be shown by the anatomical relations of the part affected.

Treatment.—When due to cold, hot fomentations should be applied to the side of the face and the head, and if any inflammation be present a blister may be applied behind the ear. If the pain is very severe, local sedatives, as cocaine or menthol, may be required, or morphine hypodermically. In cases where syphilis can be made out or suspected, iodide of potassium in full doses should be given. Faradization of the face with the wire brush has been recommended, to promote the return of sensation.

C. E. BEEVOR.

TRISMUS NEONATORUM.—

A form of tetanus only met with in infants.

Symptoms.—The onset is gradual but the course is rapid. At first the child is peevish and cannot take the breast properly, its mouth is found to be fixed, and subsequently the whole body becomes more or less rigid; general convulsions lasting perhaps half-a-minute, come on in paroxysms, at intervals of one or two minutes. During the attacks the child becomes livid, the hands and feet are clenched, and the spine is arched backwards (opisthotonos). The condition of the mouth is most important and characteristic, at first it is a little open and the angles are drawn down, then the jaws become closed, and the angles more drawn down, so that the child can neither suck nor swallow. In the intervals between the paroxysms the rigidity does not wholly pass off. A mere touch or even the attempt to swallow is sufficient to induce a paroxysm. There is generally some fever and there may be hyperpyrexia.

Prognosis.—Death results from asphyxia, usually within thirty-six hours of the onset, during a convulsion, or from coma. If the child survive the sixth day there is some chance of its recovery.

Morbid Anatomy.—Intense congestion of the vessels of the spinal cord and its membranes, with hæmorrhages external to the theca are almost constant lesions, but it is not proved that they are the cause of the symptoms: they may be the effect. Congestion of the brain and its membranes has been found.

Pathology and Ætiology.—The disease almost invariably ensues in the first five days of life, rarely after the end of the first week, it is a very fatal affection and the earlier it appears the more rapid is its course.

The theory that it is dependent upon some condition of the umbilical cord is far from proved, inflammation of the cord or thrombosis of some of its veins is by no means constant, but it may be noted that in traumatic tetanus there is frequently no inflammation of the wound. It has been attributed to pressure on the medulla and nerves by a faulty position of the occipital bone, but it appears much more probable that it is in some way dependent upon defective hygienic surroundings, for some years ago it was exceedingly common in a Dublin lying-in hospital, and became rare directly the sanitary arrangements of the building were made satisfactory.

Treatment.—Hygienic measures should be adopted as preventive whenever the disease is found to be of frequent occurrence. Placing the child on its side and manipulating the occipital bone into a different position has sometimes, it is said, resulted in the disappearance of the symptoms. During the attack hot or cold baths or ice to the spine should be tried; chloroform might be administered, and bromide of potassium or Calabar bean given internally; but treatment has not hitherto seemed of much avail.

TROPHIC NERVES.—That nutrition can go on independently of a nervous system is clear from what occurs in plants and the lower animals. Nevertheless, the theory is held that in the higher animals it is a function of the nervous system so to co-ordinate the metabolic processes in the different tissues of the body that their nutrition shall be healthy. Injury to certain parts of the nervous system is believed to disturb this co-ordination in such a way that the nutrition of the parts is visibly altered, and such alterations constitute trophic lesions. The nerves which are supposed to preside over nutrition are called trophic nerves.

It is impossible in most cases to prove the existence of trophic nerves with absolute certainty; nevertheless, in many instances their existence is extremely probable. The only certain examples of trophic influence which have been localized are, first, that which the posterior spinal ganglia have over the nutrition of sensory nerve fibres; for, if the nerve root be cut either side of the ganglion, such of the nerve as is still in connection with the ganglion remains healthy, but the part which is severed from the ganglion degenerates. Secondly, some, at least, of the sympathetic ganglia have a similar influence upon the nerve fibres attached to them.

As instances of trophic influence which cannot be precisely localized, the following may be mentioned:—

If the anterior spinal nerve root be cut, the part which remains attached to the spinal cord is unaffected, but the distal part degenerates; the degeneration of its fibres extends down into the mixed nerve, just as when the posterior root is divided on the distal side of its ganglion the degeneration of its fibres extends down into the mixed nerve. When in the rabbit the trigeminus is cut in the skull, the cornea becomes cloudy, and ulcers form inside the nose

and mouth. It is highly probable that this is owing to the fact that this nerve exerts a trophic influence upon these parts. The salivary glands are almost certainly under the control of trophic nerves.

We will now pass to a consideration of those pathological conditions which have been attributed to trophic disturbance.

1. Trophic Lesions of Nerves.—

Whenever a nerve fibre is separated from one of the nerve cells, or the only nerve cell, to which it is attached, it degenerates. Thus, we have seen that the fibres of the posterior root degenerate when separated from the posterior ganglion, and that the fibres of the anterior root degenerate when separated from the cord, because the cells in the anterior cornua exert a trophic influence on them. The fibres of the crossed and direct pyramidal tract degenerate when separated from the cells of the motor area of the cortex. Under certain circumstances other tracts of fibres in the cord degenerate, but it is not known what cells exert a trophic influence upon them. As a rule fibres degenerate in the direction in which they conduct, but exceptions are the degeneration away from the posterior root ganglion of the sensory fibres in a mixed nerve and the degeneration away from the gyrus fornicatus of the fibres connected with it. This process of degeneration is called Wallerian, after A. Waller, who first described it.

The time at which it begins varies in different species, but soon after the destruction of the trophic cells or the separation of the nerve fibres from them the nuclei of the fibres become larger, and the amount of protoplasm around them is increased. This protoplasm so increases that at places it extends right across the nerve fibres, and consequently splits up the myelin, first into large, then into smaller particles, and at the same time or rather later destroys the axis cylinder. The fatty myelin forms drops in the protoplasm; these undergo some change in chemical composition, and ultimately are absorbed. While these changes have been going on, the enlarged nuclei have subdivided. After the absorption of the myelin, the nerve fibre shrinks; the process goes on simultaneously along the whole fibre. Regeneration takes place if the trophic centre is not completely destroyed, by the new growth of axis cylinders from the healthy portion of the nerve; these grow

down among the degenerated fibres; some apparently die, but others become clothed with a sheath of myelin and are in some few months functionally active. The changes undergone by the nerve fibres of the central nervous system are the same as take place in the peripheral nerves.

2. Trophic Lesions of Muscles.—Either irritative or destroying lesions of the ganglion cells of the anterior cornua of the spinal cord and their homologues in the medulla and pons, or of the efferent fibres which unite these cells with the periphery may give rise to active trophic lesions of muscles. Thus, they are met with, for example, in acute anterior polio-myelitis and in peripheral neuritis. Whether the same cells have both a motor and a trophic function is not known, but it is clear that, if not, the motor and trophic cells must be close to each other. At first the only change to be seen in the muscles is that the individual fibres have become narrower; for the most part the striation remains as usual, but sometimes the transverse striation is indistinct; while the longitudinal is very evident. At this stage the process is recoverable, but, if it proceed, the fibres become filled with fine granular matter, in which fat globules ultimately appear, only to be absorbed. Next there is a great multiplication of the muscle nuclei and also of those of the connective tissue between the muscle fibres. These nuclei ultimately develop into fibrous tissue; by this time recovery is quite impossible, and what was the muscle becomes a mass of fibrous tissue with a few remnants of granular muscle fibres. The bulk of the muscle is considerably decreased. The whole process occupies several weeks. These trophic changes in muscle are always accompanied by a reaction of degeneration, which is never met with unless such changes are going on in the muscle. It is most important to remember that these trophic alterations in the muscle can only occur under the conditions stated, and that therefore they are never found in simple atrophy of muscle, as, for example, in the atrophy that comes from disuse, or in primary muscular atrophy, or in pseudo-hypertrophic paralysis. Nor do they ever occur when the lesion is above the motor cells in the cord, medulla, or pons.

Nothing is known of the trophic changes of plain muscle fibres.

3. Trophic Lesions of the Skin.—It is not known which part of the central

nervous system controls the nutrition of the skin. There are so many varieties of cutaneous trophic changes that they must be described separately.

(a) *Vaso-motor Disturbances.*—These occur chiefly in diseases of the peripheral nerves; for example, flushing over the painful spot is common in neuralgia, vaso-motor dilatation is seen when an aneurysm or tumour paralyses the cervical sympathetic (see SYMPATHETIC SYSTEM), and increased redness has been met with in association with disease of other nerves. Vaso-motor alterations are occasionally observed in lesions of the central nervous system, but then they are generally preliminary to some more important trophic lesion, such as an acute bed-sore. Sometimes the vaso-motor disturbance is accompanied by œdema, which may be general over the whole area of distribution of the nerve or may be patchy, giving rise to urticaria; and often in nervous diseases, even when there is no obvious vaso-motor alterations, a mild irritant produces severe and widespread redness, which readily passes on to vesication and even gangrene, hence blisters should be cautiously applied.

(b) *Vesicular and Bullous Eruptions.*—These also are mostly associated with disease of the peripheral nerves. Herpes occurring over the intercostal and other nerves is a familiar instance (see HERPES), and has been proved to be due to a neuritis situated at the exit of the nerves from the spinal canal. In the face, herpes of the fifth nerve is often accompanied by so much œdema that careless observers, failing to notice its unilateral character, have mistaken it for erysipelas. It may be accompanied by a rise of temperature, and is a very painful affection; the pain often persists after the herpes has disappeared. Herpes is met with in peripheral neuritis, and also in tabes dorsalis, when it may be due to the accompanying peripheral neuritis. Occasionally the vesicles become pustular, and then the lesion simulates eczema. The occurrence of bullæ large enough to remind one of pemphigus, which is not a nervous disease, is rare, except where they are the precursors of acute bed-sores. It is doubtful whether lesions of the central nervous system ever lead to herpes, for in most of the recorded cases the post-mortem examination has been incomplete.

(c) *Glossy Skin.*—This condition is seen in neuritis or traumatic lesions of peripheral nerves. The fingers are most

frequently affected, sometimes also the palm, rarely the dorsum of the hand. In the foot the toes suffer, occasionally the dorsum, very rarely the sole. In a well-marked case the fingers are usually tapering, smooth, hairless, devoid of wrinkles, glossy, pink or ruddy or blotched as with permanent chilblains. They are commonly also very painful, especially on motion; the pain often extends up the arm. The condition is, in some respects, not unlike scleroderma; in fact, one variety of scleroderma—viz., morphœa—is an atrophy of the skin distributed along the course of a nerve, usually the supra-orbital branch of the fifth.

(d) *Scaly Conditions of the Skin.*—In rare cases after injury to a nerve or neuritis, the skin supplied by it becomes scaly and dry.

(e) *Pigmentary Changes in the Skin.*—A few instances are on record in which, after emotional disturbance, or after injuries to nerve-trunks, patches of abnormal pigmentation have appeared upon the skin.

4. **Trophic Lesions extending deeper than the Skin.**—(a) *Bed-sores.*—The acute variety is especially met with in acute diseases of the spinal cord, such as traumatic lesions and acute myelitis, but not in diseases affecting the anterior cornua only, such as infantile paralysis. Lesions of the cauda equina, and severe cerebral hæmorrhage or extensive softening will occasionally cause acute bed-sores. In the case of cerebral lesions the bed-sore is on the opposite side to the lesion. These bed-sores may form in any part, but the favourite positions are, in order of frequency, the sacrum and coccyx, the trochanters, the ischial tuberosities, the heels, the knees, the vertebral spines, the scapulæ, and the elbows. The first sign of the bed-sore is an erythematous patch, on which in a few hours vesicles develop. These soon burst, and a sore results, which quickly spreads deeply and widely, the sides and base of the ulcer become gangrenous, and ultimately the muscles are destroyed, and the bone is exposed. The whole process is very rapid; it may stop at any point, and recovery may take place. When the sore is over the spinal column, the necrosis of the bone leads to the exposure of the spinal canal; pus thus gets into this, and purulent meningitis is set up. Occasionally also, bed-sores lead to death from pyæmia.

Sometimes, when the nervous disease

leading to the bed-sore is chronic, such as chronic myelitis, the sore is much longer in developing, a large slough forms on the skin, and ulceration around this leads to its being cast off.

Both acute and chronic bed-sores usually form on parts subjected to pressure, but mere pressure will not explain their production, for they may occur in cases in which by careful nursing the pressure has been rendered almost inappreciable, and they occur much more readily in nervous diseases than in any other maladies. It is not known precisely what part of the nervous system must be damaged to produce such bed-sores.

(b) *Perforating Ulcer.*—In this disease the nerves going to the ulcerated part have always been found to be inflamed. The patients nearly always suffer from tabes dorsalis, of which perforating ulcer is an early sign. It is generally accompanied by lightning pains, and has a large area of anæsthesia round it. Its most usual site is the sole of the foot, especially over the metatarso-phalangeal joints of the great and little toes. Rarely it is seen in the hand. First a corn appears, and in the centre of this an ulcer forms and extends deeply, ultimately reaching the bone, which at that spot soon dies. The ulcer looks more like a sinus than an ulcer. There is no discharge. The skin around it is thickened and heaped up. They may occur on both feet, in which case they are usually symmetrical, and there may be more than one. They are often accompanied by trophic lesions of the joints and bones.

(c) *Leprosy.*—The changes in the skin and deeper structures met with in this disease are due to a neuritis. They are described in the article on LEPROSY.

5. **Trophic Lesions of the Nails and Hair.**—In rare cases of tabes dorsalis the nails are particularly prone to fall off, but they grow again, and then fall off again, and this process may be repeated several times in the course of a year or two.

In certain cases of neuritis and myelitis the nails become dry, brittle, and hard.

Under severe emotional disturbance the hair may turn grey, and alterations in colour have been observed in association with neuralgia. In neuritis the hair has been stated to become very dry and brittle in exceptional cases.

6. **Trophic Alterations in the Secretion of Sweat.**—Emotion may greatly increase the secretion of sweat. A uni-

lateral secretion of sweat on the affected side of the body, is met with both in hemicrania and rarely in hemiplegia. Tumours, &c., pressing on the cervical sympathetic nerve sometimes cause an increase, sometimes a diminution, of sweat on the same side of the face (*see* SYMPATHETIC NERVE, DISEASES OF).

7. Trophic Affections of Teeth.—It appears probable that the teeth are more likely to fall out in patients affected with *tabes dorsalis* than in other persons, but the cause of this is not known.

8. Trophic Affections of Joints.—In quite exceptional cases, after injuries to nerves, after diseases of the spinal cord, and after cerebral lesions, the larger joints (on the opposite side of the body in the case of cerebral lesions) have been observed to become red and swollen, so that they look like joints affected with acute rheumatism.

The condition of joint which is known as Charcot's joint disease, and is thought by some to be a trophic lesion, is described in the article on locomotor ataxy, with which disease it is always associated.

9. Trophic Lesions of Bones.—The bones of patients affected with *tabes dorsalis* are very liable to fracture spontaneously. Sometimes nearly every bone in the body may be broken. The fractures heal with the formation of much callus. The femur is the bone most often broken, and those of the leg are more often affected than those of the arm. The inorganic constituents of the bones of patients with *tabes dorsalis* are occasionally only 24 per cent. instead of 66 per cent. as in health.

In anterior polio-myelitis the growth of the bones is retarded.

The bones of insane persons, especially general paralytics, are often so soft that they yield readily to pressure, and thus produce various deformities. At other times they are so brittle that they may crumble under the fingers, and of course are then very liable to fracture.

10. Trophic Affections of the Salivary Glands.—In neuralgia of the fifth nerve the secretion of saliva is often reflexly increased. It may be affected in lesions of the cervical sympathetic (*see* SYMPATHETIC NERVE, DISEASES OF).

In facial paralysis there may be a diminution of the secretion of saliva on the paralysed side.

11. Trophic Affections of the Lachrymal Glands.—The lachrymal secretion may be reflexly increased in trigeminal neuralgia (*q.v.*). W HALE WHITE.

TUBERCULOSIS (including *Scrofula*).—Tuberculosis is a pathological process due to the presence and growth in the tissues of a pathogenic bacillus and characterized in its most typical manifestations by the production of minute rounded or lenticular bodies, which tend to increase in size and then to become caseous in the centre.

History.—Tuberculosis was at first chiefly studied in the lungs, and more than seventy years ago Laennec perceived that the "existence of tubercles in the lungs is the cause and constitutes the true anatomical character of consumption." The next real advance in the conception of the pathological process was the hypothesis propounded by Buhl in 1857, that miliary tuberculosis was due to the absorption into the blood of caseous matter from non-encapsuled yellow tubercle. Though incorrect as a whole the hypothesis shows that the conception of tuberculosis as an infective process had gained ground. In 1865 Villemin showed that tuberculosis could easily be induced in certain animals, especially in rabbits and guinea-pigs, by the inoculation of tuberculous matter from the human subject. Other pathologists confirmed this statement, but were led to believe that tuberculosis could also be induced by inoculation with non-tuberculous material or by the maintenance of chronic local irritations (as by foreign bodies or setons). Further observation has shown that these conclusions were incorrect, the occurrence of tuberculosis under the circumstances mentioned being due to the readiness with which animals of the species experimented on contract tuberculosis if kept in company with other animals suffering from that disease. It fitted, however, with a theory subsequently very widely held that tuberculosis was a non-specific inflammatory process, the peculiar characters of its local and general distribution being due to the fact that the essential element in the process was an irritative overgrowth of lymphoid tissue in the affected organs. The nucleated cells of the so-called lymphoid type were believed to be due to proliferation; the multinuclear cells—the so-called giant cells—which were said to be present in larger or smaller numbers in all tubercles, were believed to be produced by coalescence of a number of such cells, or by protoplasmic budding from the walls of blood-vessels, such buds being the elementary stage of new blood-vessels which never reached full development.

The central caseation of tubercles was attributed to the fact that blood-vessels were not formed. On the other hand it was shown that, in the lungs especially, the cells in acute miliary tubercles might be of the epithelioid type, and one writer even went so far as to assert that acute miliary tuberculosis of the lungs ought to be renamed acute disseminated catarrhal pneumonia. To Cohnheim belongs the credit of recalling attention to the all-important fact that tuberculosis was a specific inoculable malady; he first satisfied himself that the earlier experiments, made by himself and others, which were supposed to have proved that tuberculosis could be produced by the inoculation of other than tuberculous material were not to be relied upon; in the second place he showed that in rabbits and guinea-pigs tuberculosis had a tolerably definite period of incubation. Working with Salomonsen he found that if a perfectly fresh piece of tubercle were introduced into the anterior chamber of the rabbit's eye a slight reaction only occurred, and after a few days the fragment could be seen through the transparent cornea; the fragment gradually diminished in size, and might entirely disappear, but about fourteen days or three weeks after the inoculation a crop of small grey granulations appeared on the iris, these granulations increased in size, caseated, and finally a general tuberculosis ensued. Further, a consideration of all the histological facts had led so good a pathologist as Ziegler to the opinion that a tubercle probably owed its rounded form and definite size to the fact that it was produced by the circumscribed action of an irritant of but slight intensity upon the spot which afterwards became the centre of the tubercle. In 1882 Koch announced the discovery of the tubercle bacillus, and thus supplied the last link in the chain of evidence that tuberculosis is a specific infective disease.

The Tubercle Bacillus.—The bacillus of tubercle is a small, fine, short rod, varying in length from a quarter to half the diameter of a blood corpuscle, its breadth is about one-fifth of its length; each bacillus is, as a rule, slightly bent or curved (*see* EXPECTORATION, Fig. 3). It forms spores which produce slight swellings, so that a bacillus containing several such spores has a beaded appearance. The bacillus behaves in a special manner to certain aniline dyes; the Weigert-Ehrlich staining process is that recommended by Koch. For a descrip-

tion of the method of examining the sputa for the bacillus the reader is referred to the article EXPECTORATION.

Koch first of all cultivated the bacillus outside the body on the surface of blood-serum, solidified by repeated heating to 65° C. He started cultivations from the following human morbid products:—(1) Miliary tuberculosis; (2) pulmonary phthisis: *a.* open cavities, *b.* closed cavity, *c.* caseous pneumonia; (3) scrofulous glands; (4) tubercular testicle; (5) fungous arthritis; (6) lupus. He also started them from the tuberculosis of cattle, and from tuberculosis induced in guinea-pigs by inoculation with human tuberculous material.

The surface of the blood serum was inoculated by spreading out on it a small particle of the tubercular material; the tube was then kept at a uniform temperature of 37° C. (98.6° F.): after an interval of ten to fifteen days the growing colonies appeared as white spots, resembling tiny dry scales adhering to the surface of the serum. When many such colonies form they coalesce into a thin, greyish-white, lustre-less covering. From this material fresh cultivations can be started and continued in series, and the bacilli are found to retain their power of producing tuberculosis in rodents inoculated with these sub-cultures. The bacilli will also grow on meat infusion solidified by Agar-Agar, and in shallow layers of meat infusion, but not on vegetable material. Further, the bacillus does not grow at temperatures below 28° to 29° C. (82.4° to 84.2° F.) or above 42° C. (107.6° F.). Koch points out that the lower limits of temperature at which the bacillus is just able to grow are not reached by summer heat, and that its growth is so slow that before the life cycle could be completed its colonies would be choked by other kinds of bacteria which are present everywhere and develop much more rapidly. Tubercle bacilli must therefore be regarded "not as occasional, but as true parasites—*i.e.*, as finding the conditions necessary to their existence only in the animal or human organisms."

Distribution of the Bacillus in Lesions.—The number of bacilli found in tuberculous lesions varies considerably. They occur in largest numbers at points where the tuberculous process is just beginning or where it is spreading rapidly; they are found within or in the immediate neighbourhood of the accumulated cells which are taking on the epithelioid diameter. As the process advances the bacilli increase in number

forming dense masses; meanwhile the cell nuclei begin to disintegrate, and the cells and nuclei are finally resolved into a granular material. This dead matter forms the central caseous mass, and in it but few bacilli remain, though it probably contains spores, derived from the pre-existing bacilli, by whose agency the destruction of the cells has been brought about. The relation of the bacilli to the giant cells is intimate; in chronic tuberculous processes, such as scrofula and fungous arthritis, but few bacilli are to be discovered, and these are always or almost always in the giant cells, perhaps one or two in each, when, however, the process is more acute the number of bacilli in each giant cell is much more numerous. The bacilli, if numerous, may be grouped at one end of the cell, if still more numerous they are disposed radially, reach to the periphery, and finally cause the destruction of the cell. If a large number of bacilli are introduced directly into the blood stream, and the animal killed shortly afterwards, numbers of white corpuscles in the blood are seen to contain one or more tubercle bacilli, and here and there in the lungs, liver, and spleen a few round cells may be found each containing a tubercle bacillus. It is probable that disseminated tubercle thus originates, and it has been shown that minute tubercles of the arterioles may in the human being rupture into the cavity of the vessel. From a single infective centre also tubercle may be carried along the lymphatics and eventually lead to caseation of the nearest glands.

Pulmonary Tuberculosis.—In the lungs the tuberculous process presents certain peculiarities in its development and mode of spreading owing mainly to the fact that, sooner or later, the caseous area opens into a bronchus, discharges its softened contents and thus becomes a cavity. The bacilli may continue to grow in the walls of this cavity, sometimes universally and with great rapidity, causing rapid softening, at other times at a few points only, while in specially favourable cases the bacilli may entirely disappear, and the cavity may be obliterated by a process of cicatrization. The tuberculous process may spread in the lungs through vascular or lymphatic channels, but the most frequent mode is through the air passages; the infective contents of a cavity are inhaled into other bronchi, and in terminal bronchi and air cells set up the tuberculous pro-

cess coincidently over extensive tracts. Frequently areas of consolidation of lobular form may be found, and are doubtless thus produced. In this way large portions of lung may be almost simultaneously affected producing the condition to which the term caseous pneumonia has been applied. The walls of cavities resulting from the breaking down of such areas are everywhere pervaded by a dense growth of bacilli; this leads to destruction of tissue with so much rapidity that the walls of such cavities are soft, being formed of lung-tissue in which there has been no time for indurating cicatricial processes to occur.

SCROFULA AND LUPUS.—The relation in which scrofula and lupus stand to the more acute forms of tuberculosis is most interesting. On the one hand there can be no doubt that scrofulous glands and joints and lupus-tissue contain tubercle-bacilli, and are capable of inducing typical tuberculosis in rodents, and on the other hand it is obvious that, clinically, acute tuberculosis and lupus are as far as the poles asunder. It is not at present possible to speak definitely on this point. It seems clear, however, that the virulence of the bacillus tuberculosis varies, just as the virulence of the bacillus anthracis varies. Lingard has recently published a series of remarkable experiments showing that whereas in guinea-pigs inoculated with tubercle enlargement of the lymphatic glands in the neighbourhood of the point of inoculation appears in six or seven days, and the animals succumb to the disease in about eighty days, the same animals when inoculated with scrofulous material show enlargement of the glands in two or three weeks, and survive for six or seven months, and when inoculated with lupus show enlargement of glands in four or five weeks, and do not die for eleven or twelve months. The experiments with scrofulous material further proved that as the infection was transmitted from one guinea-pig to another it grew in virulence, thus A, an animal inoculated with scrofulous material, died of tuberculosis in 206 days, B inoculated from A in 131 days, C inoculated from B in 79 days, and D inoculated from C in 60 days (averages). The resistance of the tissues to infection by the bacillus doubtless also varies in different individuals, and in the same individual at different times; it in fact appears probable that the above-noted attenuation of virulence is brought about in and by

the tissues, possibly of the affected individual.

Ætiology.—Tuberculosis is an almost ubiquitous disease, and appears to be quite independent of climate; it is especially a disease of towns and crowded localities, and is favoured by want of ventilation and unwholesome trades. A single phthisical patient ejects daily enormous numbers of bacilli (according to Bollinger, as many as twenty millions). Phthisical sputum resists desiccation and retains its infective properties for long periods, owing, doubtless, to the presence of spore-bearing bacilli in it. The healthy body is, it would seem, capable of destroying the numerous bacilli which find their way into the lungs and intestines from time to time, and it is probable that even in persons with a hereditary or acquired predisposition, infection is not established until a considerable dose of tuberculous virus is accidentally inhaled or ingested. The deteriorating influence of town life, and the fact that the air of rooms and places of public assembly in towns must often swarm with tubercle bacilli, appear to offer an explanation of the increased frequency of phthisis and other forms of tubercular disease in town as compared with country populations. The injurious influence of dusty trades is to be attributed to the catarrhal process set up by the irritating particles. Tuberculosis can also be transmitted to guinea-pigs, pigs, and calves by the milk of cows suffering from tuberculous mastitis, if not also by that of cows with tubercle in other organs, but not in the mamma. This is a probable source of infection in infants and others who drink unboiled milk in large quantities. It is possible also that the flesh of oxen in an advanced stage of tuberculosis may communicate the disease to persons consuming it, for the central parts of roast joints and grilled portions of meat are probably never brought to a temperature sufficiently high to destroy the bacillus, if it be present, as there is some evidence to show.

With regard to phthisis pulmonalis, hereditary predisposition, habits of life, and occupation are probably the most important ætiological factors, but with regard to acute tuberculosis their importance is by no means so clearly established; on the contrary, in the present state of knowledge, clinical and experimental, the more probable opinion is that the most important factor is the introduction into the economy of an adequate dose of the bacillus tuberculosis in a

virulent state, and that, in fact, acute tuberculosis is ætiologically as distinctly an infectious disorder as typhoid fever, (*see also* PHTHISIS).

DAWSON WILLIAMS.

TUBERCULOSIS, ACUTE.—Tubercle bacilli occasionally gain entrance into an artery, vein or lymphatic vessel, and are then rapidly disseminated throughout the body, miliary tubercles appearing in various organs almost simultaneously. The pia mater and the lungs may be thus attacked at or about the same time, or the serous membranes may be affected quickly, one after the other, in either case constituting the condition known as acute tuberculousis.

Speaking generally, it may be stated that when tubercle is widely disseminated, if the cerebral meninges be affected, the symptoms of that lesion will probably overshadow those due to the condition of the lungs and abdomen, and in a very large proportion of cases of acute tuberculosis, especially in children, the meninges are affected. The focus from which the bacilli are disseminated is, in the majority of cases, a pulmonary lesion, but any tubercular nodule may be the starting-point of a general infection.

It is unnecessary here to again describe the symptoms, either of tubercular meningitis, peritonitis or pleurisy; they will be found on reference to the appropriate headings (MENINGES, CEREBRAL, INFLAMMATION OF; PERITONITIS, TUBERCULAR; and PLEURISY, TUBERCULAR), but no description is elsewhere given of acute tuberculousis of the lungs.

Acute Tuberculosis of the Lungs.—A rapid infiltration of tubercle throughout the lungs is a common event in the course of phthisis (*i.e.*, pulmonary tuberculosis), and is one of the most frequent modes of termination of that disease, of which it is really only one of the most acute varieties.

The *symptoms* closely resemble those of a specific fever, and the disease at its outset is not unfrequently mistaken for typhoid fever. The early history of the case will depend upon the site of the primary tubercular lesion, but even when this is situated in the lungs there may have been no symptoms prior to the onset of the attack suggesting such a condition, or they may have been forgotten or overlooked. The patient becomes gradually ill, suffers much from dyspnoea, which tends to increase as the disease goes on. The pulse is rapid and the temperature generally high, although subject to much

variation. It may be as high as 104° or may remain below 102° . There are daily fluctuations of an irregular type, the highest point being sometimes in the forenoon. In cases due to the breaking down of an old apical lesion, the attack may be ushered in by hæmoptysis. The amount of cough and expectoration will depend upon the degree of catarrh present; as a rule, the sputa are scanty.

There is almost always an excessive degree of sweating, but in rare cases the skin is dry. The countenance is generally dusky and sometimes cyanosed, and the expression of the features is always one of anxiety. There is marked emaciation, and, as the disease progresses, symptoms of cerebral disturbance probably begin to show themselves, and eventually the patient sinks into the "typhoid state," with sordes, a dry brown tongue, delirium and stupor gradually deepening into coma.

The *physical signs* which attend these very marked symptoms are often most equivocal. The expansion of the chest may be found to be a little defective at one apex, if an old lesion be present there, but the resonance on percussion is unimpaired by the recent lesions. The breath sounds are generally harsh, and are often accompanied by fine crackling râles. If bronchial catarrh be present, rhonchus and sibilus will be audible, and the expiratory sound will be prolonged. The vocal resonance is usually unaltered.

The *diagnosis* has often to rest upon the symptoms alone. The high temperature, rapid respiration, with no obvious physical signs to account for it, and the increasing cyanosis and sweating form the main points upon which it may be established. From typhoid fever the distinction is often very difficult, especially as enlargement of the spleen occurs in both diseases. From the examination of the sputa for bacilli, and of the eye for evidence of tubercle in the choroid, positive indications may often be obtained when all other signs are of doubtful significance (*see p. 875*).

Prognosis.—The disease rarely extends beyond three weeks, and may be even more rapidly fatal.

Pathological Appearances.—The lungs are infiltrated, sometimes throughout, with milary granulations in an almost uniform stage of development. These are of a pearly white or greyish tint and of firm consistence, but may be softer and of a yellowish colour, tending towards rapid caseation. When acute tuberculous has supervened upon pre-existent

tubercular lesions in either lung, the appearances proper to such changes will, of course, be present in addition. In the rapidly fatal cases the granulations are unaccompanied by any obvious inflammatory change. The tubercles are formed for the most part in the spaces around the minute arterioles.

The tubercles are generally more numerous in the upper lobes, particularly if old phthisical lesions be present there. When not situated in the lung a careful search is often necessary to discover the source of primary infection. The bronchial glands should be closely examined; attention must be paid to any bone disease present; whilst in males the prostate gland and the vesiculæ seminales, and in females the Fallopian tubes, are in rare cases the starting-point of a general tubercular infection, in which the lungs share.

Ætiology.—Acute tuberculosis of the lungs may occur at any age; it is decidedly more common in males than in females. In children the disease is commonly associated with tubercular meningitis, the lungs being often free from old lesions, whilst in adults there is often evidence of an arrested pulmonary tubercular lesion which has recently broken down.

Treatment can only be directed towards the maintenance of the patient's strength by appropriate food and stimulation, and to the relief of troublesome symptoms as they arise.

TYMPANITES (Meteorism).—

Distension of the abdomen from inflation of the intestines with gas. In very exceptional cases, and then usually after perforation of the stomach or intestine, the gas may be in the peritoneal cavity. It is due partly to an increased formation of gas and partly to a sub-paralytic condition of the intestinal walls. In peritonitis, enteric fever, and acute intestinal obstruction, it is sometimes very marked, and may be the source not only of some discomfort but of actual danger to life from the impediment to respiration owing to the pushing up of the diaphragm. The abdomen is everywhere resonant. In less degree flatulence accompanies all forms of chronic, gastric and intestinal disturbance.

Treatment.—Internally, antispasmodics (such as spirits of ammonia in 30-minim doses) may be tried, or brandy may be given; enemata of turpentine have sometimes been found of service. The pas-

sage of a long tube into the large bowel as high as possible may give relief, or, as a last resort, the large bowel may be punctured in two or three places with a fine trocar, but this latter measure is by no means free from danger.

TYPHOID FEVER (Enteric Fever).—A febrile disease, produced by a specific poison and characterized by inflammation and sloughing or ulceration of the glands of the small and sometimes of the large intestine, and especially of the agminate and solitary glands of the ileum, together with infiltration of the mesenteric glands, and enlargement of the spleen, and the presence of an inconstant roseolous rash.

SYMPTOMS.—After infection a period of latency or incubation elapses before the commencement of the symptoms. In cases where this has admitted of being accurately fixed, it has generally been between 10 and 14 days, but it may vary from 5 days to upwards of three weeks.

Commonly this period is free from symptoms, but sometimes there is more or less malaise, and occasionally, at the commencement, diarrhoea and vomiting, which subside again after a few days.

The onset of the disease is often somewhat insidious, the patient feels languid and indisposed to exertion, has aching pains and a sensation of weight in his limbs, suffers from headache, passes restless nights, his sleep is disturbed by dreams and appetite is lost. Occasionally in this early stage there are signs of intestinal irritation, as abdominal pain and diarrhoea, and, especially in children, vomiting. These cases are often at first regarded as ordinary diarrhoea. The tongue becomes furred and red at the tips and edges, the pulse accelerated, and the temperature rises, often by somewhat regular gradations, so that every night it is 1 or 2 degrees higher than on the previous night, the morning temperature being 1 or 2 degrees below the evening.

Usually these premonitory symptoms last for from 5 to 6 days before the patient is compelled by increasing weakness to take to bed.

Not unfrequently, however, typhoid fever begins like other acute diseases with distinct chills or even rigors, headache, pain in the back and limbs, and the patient takes to his bed after 2 or 3 days.

Sometimes the early stage of typhoid is accompanied by anomalous symptoms which may greatly increase the difficulty

of diagnosis. Neuralgic pains and hyperæsthesia of the muscles, much increased on movement, simulating rheumatism, may occur; these may be associated with cutaneous hyperæsthesia. Sometimes there is hemicrania, or supra-orbital or occipital neuralgia or even earache. In other cases the patient complains of dryness and soreness of the throat, and as there is occasionally a slight diffused febrile blush on the skin and the tongue is red, the case may be mistaken for scarlatina.

By the end of the first week the symptoms of the disease are usually well pronounced, the patient, who complains of headache, thirst and general malaise, has a wearied, languid aspect, but does not present the stupid, heavy look which characterizes typhus. There is often a pink flush on the cheeks, the eyes are not suffused, the pupils are often large, the tongue is red at the tip and edges, and coated with a white or yellowish fur, sometimes the centre of each half presents a furred strip, the intervening portions being red. The lips are parched and desquamating, the pulse may vary from 100 to 120, and though often full, is soft, with a tendency to diastolic, the abdomen is commonly tumid, often there is gurgling on palpation in the right iliac fossa with some pain and tenderness. The bowels are usually loose, the motions liquid, of a yellow ochre colour, resembling pea soup, and of an alkaline reaction. Not unfrequently, however, there is constipation. The spleen is enlarged, sometimes the lower end can be felt at the costal arch. Usually the enlargement can only be detected by percussion in the lower axillary region, but when the stomach is much inflated this sign, which is of great diagnostic importance, may be obscured.

Epistaxis not unfrequently occurs, and is sometimes so profuse as to endanger life; it may take place at any period of the fever.

The skin commonly feels hot and dry, but this condition often alternates with perspiration. The temperature may vary from 102° to 105° F. in the evening, and is generally one or two degrees lower in the morning. The characteristic eruption, when present, usually makes its appearance between the seventh and twelfth days. It consists of slightly elevated papules of a rose pink colour, measuring about two lines in diameter, uniform in size, and disappearing on pressure. They come out in successive crops, each spot lasting from 3 to 5 days and then fading,

and they continue to come out during the whole course of the fever. In rare cases the spots have been observed to be acuminated, with a small vesicle on the summit. Sometimes, when the rash is very abundant, the spots are much darker in colour and persist on pressure. The spots have been observed as early as the fifth day, and their appearance may be delayed till the fourteenth, or even later. They generally cease to appear after the middle or end of the third week, but in cases in which intercurrent relapses take place they may continue to come out for five or six weeks. The number of the spots is often very small, so that they may be easily overlooked; they are generally confined to the abdomen, chest, and back. Sometimes the eruption is very copious, and may then extend to the extremities, and even to the face. It is often considered that there is no relation between the amount of the eruption and the severity of the attack, but, in the experience of the writer, when the eruption is very profuse and dark the case is usually a severe one. The eruption is by no means always present, and is more frequently absent in children under 10 and in adults over 30 than between those ages. As in most specific fevers hæmorrhagic spots occasionally occur, but they are independent of the rose spots. In rare cases pale blue spots have been observed, the *tâches bleuâtres* of Trousseau. They appear to have no significance. *Sudamina* are not very uncommon, and usually the so-called *tâche cérébrale*, a red line with a white border on each side, can be elicited by drawing the back of the nail across the skin; this is an indication of increased irritability of the vaso-motor nerves, and is especially frequent when the pulse is dicrotic. It should most probably be regarded as a phenomenon of fever generally, rather than of the specific typhoid process.

The urine presents the usual characteristics of fever; it is concentrated, high-coloured, strongly acid, contains an excess of urea and uric acid, sulphates and potash salts, with deficiency of chloride of sodium. In the later stages of the disease it is often albuminous.

Ehrlich's Test.—The urine of cases of typhoid fever may give a peculiar reaction with sulpho-diazobenzol. This is produced by adding to an equal volume of urine a mixture consisting of 25 parts of a 20 per cent. solution of hydrochloric acid saturated with sulphanilic acid, and one part of a half per cent. solution of

sodium nitrite, an excess of strong liquor ammoniac is then added. A deep orange-red or purple colour is produced, the colorization of the froth on shaking the mixture is especially characteristic. This reaction cannot, however, be always obtained, and may be present in many other diseases, especially measles. The acid solution and the sodium nitrite solution should be mixed together immediately before using.

During the second week the patient usually ceases to complain of the headache and other pains, but there is increasing weariness, progressive emaciation, and in severe cases delirium may begin to appear, at first during the night, or on waking out of sleep. Sometimes the patient is sleepless and restless at night, sometimes drowsy and apathetic; deafness is a common symptom, it is often regarded as not unfavourable, but it usually indicates a severe case.

During the third week the diarrhœa usually becomes more severe, the motions are often very offensive and may contain shreddy sloughs. Signs of pulmonary complications may appear, there is not usually cough, but the breathing is accelerated, the face somewhat dusky, and moist râles are audible over the backs of the lungs. In severe cases what is known as the **typhoid state** may become developed, the patient lies on his back and sinks down in the bed, there is muttering delirium and stupor, subultus tendinum, the tongue is dry and brown or glazed and red and transversely fissured, there are sordes on the lips and teeth, the impulse of the heart is feeble, the first sound faint and short, the pulse markedly dicrotic, the belly distended and tympanitic, the bladder often paralysed, the urine albuminous, the motions are passed involuntarily, bed-sores form over the sacrum, and the patient may die in a state of coma.

It is only in very severe cases that this condition is developed to such a degree: but during the third week the patient is liable to severe hæmorrhage from the bowels and perforation.

Commonly towards the end of the third or the beginning of the fourth week the fever begins to abate, the morning temperature falling more rapidly than the evening, so that the type of the fever becomes more and more remittent, and after a few days defervescence is complete. For some time the temperature is subnormal, but is liable to be temporarily sent up by very slight causes. The presence of compli-

cations or the occurrence of recrudescences may much prolong the course of the fever, which may thus extend over periods of five or six weeks, or longer. Convalescence, too, is liable to be much retarded by the presence of complications, especially the slow healing of the intestinal ulcers; it is also liable to be interrupted by relapses.

Though this may be regarded as the typical course of a case of well-marked typhoid, few diseases are subject to such great variations. The forms of typhoid may be divided into those where the symptoms caused by the general infection of the system predominate, and those in which they are in the main due to the intestinal lesions.

The severity of the constitutional affection and the extent of the intestinal lesions, though commonly, are not always, in agreement.

Varieties of the Disease.—Among the more common forms of typhoid are:

1. *The Acute Form.*—This is characterized by severe febrile disturbance of rapid onset, often preceded by rigors, high temperature, great nervous oppression, early delirium, and by a tendency to pulmonary congestion; death may take place in the second or even in the first week, though usually the disease runs on the usual time; there may or may not be severe intestinal lesions.

2. *The Abortive Form.*—Here the early symptoms are often well marked, but sometimes between the eighth and fourteenth day defervescence takes place often by a pretty sudden crisis. It is probable that in these cases resolution and absorption has taken place in the inflamed intestinal glands without the occurrence of sloughing or ulceration.

3. *The Latent Form.*—The febrile disturbance is very slight, but the intestinal lesions have the usual characters. Commonly these patients have diarrhoea, and some degree of general malaise, and their temperature is above normal, but they continue to follow their ordinary avocations and walk about as usual, hence this is often termed the "ambulant" form. The neglect of proper precautions renders these cases very liable to perforation and hæmorrhage.

4. *The Afebrile Form.*—This form is of rare occurrence. Although the general symptoms, and especially the nervous symptoms, as delirium and stupor, may be well marked, and the rash abundant, the temperature throughout is normal or even subnormal. The intestinal lesions are usually slight, and

the disease often terminates at the end of a fortnight. An epidemic of this type occurred in the German army besieging Paris, and was attributed to the great hardships which the soldiers had undergone. Isolated cases occur occasionally, in these the severe symptoms noticed in the above-mentioned epidemic are seldom observed.

Mild forms of typhoid are often termed gastric fever, bilious fever, infantile remittent fever, &c. In malarial districts the disease is modified by the influence of the malarial infection, and the term typho-malarial fever has been applied to the fever under these circumstances.

Complications and Sequelæ.—Under this head will be included not only those affections which only occasionally occur, but also the ordinary effects of the disease when they are more marked than usual.

Of the complications due to the intestinal lesions hæmorrhage and perforation are the most important. They may occur at two periods, which may be termed the early and late; the early during the detachment of the sloughs, most commonly in the latter half of the third and the first half of the fourth week, though they have been met with as early as the beginning of the second week; the late may occur at any time from the separation of the sloughs to the complete healing of the ulcers, and are due to the ulcers not granulating but becoming atonic. These accidents may therefore occur when the patient appears to be convalescent.

The Symptoms of Perforation are usually the occurrence of a sudden pain, followed by general peritonitis, diffused abdominal pain, great tenderness, and tympanites, together with symptoms of collapse. The pulse becomes very frequent and small, the breathing is thoracic, the countenance pinched, the temperature may either rise or fall, according as the symptoms of inflammation or collapse predominate. Not infrequently, especially if the patient be in the typhoid state, these severe symptoms are absent, and the chief indications are abdominal distension and increase in the prostration. The abdominal distension is generally due to the intestines being paralysed by the peritonitis, but sometimes a considerable quantity of gas escapes into the peritoneal cavity. This can often be recognized by the liver dulness being completely obliterated, owing to the gas accumulating in the upper part

of the abdominal cavity between the liver and the diaphragm and abdominal wall, whereas in flatulent distension of the bowels the liver is usually merely displaced upwards, unless indeed the colon, as sometimes happens, rolls over it. Perforation of bowel almost always proves fatal within two days, but where the extravasation and peritonitis have been limited by adhesions, recovery with or without the formation of a faecal abscess has been known to occur. Acute general peritonitis occurring during typhoid fever is by no means necessarily fatal, but probably where recovery has taken place there has not been actual perforation. Peritonitis may also be set up by the rupture of an inflamed and softened mesenteric gland.

Hæmorrhage.—Intestinal hæmorrhage, like perforation, most commonly occurs during the latter half of the third and the first half of the fourth week, and often recurs several times. The amount may vary from a slight oozing to several pints of arterial blood. The blood passed may be either dark or bright red, and is often more or less clotted. When the hæmorrhage is at all profuse it causes a sudden fall of temperature, pallor and collapse. A moderate hæmorrhage does not in itself necessarily give rise to any serious symptoms, but it is an indication of deep ulceration, and we often see hæmorrhage and perforation in the same case. Severe hæmorrhage sometimes proves fatal. Hæmorrhage, like perforation, though more frequent where there has been much diarrhœa, may also occur where the bowels have been constipated.

Tympanites is another frequent symptom in typhoid; a moderate degree is usually present; but when the amount is very great it is a most unfavourable symptom. It usually indicates severe intestinal ulceration, and also, especially when it occurs early, a failure of nerve power. It may greatly distress the breathing, and it favours perforation by stretching the ulcerated bowel. Murchison considered that the gas is chiefly contained in the colon, but there can be little doubt but that the small intestines are also distended. It is greatly increased by the occurrence of peritonitis, and often a distended motionless belly is the chief indication of perforation.

Ulceration of the large intestine, affecting the solitary glands, occasionally occurs, and the lesions may even be more extensive here than in the ileum. Hæmorrhage and perforation are liable

to occur. This condition may often be recognized by the frequency and persistence of the diarrhœa, the extremely offensive motions, and often by the presence of a good deal of pain. Sometimes the condition of the intestine is much the same as in chronic dysentery.

Severe gastric disturbance may be present, there is a tendency to great flatulent distension and even acute dilatation of the stomach, and persistent vomiting, rendering the feeding of the patient extremely difficult; this condition may be associated with severe headache. The term "bilious typhoid" is often applied to this form.

Jaundice occasionally occurs, usually in the later stages of the disease, and the cases often terminate fatally, the liver has been found in a condition of fatty degeneration, but the cause of the jaundice is somewhat doubtful.

Affections of the larynx and pharynx are not uncommon, sometimes a diphtheritic exudation forms on the fauces; this should perhaps be regarded as the result of a diphtherial infection and not as a manifestation of the typhoid poison. Sometimes herpetic ulcers are present, and cases have been described where circular or oval ulcers of larger size with greyish white surface have appeared on the soft palate.

Ulceration of the Larynx frequently occurs. The ulcers are usually situated on the posterior wall, and often extend deeply; they have been variously ascribed to an infiltration and ulceration analogous to that in the intestine, or to the effects of pressure from the decubitus of the patient. Sometimes they give rise to few symptoms, at others they cause hoarseness, and pain in swallowing, they may produce necrosis of the cartilages, œdema and stenosis of the glottis necessitating tracheotomy, or may perforate and give rise to emphysema of the tissues of the neck. Sometimes they cause hæmoptysis.

Besides bronchitis and hypostatic congestion, which are often present in severe cases, true lobar pneumonia occasionally occurs; it is most common in the third and fourth weeks. Embolic and pyæmic processes in the lungs may also take place, and may cause abscesses, or empyema or pneumothorax.

The tissues of the heart in severe cases of typhoid fever become granular and softened, sometimes giving rise to a certain amount of dilatation, but endocarditis is very rare. Not unfrequently, as the result probably of asystolism—i.e., a

condition in which the cavities do not completely empty themselves, coagulation takes place during life. This may cause sudden death from obstruction of the pulmonary artery, or may give rise to embolism of distant organs.

Thrombosis of the veins, especially of the iliac and femoral veins is of common occurrence; usually during the period of convalescence. The leg becomes oedematous, and there is pain and tenderness along the course of the affected veins, and often the vein can be felt as a solid cord. Most commonly, in a period varying from two to six weeks, the coagulum becomes absorbed, sometimes, however, the vein remains permanently blocked, and though the circulation gets carried on by the collateral channels, the patient continues to present some signs of venous obstruction of the limb.

Occasionally portions of the clot get dislodged and cause pulmonary embolism.

Renal Complications.—Albumen is often present in the urine in severe cases, but usually disappears with defervescence, but sometimes, though rarely, acute nephritis resembling that of scarlatina occurs, the urine becomes scanty, bloody, highly albuminous, or may be suppressed, and uræmia and dropsy may ensue. The term "nephro-typhus" has been given to this complication by foreign observers.

Sometimes, in addition to the ordinary nervous symptoms of severe fever—as tremors, subsultus, floccitatio, delirium—various spasmodic and paralytic affections occur, as general convulsions, muscular spasm, which may cause retraction of the head, rigidity of the trunk or limbs, strabismus, trismus. Sometimes acute meningitis has been set up, probably of septicæmic origin. Consecutive paralysis has frequently been observed. Sometimes there is hemiplegia from cerebral embolism, more often the paralysis is monoplegic or paraplegic, and must be ascribed to a peripheral neuritis; sometimes the attack is followed by various forms of sclerosis of the spinal cord. Occasionally there is a temporary aphasia, this has generally been noticed in boys. Mania or dementia have often followed an attack of typhoid, but are generally of only short duration.

The deafness of typhoid fever is usually only temporary, but sometimes inflammation of the middle ear takes place and may lead to perforation of the membrana tympani.

Bed-sores, abscesses in the connective tissues, sometimes erysipelas, and occasionally acute suppurative parotitis, or

parotid bubo occur. Sometimes during convalescence periostitis or more probably a superficial osteitis, often leading to suppuration and necrosis, affects many of the bones, especially the lower jaw, the sternum, the ribs, the femur and tibia. All these complications are probably septicæmic in their origin. Occasionally there is pyæmia, set up either by bed-sores or by the intestinal ulceration. This is usually characterized by recurrent rigors, but rigors may occur during the course of typhoid without any obvious cause.

Sometimes after an attack of typhoid the patients do not regain flesh and strength, but fall into a state of marasmus and continue to emaciate. This may be due to unhealed ulcers in the intestine and the persistence of the diarrhoea, in other cases to chronic atrophy or caseation of the mesenteric glands, and death may ensue after many months or even after years.

Sudden death is liable to occur either during the attack or when the patient is apparently convalescing; sometimes it is the effect of the granular degeneration and softening of the heart, or to embolism or thrombosis of the pulmonary artery; at other times no cause can be detected.

Relapses are liable to occur between two and twelve or fourteen days after the subsidence of the primary attack, but much longer intervals have been observed, even ten weeks. Fresh infiltration and ulceration of the intestinal glands take place, the rose spots again appear and all the symptoms recur. Most commonly the attack runs a shorter course, the fever attains its maximum sooner, between the fourth and sixth days, and defervescence begins before the end of the second week, but not infrequently the relapse lasts 21 or more days. Relapses are generally milder than the primary attack, but perforation is very liable to occur. Sometimes there is a second or even a third relapse. The relapse is often intercurrent—i.e., takes place before the subsidence of the primary attack, and is indicated by an exacerbation of the symptoms and the reappearance of the rash. The frequency of relapses has been estimated at from 3 to 10 per cent. The causes are very obscure, they have often been attributed to irritation of the intestine by improper food; but this is very doubtful. They certainly frequently occur where every precaution has been strictly observed. There is reason to believe that the germ of typhoid fever remains in the intestinal glands long after defervescence has taken

place, and may be excited to fresh activity.

DIAGNOSIS.—In consequence of its insidious onset and the somewhat indefinite symptoms at first, the diagnosis of typhoid fever in its early stage is often difficult. The main points which serve to distinguish it are the type of the fever, the tongue, the abdominal symptoms, as diarrhoea, distension, the enlargement of the spleen, and the rose spots. A temperature of 104° and upwards in the first two or three days of illness is more likely to be due to some other febrile disease, as pneumonia, meningitis, typhus or small-pox. So a normal evening temperature during the first week would generally exclude typhoid. Any fever in this country which lasts six or seven days without any local cause or the appearance of a characteristic rash is almost always typhoid, especially if the spleen be enlarged.

The diseases with which typhoid is most likely to be confounded are, first tuberculosis, especially tubercular meningitis and general miliary tuberculosis. In tubercular meningitis the vomiting is often more marked, the headache more severe and persistent, there is greater intolerance of light and sound, the tongue is not red, the belly often retracted, there is no enlargement of the spleen, the temperature is more irregular, the pulse often slow while the temperature is high, bowels usually constipated, motions have not the typhoid character. Sometimes tubercles can be detected in the choroid, there is often precedent emaciation. The knee-jerk is frequently absent, whereas in typhoid it is normal or exaggerated. Nevertheless, until spasm or paralysis of the cerebral nerves appears the diagnosis may be doubtful.

Acute miliary tuberculosis may also give rise to many of the symptoms of typhoid; there is, however, usually much greater rapidity of the breathing, and earlier and more severe bronchitic signs and greater emaciation.

Tubercular peritonitis, especially when associated with tubercular ulceration of the intestine may closely resemble typhoid, but the course is usually much more chronic; often there is peritoneal effusion, and signs of tuberculosis of other organs. In all these cases the presence of the rash is of the utmost importance, but a rash much resembling the roseola of typhoid is said to occur sometimes in acute tuberculosis.

Pneumonia is liable to be mistaken for typhoid, especially the asthenic forms,

which may no doubt be caused by septic infection. Generally the physical signs are a sufficient distinction, but as pneumonia itself is not a very uncommon complication of typhoid it may be difficult to decide whether it is primary or secondary; pneumonia, however, is a late complication of typhoid, and therefore the history and duration of the illness will generally distinguish them.

Typhlitis sometimes gives rise to symptoms like those of typhoid, but the presence of a swelling in the iliac fossa will distinguish it. This symptom is very unlikely to occur in typhoid, especially in an early stage.

Ulcerative endocarditis and pyæmia from internal causes may closely resemble typhoid, and in the former case may even produce intestinal hæmorrhage due to embolism. The greater irregularity in the type of the fever, the occurrence of repeated rigors (though rigors occasionally occur during the course of typhoid), the presence of some local inflammation, either internal or external, the signs of embolism, as purpuric spots, hæmaturia, hæmoptysis, and in ulcerative endocarditis the cardiac lesion, are the chief points of distinction.

In malarial districts, and especially in military practice during the exposure of a campaign, there is often great difficulty in distinguishing malarial and typhoid fevers, and there can be little doubt but that both forms may co-exist in the same patient.

For the diagnosis from typhus, see the latter fever.

PATHOLOGY.—Typhoid fever belongs to the class of miasmatic contagious fevers—*i.e.*, those fevers whose virus is capable of development outside the body, and which are usually communicated not by direct transmission from the sick to the healthy, but indirectly through the contamination of the soil or water.

In all probability the virus is associated with a specific bacillus described by Klebs and Eberth. The invariable presence after death, of this organism in the intestine, the mesenteric glands, the spleen, and sometimes the liver and in blood drawn from the spleen during life, has been verified by so many competent observers, that its connection with the disease can no longer be doubted. It is not met with in the general circulation, or in the secondary inflammations, which are probably septicæmic and not due to the direct action of the typhoid poison. The bacillus can be distinguished from all other organisms

by its mode of growth when cultivated on the potato, where it forms a uniform thin layer or pellicle. It has been detected in contaminated drinking water and cultivated. When introduced into rabbits and other animals, though it appears to multiply, and may cause death, it does not give rise to any disease which clinically can be identified with typhoid fever. The injurious effects on the human system are probably due to its generating some kind of poison of the nature of a ptomaine, which gets absorbed into the circulation. It would appear that the bacillus may remain in the intestinal glands for a long time after the subsidence of the fever. In one case it was detected in the discharge of an abscess, due probably to the breaking down of a mesenteric gland, five months after the commencement of the fever. Quincke also found that infection has been communicated by patients many weeks after defervescence.

The characteristic lesions of typhoid fever are an inflammatory affection of the solitary and agminate glands of the ileum and sometimes of the colon, and of the mesenteric glands, together with parenchymatous swelling of the spleen. The changes in the glands consist first of hyperæmia and swelling due to great hyperplasia or exudation of lymphatic elements. Peyer's patches in this stage form raised masses of a pinkish-grey colour, with reticulated, rugose, or nearly smooth surfaces, according as the inflammatory infiltration is uniform in all the tissues of the patch, or is greater in the follicles, or in the intervening structures. The solitary glands present similar changes. This stage is usually completed about the tenth day.

In the second stage necrosis of many of the patches takes place, giving rise to yellowish-brown sloughs, the separation of which occupies the third, and sometimes the fourth week also. There is left the typhoid ulcer, which is usually oval and opposite to the attachment of the mesentery, when it corresponds to a Peyer's patch, circular when to a solitary gland. Its surface is smooth, the edges undermined. Its depth depends on the extent of the original inflammatory exudation. Usually it does not go deeper than the mucous coat, but may reach the peritoneum and so perforate. As the ulcers heal, the undermined edges become adherent, the surface granulates, and ultimately the epithelium is restored, no contraction taking place. The healing of the ulcers takes an uncertain time,

it may be completed in a week or ten days. Sometimes the ulcers become chronic, and may continue to extend and give rise to the late hæmorrhages and perforations. These changes in Peyer's patches are always most marked and most advanced in the lower part of the ileum near the valve.

The mesenteric glands become swollen by a similar hyperplasia of their lymphatic elements, and sometimes they soften down and burst into the peritoneal cavity. Generally, resolution without necrosis takes place; sometimes they pass into a caseous condition. The spleen also presents a lymphatic hyperplasia with congestion, and it always contains the bacillus.

The other organs show more or less cloudy swelling of their cellular elements; this change is especially marked in the glandular epithelium. In severe cases the heart is more or less softened. Deposits of leucocytes are found in the liver; and here, too, the characteristic bacillus has been detected.

The voluntary muscles, especially the recti abdominis and the adductors of the thighs, usually show the changes known as "myositis typhosa," though they are by no means peculiar to typhoid fever; the muscular fibres lose their striation, become swollen and homogeneous, so as to resemble cylinders of wax, and then break up by transverse cracks into fragments and disappear, at the same time there is an interstitial exudation of leucocytes (Zenker's degeneration). Ultimately the fibre is regenerated by a cell-growth within the tube of sarcolemma. Sometimes this change causes muscular rupture and hæmorrhage during life, and is an additional reason for keeping the patient strictly at rest.

Deep ulcers which may lead to necrosis of cartilage are sometimes present in the larynx, usually on the posterior wall between the arytenoid cartilages. Bronchitis, lobular and lobar pneumonia and hypostatic congestion of the lungs are frequently met with.

ÆTIOLOGY.—Typhoid fever is chiefly disseminated by contamination of the air, or water, or food, by the specific typhoid virus which is contained in the intestinal discharges of persons suffering from the disease. The virus may retain its activity for an indefinite time in a suitable locality outside the body, and may possibly even multiply.

The most common ways in which it is communicated are :—

1. Inhaling effluvia from drains, cesspools, badly constructed water-closets, &c.

2. Contamination of the drinking water. This is the most common cause, especially of wide-spread epidemics. It takes place from soakage of sewage matter from cesspools into wells and springs, by contamination in various ways of ponds, reservoirs, even rivers of considerable size, as was the case in a recent epidemic at Zurich; contamination of house cisterns by the faulty arrangement of waste pipes; by the sucking back of sewer gas into water pipes, &c. The virus has often been distributed by milk. This is in all cases due to contamination of the water used for dairy purposes. Boiling destroys the virus both in milk and water. Outbreaks have also been attributed to eating the flesh in a state of putrefaction of calves affected by the disease.

Pettenkofer considers that contamination of the soil and height of the ground water play an important part, but it is probable that a low height of the ground water favours contamination of the water supply.

3. Direct contagion from the sick to the healthy. This probably plays but a small part in the dissemination of typhoid, and when it occurs it is probably through the medium of the stools. It would appear that the stools are much less virulent when first passed than after the lapse of some hours or days. Great care should be taken to disinfect all the discharges, to observe perfect cleanliness with regard both to the patient's person and the linen, and the attendants should never eat with unwashed hands. The linen soiled with typhoid discharges has frequently communicated the disease to laundresses. If the sanitary arrangements of a house or neighbourhood are defective, the introduction of a case of typhoid may easily cause an outbreak.

Although in civil practice in temperate climates outbreaks of typhoid can almost always be traced to some definite contamination acting in one of the above-mentioned ways, in military practice, especially during campaigns, typhoid fever appears to break out among unseasoned troops without it being possible to trace any source of infection, hence many military surgeons have come to the conclusion that it may arise *de novo*, and some have even denied its specific nature.

With regard to *predisposing causes*, typhoid fever occurs in all climates, but is most prevalent in temperate or sub-

tropical regions. In temperate climates it especially prevails during the autumn months, and is favoured by a hot, dry summer. It occurs at all ages, but is most common in young persons under the age of thirty. It is frequent in children. Age has much less influence on the mortality than in typhus, though it is more fatal in advanced life. It affects all classes of society, and occurs with equal frequency in both sexes. New comers into an infected district are generally supposed to be more liable than old residents. One attack confers a protection, though not a complete one, against a second attack.

TREATMENT.—The following rules are chiefly applicable to the more severe forms of the disease, but as concerns diet and general regimen, the mild and severe cases should be treated alike.

As soon as we have reason to suspect a patient is suffering from typhoid, he should at once be confined to his bed. A quiet, well-ventilated room should be selected and should be kept cool, and the covering of the bed should be light. The temperature of the room should not, if it can be managed, exceed 60° F. It is an advantage to have two beds in the room so that when necessary the patient can be shifted from one to the other. At least one trained nurse should be in attendance, and the patient must be watched day and night. He should never be allowed to get out of bed, especially after the middle of the second week, but should always use a bed-pan and urine bottle in the recumbent posture. Allowing the patient to get up to stool greatly increases the risk of perforation, hæmorrhage and fatal syncope. His temperature should be taken every four or six hours.

The diet is a matter of primary importance. During the prolonged fever great waste and consumption take place, not only of the fat, but also of the tissue-albumen, and though this cannot be altogether prevented, much may be done to limit it by a suitable diet, which must contain the necessary amount of fat, hydrocarbons and albumen. The last requires to be given in greater proportion to the other constituents than in health. At the same time the food must be given in a non-irritant, easily assimilable form. As a rule food should be given at least every three hours, and refreshing drinks, as lemonade, barley water, &c., may be taken in the intervals if the patient be thirsty and his mouth dry: Unless there is great prostration a longer

interval may be allowed during sleep. Often it is necessary to give food much more frequently. The food which best fulfils the indications for supplying albumen and fat is milk, and when it can be digested it should form the chief part of the diet. From 2 to 3 pints may be given in twenty-four hours. The stools should be observed to see that undigested curds do not pass. When this is the case the amount must be diminished. It may be given by itself or with arrowroot, barley water, thin gruel, rice water and soda water. Sugar may be added to the patient's taste. Beef tea, chicken broth, and other animal broths are useful, and should be given from time to time between the milk foods. Some patients can take without difficulty one to three eggs beaten up during the twenty-four hours, though many are unable to digest them. When milk cannot be digested in sufficient quantity it is often difficult to introduce sufficient albuminous and fatty matter for the wants of the system. Beef tea made in the ordinary way, though no doubt a useful stimulant, cannot be looked upon as supplying much nourishment; we may have recourse to solutions of meat extract by cold water and hydrochloric acid, or the various meat juices and peptonised meat jellies which are so largely manufactured. These should be added to the beef tea. When milk cannot be otherwise digested, Nestlé's food, made thin, can be tried, or the milk may be peptonised.

Severe cases of typhoid fever necessitate the free administration of alcoholic stimulants; the amount will depend on the age, the previous habits, and the actual condition of the patient.

Older subjects need them more than younger ones, free drinkers more than temperate persons. The especial indications for their use are a dicrotic pulse, feeble cardiac impulse, short and faint first sound of the heart, muscular prostration, subsultus tendinum, dry brown tongue, and muttering delirium. The best form is brandy, which should be given well diluted at regular intervals. The amount required may vary from a few ounces to twelve or more in the twenty-four hours. To tide over a period of temporary collapse perhaps the best stimulant is ether administered subcutaneously, 30 to 60 minims at short intervals. The less severe forms of typhoid, especially in young persons, do not require alcoholic stimulants.

The next point is the treatment of

the febrile condition. Very different opinions are entertained as to the effect on the system of the high temperature of fever. Some regard it merely as an indication of the severity of the disease, but as not in itself exercising any injurious influence, nay, as possibly a conservative process. Others consider that it has a most injurious influence by increasing the febrile combustion and disintegration of the tissues, and by impairing all the functions of the body, especially those of the nervous and circulatory systems. There can, however, be no doubt in the minds of those who have observed the effects of systematically reducing the temperature in typhoid, especially by the external application of cold, that by this means the disease is made to run a much milder course, and that the mortality is greatly lessened. Under this method of treatment, if begun sufficiently early, the so-called typhoid symptoms, delirium, &c., are seldom seen. It is, however, very probable that the mere reduction of the temperature is only one factor in the treatment, and the good results are largely due to the stimulating effect on the nervous and vascular systems, by which the tone is restored to the relaxed vessels, and then to the paralysed heat-regulating centres.

By far the most effectual way of applying this treatment, when circumstances permit, is by tepid baths, and as a rule whenever the temperature exceeds 103° F. the patient should be lifted into a bath of a temperature from 85° to 80° F. The duration of the bath must vary with the condition of the patient and the obstinacy of the temperature, generally from fifteen to twenty or thirty minutes are necessary. It is sometimes advantageous to lower the temperature of the water after immersion, but it is not, as a rule, advisable to begin with a temperature below 80° F. At this temperature the bath is generally agreeable to the patient's feelings, though towards the end he usually begins to feel shivery. Brand, as is well known, obtained the most successful results by baths of 65°, but his cases were mostly soldiers—i.e., strong young men in the prime of life.

The treatment by tepid baths is especially indicated in the acute forms of the disease and during the earlier stages; the more completely the fever is held in check during the first fortnight the less severe will be symptoms during the third week. Hæmorrhage or peritonitis is of course an absolute contra-indication, and

when towards the end of the fever the morning temperature begins to fall below 100° we may safely neglect a high evening temperature. We should administer a stimulant to the patient before each bath. As substitutes or adjuncts to bathing are cold sponging, cold compresses, and the cold pack; the two former may be used when, from the want of sufficient assistance, bathing is impossible, or when in the third week from the occurrence of hæmorrhage, or from fear of perforation, we do not like to move the patient.

Temperature may also be reduced by various drugs, the most important of which are quinine, antifebrine (acetanilide), and antipyrine (dimethyloxy-chinizin), and there can be little doubt but that when judiciously employed they have a beneficial action; it is however very doubtful whether in a long fever like typhoid they can be safely used continuously as a substitute for bathing.

In order to produce a decided fall of temperature quinine requires to be given in doses of from 10 to 25 grains, and should not be administered oftener than once in twenty-four to forty-eight hours. It is liable to cause sickness, to prevent which a little opium may be added. Perhaps the most convenient form for these large doses is the hydrobromate. It is, of course, liable to cause the usual disagreeable effects of cinchonism. It is best adapted for the later stages of the fever when the temperature is assuming a more remittent type. Antifebrine is to be preferred to antipyrine; smaller doses are required, it is less depressing, and is not liable to cause a measly rash. Like the former drug it often produces profuse perspiration, though its antipyretic effects do not appear to be due to this. The requisite dose does not usually exceed 5 grains. It is best given dissolved in rectified spirit and added to warm water. An occasional dose will much increase the effect and enable us to diminish the frequency of the baths, and it may be employed where baths are contra-indicated. It must be borne in mind that all these remedies if pushed beyond moderate limits have a depressing effect on the heart.

Recently the practice has been introduced of treating typhoid fever by antiseptic remedies, in the earlier stages with the intention of destroying or weakening the specific typhoid virus, in the later with the hope of preventing the septi-

cæmia caused by the sloughy condition of the intestinal glands. Their efficacy for either purpose is still very doubtful.

Complications and Special Symptoms.—These are numerous and require careful treatment. If the diarrhœa be only moderate in amount it need not be interfered with, if the number of motions exceed four daily, it should be held in check. The best remedy is opium, which may be advantageously administered as an enema. Where there is constipation a small enema may be administered from time to time to unload the rectum; for this purpose glycerine is often useful, but purgatives should never be given after the end of the first week. It is the custom in Germany to commence the treatment with one or two doses of calomel, and this is said to render the subsequent course milder.

If a profuse hæmorrhage should occur our aim must be to keep the bowel perfectly at rest; the patient should not be allowed to move from the recumbent posture. It is best for him to pass his motions into a draw sheet, and no food should be given for some hours. If there be danger from collapse a little cold brandy and water may be administered or a hypodermic injection of ether. An ice bag or an ice compress may be applied to the abdomen. The only drug of much use is opium, which arrests peristaltic action. It should be given in full doses, either by the mouth or in a clyster, or hypodermically as morphine. Many practitioners also administer styptics, especially gallic and tannic acids, turpentine, ergot, the latter hypodermically, but their utility may be questioned.

Peritonitis requires full doses of opium or morphine subcutaneously, and food should only be administered in very small quantities. If the temperature be high a cold compress should be applied to the abdomen; when not due to perforation, peritonitis admits of recovery. If we are satisfied that perforation has taken place, from the sudden onset of pain in a particular region, collapse, the presence of gas in the peritoneal cavity, the treatment will depend on the period of the disease; if, during convalescence, the peritoneal cavity should be opened and washed out, and the perforation excised, and the bowel stitched up. This operation has been successfully performed, and affords a sufficiently fair prospect of remedying an otherwise fatal accident. If, however, perforation takes place during the third or fourth week, when the

bowel is sloughy and the patient still under the influence of the fever, the prospect must be regarded as almost desperate. In one case where the operation was performed at this stage, the patient died collapsed within five hours, and the stitches in the bowel were beginning to slough. If it should be thought advisable to attempt an operation, it is evident that no endeavour should be made to excise the perforation, but the gut should be brought to the surface of the wound and allowed to discharge externally.

Meteorismus is a dangerous and distressing symptom and one which it is very difficult to overcome; an ice bag or iced compresses to the surface of the abdomen, the administration of stimulants and opium are useful measures. Ziemssen recommends a turpentine enema. Attempts have been made, sometimes with success, to draw off the gas by a long narrow rectal tube or elastic catheter.

Obstinate vomiting in the bilious form of the disease must be combated by ice, by limiting the food and by subcutaneous injections of morphine. Sometimes it becomes necessary to desist from food and to administer nutrient suppositories.

Pulmonary complications, as hypostatic congestion, lobular and lobar pneumonia, which latter are probably of septicæmic origin, require stimulants. Counter-irritation may be used in the form of turpentine stupes, and stimulant expectorants, as ammonia and turpentine, may be given.

Sleeplessness and delirium are best relieved by tepid baths, we should also give opium in moderate doses, or a subcutaneous injection of morphine; other hypnotics may be tried, but as a rule opium agrees best. It is of great importance not to allow the patient to pass restless, sleepless nights.

The other complications must be treated on general principles. Bed-sores must be guarded against by great cleanliness; sponging the back with spirit lotion, the early use of a water mattress, the bladder also must be carefully attended to.

Great care is needed during convalescence; we have especially to guard against the too early resumption of solid food; three or four days should elapse after the evening temperature has fallen to the normal point, before any solid food is given, and a longer interval may be necessary if the signs of ulceration continue; but it must be remembered that in order to get atonic ulcers to heal ample

nourishment is necessary. The patient should begin with a rusk and a lightly poached egg, then a little boiled fish, and then chicken. Bread, potatoes, and other vegetables should not be allowed at first. The patient should not sit up too soon for fear of causing fatal syncope. If thrombosis occur, the leg should be kept motionless by sand-bags on each side, and belladonna ointment and hot fomentations may be applied along the course of the vein, if there be pain.

Persistence of the diarrhœa is often due to ulceration of the large intestine. Astringents are now useful, especially the metallic ones, as lead and copper, combined with opium.

W. CAYLEY.

TYPHUS FEVER.—An acute specific infectious fever, distinguished by its sudden onset, by a peculiar rash, which usually appears on the fifth day of the disease; by profound prostration accompanied by cerebral disturbance, and by its termination by a crisis which most commonly occurs on or about the fourteenth day.

Symptoms.—The incubation period usually lasts twelve days. The onset is well marked as a rule, and may be sudden. Shivering, frontal headache, loss of energy and of appetite, severe aching pains in the limbs and back, thirst and constipation are generally the earliest symptoms. The tongue is pale in colour, covered at first with a thin white coating, later on plastered and finally often encrusted, as are also the teeth, gums and lips, the latter being usually dry and cracked. The colour of the coating changes, as the disease advances, to yellow, and finally to brown, or even black in severe attacks.

Early in the disease the patient takes to his bed and lies low down in it, flat on his back. He looks vacant, dull, and apathetic, and is careless of his fate. His eyes are half shut, the conjunctivæ injected, and the mouth not firmly closed. A dull red flush covers the face.

Usually on the fifth day, but in some cases on the fourth, sixth, or seventh, the *rash* appears, the percentage of attacks in which it is absent being very small. It consists of a subcuticular mottling and of very slightly raised "spots," but both are not always present in the same case. The mottling varies in character in different cases; in some having the appearance of a marbling, in others seeming to be made up of spots similar to those visible upon the surface, but

dimmed by being seen through a partly transparent layer. The "spots" much resemble those of measles, and when very numerous may be similarly grouped, but their size is smaller and their distribution different, the typhus rash being very seldom seen upon the face. Their colour is at first pink or red, and fades upon pressure, but in the majority of cases soon becomes browner and persistent, in some petechial. The spots may be very few in number, and the rash easily overlooked, or there may be an abundant crop. It is found chiefly on the sides of the chest and abdomen, on the arms and on the back, in which latter situation, as on the dorsal surface generally, the colour is usually darker. The legs may be invaded by the rash. The dull red flush usually seen upon the face sometimes covers the whole surface. The rash does not appear in crops as in enteric fever, but attains its maximum development in a few days. Sudamina and miliaria are not uncommon, though the skin is usually dry.

A distinctive odour is said to be given off from the skin, but it is doubtful whether it is sufficiently characteristic to be of any use for diagnostic purposes.

As a rule, headache is present during the first week of the illness, delirium during the second. The latter is commonly of the stupid, muttering kind, more rarely of the violent or erotic. In grave cases coma or coma-vigil may supervene. Deafness is a common symptom. Other affections of the nervous, or nervous and muscular systems, come on for the most part towards the end of the attack, and are presumably due to the exhausting effect of the fever. Of these muscular tremors, paralysis of the bladder and rectum, and in very severe cases subsultus, carphology, and hiccough occur most frequently. Convulsions, which are said to be usually uræmic in origin, are seldom followed by recovery.

Of the digestive organs the state of the tongue has already been mentioned. Abdominal distension, or tenderness, and vomiting have been observed in a small percentage of cases, but the tenderness may often be ascribed to an enlarged liver and spleen.

The urine is usually diminished in quantity, dark in colour, of high specific gravity, and albuminous. The presence of albumen or blood is seldom of serious import unless in large quantity, or associated with a very marked diminution of the excretion. Urea is in excess,

although its elimination is probably defective. The chlorides are sometimes absent and usually deficient.

The action of the heart is much impaired, the impulse being rendered feeble and the first sound weak. The pulse is rapid, soft, and compressible, full at the beginning of the attack, small and weak as the end approaches. Its rapidity varies as a rule with the gravity of the case, seldom exceeding 100 in a mild one, but rising to 140, 150 or even more in a very severe one. In a few instances, a remarkable slowing of the pulse has been noticed.

Hypostatic congestion of the lungs occurs in all but very mild cases.

The *temperature* may be considerably elevated even on the first day, and often attains its maximum by the third or fourth day of the attack, keeping nearly at the same height until about the seventh day, when, unless the type be very severe, there is a fall, and the average temperature during the second week is lower than during the first. About the fourteenth day, if all go well, the crisis usually occurs, the temperature rapidly declining to the normal. In some cases it rises again after the critical drop and then falls gradually. Complications may alter the course of the fever, and in fatal cases death is often preceded by a rapid rise, or by a fall of the temperature to a point much below the normal. The average morning remission is stated to be $1\frac{1}{2}^{\circ}$ F.

Complications and Sequelæ.—Of the former, bronchitis and pneumonia are the most common. Gangrene of the lung is much rarer. Venous thrombosis and pyæmia sometimes occur (either as complications or as sequelæ); meningitis hardly ever. Of sequelæ, gangrene is the most frequent, either in the form of bed-sores, or of necrosis of the tips of ears, heels or nose. The gangrene commencing in the feet may extend up the legs. The marked inefficiency of the circulation and the tendency to thrombosis easily accounts for these and other forms of gangrene. The corneæ sometimes slough. Buboës often form in the parotid and axillary glands, in those at the angle of the jaw, or in the groin. Paralysis of various muscles may supervene and the patient may be left in a state of temporary mental imbecility. So profound are the changes in the organism which must necessarily be brought about by the fever, when severe in type and affecting persons already weakened by privation and unhealth,

surroundings, that almost any sequelæ may be expected.

Termination.—If the patient live long enough the disease ends by crisis or by a mixture of lysis and crisis, but death may follow later on from persistence of complications or from sequelæ. Death from the primary fever occurs usually towards the end of the second week and by exhaustion or coma, or both combined.

Diagnosis.—At the onset of the attack the case may be mistaken for one of pneumonia, meningitis, variola or enteric fever, but in a few days all except the last of these diseases may be excluded. If, as sometimes happens in typhus, there be no rash and the attack be a mild one, it may not be possible to ascertain whether the case be one of typhus or of enteric fever without rash and terminating abruptly at the end of the second week.

At the eruptive period enteric fever may simulate typhus, if the onset be more sudden than usual, the rash very profuse, and if there be constipation and delirium. In some instances the rash of measles is not unlike that of typhus, but the spots are larger and more conspicuous in the former disease and the pre-eruptive symptoms quite different. Malignant variola is often confounded with typhus, but in the former the rash appears early, in no way resembles that of the latter, and is accompanied by sub-conjunctival and other hæmorrhages, but not, as a rule, by pyrexia.

Prognosis.—The chief factors which have to be taken into account are the age, sex and mode of life of the patient, the intensity of various symptoms, and the type of the epidemic. The average mortality at all ages is 15 per cent., but it varies from 2 per cent. or 3 per cent. between the ages of ten and fourteen, to about 75 per cent. at seventy, and to a still higher rate above that age. In children under ten years old the case-mortality is higher than in the next ten years of life, but with this exception the percentage of deaths increases steadily with increasing age. The mortality is greater in males than in females. Intemperate habits, destitution and debility, and the general impairment of health caused by unhygienic surroundings, will of necessity lessen the patient's chance of recovery. Of unfavourable symptoms the chief are: high average temperature and pulse rate, failing heart, severe lung affection, delirium with

sleeplessness, carphology, general convulsions, great distension of the abdomen and deficient elimination of waste products by the kidneys, especially if there be much albumen or blood in the urine. A very dark-coloured and profuse rash is also a sign of great danger.

Post-mortem Appearances.—Rigor mortis is not well marked. The blood is dark and fluid or forms but soft clots, which rapidly decompose, as also does the body generally. The liver and spleen are large, dark, soft and congested. The kidneys may show signs of acute inflammation. Peyer's patches are not swollen or otherwise affected. The heart is fatty and friable. In addition all organs show signs of the degeneration which is caused by continued fever. There is no distinctive affection of the brain or its coverings.

Ætiology.—Although no germ which can be looked upon as the exciting cause of typhus has as yet been discovered, the character of the disease renders it almost impossible to doubt the existence of such a microbe.

The best known predisposing causes are dirt, overcrowding, famine, fatigue, certain climatic conditions, and personal predisposition or susceptibility. Some of these may act by providing the germ with a better soil for its maintenance outside the human body; some by increasing the number of germs which can obtain access to it, and others by lessening the resistance to the germs effecting a lodgment, or producing conditions more favourable to their multiplication within the body.

Treatment.—The patient, both for his own sake and for that of his attendants, should be placed in a well-ventilated room. If possible, nurses who have had typhus fever should be procured or, if this be impracticable, only young nurses should be employed. The room should be kept cool and the bed-clothing light, but the patient's extremities should be kept warm. A combination of hair mattress and close-woven wire mattress forms the best bed, unless the attack of fever be very severe, in which case it is better to place the patient on a water bed at once. He should never sit up, but his position in bed should be often altered.

Food should be given at short and regular intervals, and should consist of milk, eggs, meat-juice or peptonized beef-jelly, and in most cases alcohol. Water and other diluents may be given in moderation.

As medicines, the mineral acids and

sodic chloride have been recommended, and tea, coffee or caffeine may be of use if it become necessary to stimulate the kidneys. Complications may be treated by the ordinary methods.

The ill effects which are produced by the continuance of a high temperature may be minimized by antipyretic treatment. Cold baths or sponging, antipyrin or acetanilide are the most commonly used means to this end. The first named is especially useful for inducing sleep. When the temperature has fallen to the normal the patient's appetite quickly returns and solid food may

be given. During convalescence care should be taken not to overtax the strength either of mind or body.

At the conclusion of the illness thorough disinfection should be carried out.

E. O. HOPWOOD.

TYROSIN, like leucin, is a product of the decomposition of nitrogenous bodies, and is never found except in association with leucin. It is present in the liver and in the urine in cases of acute yellow atrophy of the liver, and appears under the microscope as fine, colourless needles.

U

ULCERATIVE COLITIS AND ENTERITIS.—Ulceration of the intestine most commonly arises in the course of certain diseases, and is referred to under the appropriate headings (*see* **INTESTINES, TUBERCULAR DISEASE OF, TYPHOID FEVER, DYSENTERY, DUODENUM, ULCER OF**). The following affections are described in this article:—

- A. Simple Ulcerative Colitis.
- B. Follicular Ulceration.
- C. Distension Ulcers.
- D. Ulceration due to Vascular Obstruction.
- E. Stercoral Ulcers.
- F. Ulceration due to Perforation of the Intestine from without.
- G. Catarrhal Ulcers.
- H. Neurotic Ulcers.

A. Simple Ulcerative Colitis.—A disease, without obvious cause, which is characterized by severe symptoms, and by a peculiar form of ulceration attacking chiefly the colon.

Symptoms.—The onset is insidious, diarrhoea, which begins gradually, being the most striking and constant symptom. The bowels are ultimately open very frequently, sometimes every two hours. The motions are fluid, the colour is very various, depending much upon the amount of blood present, which, however, is not thoroughly incorporated with the motions. These are never dysenteric, and probably never contain pus; the amount of fecal matter is small, sometimes there is a little mucus and sometimes the odour is offensive, and in rare cases an occasional slough may be seen. The diarrhoea very often alternates with constipation, lasting two, three or four days at a time. In about a third of the

cases there is some vomiting. Abdominal pain is usually present from the beginning of the illness, but it bears no relation to the ingestion of food. Abdominal tenderness is exceptional. The usual course is for the patient soon to become sallow, to waste and to get weaker, and finally, to die collapsed in about eight weeks, with a subnormal temperature and a feeble pulse. The disease is uncomplicated by any other malady, but chronic Bright's disease was present in three out of eleven fatal cases. It may kill by perforation of the intestine.

Diagnosis.—The rarity of the disease and want of knowledge concerning it make it quite likely that slight cases very often pass unrecognized. In severe cases the character of the motions and the absence of an exciting cause separate it distinctly from dysentery. The duration and the alternating attacks of constipation distinguish it from simple diarrhoea. Especial care must be taken to avoid confounding it with intestinal obstruction; in one case the severe vomiting, the collapse and the fact that the bowels had not been open for a few days led to this mistake, which was corrected by an enema, which first brought away scybala and subsequently caused the passage of much fluid motion and flatus. In another case motions full of blood, abdominal pain, and the fact that an ulcer could be felt per rectum led to the diagnosis of malignant disease of the intestine. The diagnosis from follicular ulceration will be considered under that heading.

The *prognosis* is very grave; if the patient die, it is usually about eight weeks from the time when the symptoms

began, occasionally, however, the malady is fatal in a few days.

Pathology.—In a typical case, the muscular coat is exposed, and the ulceration is so extensive that only islets of mucous membrane are left here and there. Often these are considerably swollen and consequently they look taller than they otherwise would, and frequently they are more or less sessile, because the irregular ulceration undermines them. The result is that a careless observer concludes that the islets of mucous membrane are polypoid growths and the exposed muscular coat is the natural level of the colon. The vessels of the mucous membrane are dilated, and sometimes it is black as though from long-standing congestion. The muscular coat is hypertrophied. Sometimes perforation occurs and sets up peritonitis. Usually the large intestine is the only part of the gut which is affected, but in some cases enteritis and ulceration are present in various parts of the small intestine. Even at the autopsy sloughs are exceptional, from which we may conclude that the dead tissue is discharged as small shreds. Generally there is no attempt at repair, but one case is recorded in which, while one part of the bowel was severely ulcerated, pigmented spots in other parts were very suggestive of healed ulcers. As a rule, Peyer's patches are healthy, but in some cases they may be slightly swollen. Enlargement of the mesenteric glands is very rare. Constriction of the bowel and plugging of the mesenteric vessels are unknown. In the majority of the cases the rest of the body is healthy, but in some the kidneys have been granular.

Ætiology.—The disease is not dysentery; the clinical differences are so well marked that this is certain, although in some cases there may be a resemblance in the pathological anatomy of the two conditions. Some have considered that the ulceration begins in small submucous collections of pus, which burst and discharge, but this is not so; others have thought that it commences in the solitary follicles. The reasons against this view will be given presently under the head of follicular ulceration. On the whole the most probable hypothesis is that the disease begins as a catarrh of the intestinal mucous membrane. Of the ultimate cause we know nothing. It is commoner in men than in women, in the proportion of eight to three. It never occurs in childhood, but usually between 35 and 55 years of age.

Treatment.—The best hope for the patient lies in abundance of easily digestible food, peptonised if necessary, so that there may be as little fecal matter as possible to irritate the ulcerated surface, hence the patient should take little but milk in small quantities each time, but at frequent intervals, and any alterations in diet which may be resorted to during convalescence must be made very gradually. He should be kept under the influence of opium, as it is probably the best drug for restraining the diarrhoea. Usually he is better for some alcohol.

B. Follicular Ulceration.—This variety is frequently found in patients who die of exhausting diseases, sometimes, therefore, it complicates malignant diseases of the intestines, typhoid fever and tuberculosis, and thus cancerous, typhoid or tubercular ulcers as well as follicular ulcers, may be present at the same time. The condition is far more common in the large intestine than the small, it consists in the disintegration of the solitary follicles, the result being many small round ulcers with sharply cut edges, not at all undermined and not extending deeply. In a well-marked example the gut is quite honeycombed. No attempt at healing can even be seen, therefore there is no cicatrization. Perforation does not occur. The mucous membrane between the ulcers is usually not affected at all, but it may be slightly inflamed. It is doubtful whether these ulcers are of themselves capable of causing death, and no symptoms can for certain be attributed to their presence. The distinctions between simple ulcerative colitis and follicular ulceration are the following: (a) the appearance of the two conditions is quite different; (b) the two forms of ulceration are never seen to pass one into the other; (c) in simple ulcerative colitis the follicles are not described as affected, and when the small intestine is ulcerated Peyer's patches are rarely implicated; (d) simple ulcerative colitis is usually uncomplicated, and is generally the sole cause of death; follicular ulceration is usually a complication of some exhausting disease and is never the sole cause of death; (e) perforation of the intestine occurs in simple ulcerative colitis, but not in follicular ulceration; (f) chronic Bright's disease is the commonest complication of simple ulcerative colitis, but it is very rare in association with follicular ulceration; (g) other intestinal lesions are common in follicular ulceration, but are very exceptional in simple ulcerative colitis.

C. Distension Ulcers.—Whenever there is any obstruction of the passage of the intestinal contents, the distended gut behind the seat of obstruction is very liable to become ulcerated. The exact mechanism of the production of these ulcers is not known, probably they are due to irritation of the coats of the intestines by its contents. There is nothing particularly characteristic about the ulcers as regards their shape and position. They begin as small superficial erosions, and if the obstruction lasts long enough they, like all chronic intestinal ulcers, tend to become transverse to the long axis of the bowel. They may slough and lead to perforation of the gut, or may extend so deeply as to set up peritonitis without perforation. Usually, but not always, they are immediately above the seat of obstruction. The furthest distance above the obstruction in cases observed by the writer was six feet. The ulceration furthest from the obstruction is usually the least severe, and if recovery take place the first to heal. The obstruction must last some time for ulcers to form, but the writer has found them in abundance nine days after the onset of acute obstruction. The lymphatic follicles are not more liable to be ulcerated than any other part of the intestinal wall.

D. Ulceration due to Vascular Obstruction.—Severe ulceration of the intestine is sometimes due to a growth pressing upon the mesenteric vessels, and sometimes to vascular obstruction from atheroma, thrombosis, or plugging by infarcts of the mesenteric arteries. Our knowledge of this condition is too scanty for us to say whether there is anything characteristic in this variety of ulceration. It is interesting to observe that it may be transverse even when not chronic; possibly this is due to its following the distribution of the vessels. Strange to say, although the inner coats of the bowel are inflamed and ulcerated, the peritoneum usually escapes, and thus peritonitis is generally absent. It is an interesting fact that the ulceration may be severe without producing any symptoms.

E. Stercoral Ulcers.—In cases of long-standing constipation, especially if it be severe enough to constitute fecal impaction, the irritation of the hard masses of feces leads to the formation of small ulcers. These do not produce any symptoms and usually heal when the constipation is overcome; they, and the intestinal catarrh which accompanies them,

are the cause of the diarrhœa, which may persist for a few days after the removal of the feces in a case of fecal impaction.

F. Ulceration due to Perforation of the Intestine from without.—This is an extremely rare condition seen in those cases of chronic peritonitis in which a number of small localized abscesses have formed between the matted coils of intestine, which, bursting into the gut, form a number of small rounded ulcers.

G. Catarrhal Ulcers.—Some authors, as, for example, Leube and Nothnagel, describe simple catarrhal ulcers, which may begin with simple lesions of the epithelium, or as minute collections of pus, which burst and give rise to small ulcers. This form of ulceration is decidedly rare, and nothing is known of the symptoms which it produces.

H. Neurotic Ulcers.—It has been suggested that ulcers due to nervous diseases may form in the intestine just as a perforating ulcer forms in the foot, but on this subject we have no information of value.

In certain cases severe ulceration of the intestine, which cannot be referred to any known group, is found on autopsy.

W. HALE WHITE.

URÆMIA.—A condition caused by the retention within the body of poisonous products which should be eliminated by the kidneys.

Symptoms.—The animal organism is a laboratory in which poisons are being constantly generated. Many of these are eliminated by the kidneys as rapidly as they are formed. If, however, from any cause these organs make default, or if there be any prolonged obstruction to the outflow of urine, accumulation of some or all of the poisons takes place, and characteristic symptoms are manifested. But the accumulation may be very slow, and the earlier symptoms, corresponding to the comparatively small dose of poison, may be but slight; yet they are in kind, though not in degree, as indicative of uræmia as are the more alarming ones which appear towards the end, and to which alone the name of uræmia is often given. Not only from the varying rapidity of this accumulation, but from other causes to be mentioned, will the symptoms of different cases of uræmia vary greatly. Whatever be their nature or intensity, however, they always point to an intoxication, and most frequently to an intoxication of the nervous

centres. Facts now established by experiment are gradually helping to explain many of the anomalies arising from the widely different clinical pictures presented by different cases. Thus, from healthy urine Bouchard has obtained at least seven distinct poisons, of which two are convulsivant, one diuretic, one narcotic, one sialagogue, one pupil-contracting, and one temperature-reducing. He has further shown that these poisons are produced in different relative amounts at different periods; for whereas the night urine contains so large a proportion of the convulsion-producing substances as to make it predominantly convulsivant, the day urine has more of the narcotic poison and is hence soporific in its action. In diseased conditions there is evidence of the formation of yet other poisons over and above those produced in health. Taking all these facts into consideration, and remembering the occasional deviation from the usual symptoms in cases of poisoning by a single substance like arsenious acid, depending probably upon the special reaction of the individual, there is no longer room for surprise at the anomalies presented by uræmia. There is good evidence, too, that poisonous alkaloids, such as xantho-creatinine and others, whose nature is only now beginning to be studied, are formed within the animal body in health and still more in disease, and that they, if retained, as they are apt to be in derangements of the kidneys, produce special toxic effects.

One of the earliest and most constant of all the symptoms is vomiting. It is seldom entirely absent, and sometimes is so frequent and persistent as ultimately to lead to death by exhaustion. In such cases the nervous system usually remains unaffected throughout, neither muscular twitchings, convulsions, paralysis, coma, nor other nervous symptom appearing. The writer has seen this not only in cases of acute and chronic parenchymatous and interstitial nephritis, but in permanent plugging of both ureters. No special poison having emetic properties has as yet been obtained from urine, but urinous products are certainly at times excreted freely by the gastric mucous membrane in uræmia; and when there is such excessive vomiting the amount of liquid thus discharged seems often to be in excess of what is ingested. The patient under such circumstances wastes rapidly, even if sustained by nutrient enemata.

Much more frequently, however, the

retained poisons affect the nervous centres, headache or various disturbances of special sense, especially of the sight, convulsions, coma, paralyses, or nervous dyspnoea of asthmatic type, with, at the same time, always some amount of vomiting, occurring alone or variously combined, and presenting various clinical pictures allied to those of alcoholic intoxication, epilepsy or apoplexy, but always distinguished by the fact of a relation to antecedent renal trouble.

As to the mechanical theories of uræmia, such as cerebral anæmia, or œdema, or plugging of arteries, it is not necessary to do more than allude to them here, for although cerebral œdema and anæmia are doubtlessly often present, and when present must produce symptoms, it is equally certain that they are often absent, and that the only constant and invariable factor is the retained urinary poisons. One must not omit to mention among the signs of the uræmic state unpleasant and sickening odours both from lungs and skin, which are sometimes recognizable on approaching the patients' beds. Volatile poisonous products are probably discharged from the lungs and skin to the partial relief of the patient.

The relation of the amount of total daily urinary products to the body weight of the individual is a matter of great importance, and where for several successive days the proportion falls below what is normal, some significant symptom or symptoms of poison will certainly appear. If the kidney be contracted and the heart large, besides the headache and epistaxis, which may simply result from heightened blood-pressure, vomiting is almost certain to occur, or irritating cutaneous eruptions. Later on sight may suddenly disappear and as suddenly reappear, the ophthalmoscope revealing no change in the fundus oculi.

Uræmia, as manifested by one or more of the symptoms mentioned, may occur in all forms of Bright's disease, but it is only in the acute parenchymatous inflammations of the kidney, such as those following scarlatina, that it is ushered in very suddenly and sometimes with overwhelming violence, convulsions, coma, and death succeeding each other in a few hours. In most, if not all other conditions, there are significant warnings that should prevent us from being surprised by the patient lapsing into stupor or some similarly alarming state.

The safe plan is to regard the earlier and slighter symptoms, not as indicative

of a condition that may lead up to uræmia, but as indicating uræmia itself.

Treatment.—How far can the uræmic condition be combated? The four great sources whence the urine derives its toxicity are:—(1) Aliments, and especially their potassium constituents; (2) the absorbed products of intestinal putrefactions; (3) secretions, such as bile, &c.; and (4) tissue disintegrations. We can control the food, disinfect the intestinal contents, limit the secretions, and to an extent check disintegrations, and by all these means do good. Milk contains but little potassium compounds, requires but a small amount of bile for its digestion, and is closely allied to healthy blood. Milk is hence the best diet. By the use of such drugs as salol, or Bouchard's well-known mixture of naphthaline, iodoform, and animal charcoal suspended in glycerine and water, we can disinfect the intestinal contents. In very acute cases, such as those following scarlatinal nephritis, a free bleeding will often abstract enough of the poison to restore the patient from an apparently desperate condition and even permanently cure him. Freë purgation will almost always give relief; while transfusion has, in extremely critical cases, occasionally warded off death for some time. Experience has fully shown the value of free purging and diaphoresis; while there is a growing evidence that increased oxidation, obtained by active exercise, when the condition of the patient permits this to be taken, by the employment of the compressed air bath, or by the inhalation of oxygen itself, is useful instead of injurious.

When the pupils are dilated and the preponderating physiological effects of the retained urinary poisons are like those of atropine, the hypodermic injection of morphine is of the greatest advantage. Where purgation is required, but vomiting is persistent, the slow introduction of the enema magnesi sulphatis will produce a copious evacuation in from five to seven hours.

WILLIAM CARTER.

URETHRA AND BLADDER, FEMALE, DISEASES OF.—Dilatation of the Urethra is occasionally met with. It has been produced by the passage of calculi or tumours; by excessive dilatation for surgical purposes; by the introduction of foreign bodies by the patient herself, by lupous ulceration; and there are cases in which the urethra appears congenitally of unusual capacity.

The condition gives rise to irritability of the bladder, or in the worst cases to incontinence of urine. In simple congenital largeness there are no symptoms, or they are slight only.

Treatment.—The best treatment is to insert a bulbous actual cautery into the urethra for a second or two, so that a small slough may be produced, and the resulting cicatrix contract the urethra. In bad cases treatment is very unsatisfactory.

Partial or Saccular Dilatation of the Urethra (*Urethrocele*).—This condition is rare. Such diverticula as are of any size are produced by cysts which have opened into the urethra. The diagnosis and treatment of these is described below under Dermoid Cysts. Saccular dilatation of the urethra, independent of a cyst in its wall, is exceedingly rare, does not reach a high degree, nor, when uncomplicated, cause any symptom.

Prolapse or Inversion of the lining membrane of the urethra, or even of the bladder, is occasionally met with. The latter is the rarer. It seems to be associated with congenital largeness of the urethra. Prolapse of the urethral mucous membrane occurs usually in children, as a result of some straining effort, such as a violent attack of coughing. It forms a sort of deep red frill round the urethral orifice. The protruded part quickly becomes congested, deep red or purple in colour, and readily bleeds, but is not very tender.

Treatment.—The protruded part should be cut off, either with the Paquelin cautery knife or with scissors, the edges of the cut mucous membrane being in the latter case united by sutures.

Stricture of the Urethra is much less common in women than in men. Normally, the female urethra is almost always large enough to admit a No. 14 catheter, and generally No. 17, but it may be congenitally small.

As in men, urethral stricture may be the result of gonorrhœal inflammation. It may be cicatricial, following injury received in labour, or result from syphilitic ulceration. There is a form of stricture met with in old women, in which there is fibrous thickening of the whole length of the canal. As the urethrovaginal septum is the homologue of the prostate gland in the male, the writer has suggested that these cases are analogous to enlargement of the prostate in the male. There are also cases of stricture due to the fibrous overgrowths which accompany the disease known as lupus

of the vulva (*esthioméne*) (*q.v.*). These growths sometimes surround the meatus and make the channel so small that it is difficult to get in even a fine probe. Cancer occurring in the anterior wall of the vagina leads to great narrowing of the urethra. Lastly, there are rare cases of passing retention of urine following cold, drink, and debauchery, and believed to be due to spasmodic stricture, such as occurs in the male. It is very rare for stricture of the female urethra to lead to the serious diseases of the bladder, ureters and kidneys that are such common results of stricture in the male, for the reason that the treatment of stricture in the female is so simple and so successful. But these secondary morbid changes do sometimes occur.

The *symptoms* are simply irritability of bladder, with often tenesmus and pain in micturition, and occasionally retention of urine.

The *diagnosis* is readily made by the obstruction encountered by the catheter.

The *treatment* of stricture in the female is rapid dilatation by the passage of bougies of gradually increasing size. This treatment is almost invariable successful, except in cancer, in which the best course is to open the bladder from the vagina with the knife, and so establish a vesico-vaginal fistula. This will relieve the patient from the intolerable tenesmus. In spasmodic stricture the passage of a catheter is all that is required.

Urethritis (*Inflammation of the Urethral Mucous Membrane*) is very common, arising by extension of inflammation from the vagina. It is usual in gonorrhœa, and in vaginitis from other causes. Some reflex congestion of the bladder and urethra occurs in most pelvic inflammations, and causes the vesical irritability and scalding in micturition which are usual symptoms in these conditions. This slight superficial urethritis seldom requires special treatment apart from the accompanying inflammation elsewhere, to which it is due.

Congestion of the Urethra and of the cellular tissue around it is most often seen during pregnancy. The urethra is swollen, thickened and tender; it may feel like a cord as thick as the thumb, or even larger. The symptoms are pain and frequency in micturition, and dyspareunia. The cause of these symptoms will be ascertained by vaginal examination, when the tender swollen urethra will be felt. The treatment consists in recumbency, laxatives, warm hip baths, and

vaginal douches, and avoidance of alcohol. If not treated this form of disease is apt to be very chronic, and may go on to the formation of an *abscess* in the urethro-vaginal septum. In that case the swelling becomes larger, harder, rounder, and more tender, and the symptoms more troublesome. The condition may remain apparently stationary for many months, but at length the abscess bursts, and the patient is relieved.

Treatment.—If there be doubt about the nature of the swelling the urethra should be dilated and the abscess opened, either on the urethral or the vaginal aspect, according to the side on which the tissue limiting the pus seems thinner.

Dermoid Cysts sometimes occur in the urethro-vaginal septum. Cysts are also met with which do not show evidence of a dermoid character. Such cysts, dermoid and others, sometimes suppurate and discharge into the urethra. A suppurating cyst will be distinguished from an abscess by its internal surface being smooth, not irregular and granular like the cavity of an abscess, and later on by its course, for it does not heal but continues to discharge.

The *treatment* is to excise from the vagina as much of the cyst wall as forms a diverticulum from the urethra, and then bring together with sutures the raw surfaces left by the incision.

Urethral Caruncle is a small, bright red growth from the posterior part of the meatus urinarius. These growths vary from the size of a hempseed to that of a filbert. When large they look something like a cock's comb. They consist of connective tissue, which may be found to have undergone at places myxomatous degeneration, are very vascular, are usually covered with pavement, sometimes with columnar epithelium; they may contain many glandular follicles, and are very rich in nerves.

Symptoms.—These depend upon the extreme sensitiveness of the growths. They consist of severe pain during micturition, during sexual intercourse, or whenever the part is touched. If the growth be large, walking therefore becomes painful. They readily bleed, and hæmorrhage on contact is a frequent symptom.

The *diagnosis* is easily made by inspection. The growth is quite superficial, springing from the mucous membrane, and not invading deeper parts; this distinguishes it from cancer.

Ætiology.—Nothing is known of this. They are hardly ever seen in children;

but may occur at any age after puberty. It has been asserted that they are of gonorrhœal origin; but they are often found without any evidence of past or present gonorrhœa. They occur in virgins as well as in those who have borne children.

The *treatment* is to cut away the growth and destroy its base. This is most easily done by putting the patient in the lithotomy position, protecting the adjacent mucous membrane with a piece of wet lint, guarding the rest of the urethra by a wooden staff passed into it, and then cutting through the base of the growth on to the staff with the red-hot knife of the Paquelin cautery. These growths are apt to return, even after what appears to be thorough removal.

A condition resembling caruncle, viz., *bright red patches*, exceedingly tender, is sometimes seen along the course of the urethra. Attention is called to this condition by the pain which the patient suffers in micturition, and the great sensitiveness which is manifested when the catheter is passed. If then the interior of the urethra be examined with a speculum (of which French's is the best), these red patches will be seen. Their nature has not yet been ascertained.

The *treatment* which is generally successful is the application of iodoform. This may be blown in by means of a quill, or applied in the form of an iodoform bougie.

Very similar symptoms are produced by the presence of *congestion and ulceration* around the vesico-urethral opening. These changes have been seen by the endoscope. They are cured by *treatment* such as is effective in cystitis—viz., urethral dilatation, or the making of a temporary artificial vesico-vaginal fistula.

Varicose Veins in the wall of the urethra are occasionally seen in women who have had many children. They usually accompany varicose veins of greater size in adjoining parts. Such varicose veins and urethral caruncles have alike had the term "urethral hæmorrhoid" applied to them. But the purplish red swellings which varicose veins form, do not present the extreme tenderness characteristic of caruncles. They scarcely ever require special treatment.

New Growths are occasionally met with in the urethra, but are comparatively unimportant, because they are so rare. *Mucous and fibrous polypi* have been observed. They can be removed by twisting them off, if small and near the

meatus; but if large and near the neck of the bladder, their removal should be accompanied by opening the bladder from the vagina. *Sarcoma* of the urethra has been once observed. The urethral orifice may be affected in common with other parts of the vulva by various diseases which are described elsewhere, such as syphilitic condylomata, ulceration, &c., follicular inflammation, lupus of the vulva (*esthioméne*). The urethra may be invaded by cancerous or tubercular disease; but these diseases very seldom primarily affect it.

Neuroses of the urethra have been described, but this is generally a convenient term for a case which has been incompletely investigated, and in which consequently therefore the real disease has not been diagnosed.

BLADDER.—Cystitis (*Inflammation of the Bladder*).—Cystitis in women differs from that disease in men as to its causation. It is most common as a result of retention of urine due to retroversion of the gravid uterus; or following labour, or after operations on the uterus or its appendages, but is rare as a result of urethral stricture. In connection with pregnancy and labour cystitis of great severity is sometimes seen. It may go on to sloughing and exfoliation of the whole vesical mucous membrane; or it may produce gangrene of the vesical wall at one spot, having as its result perforation of the bladder.

The *symptoms* are the same in both sexes. Exfoliation of the vesical mucous membrane should be suspected when, in a case of severe cystitis, the urine containing much deposit, we find the bladder apparently full, and on passing a catheter urine flows out, but suddenly stops before the bladder is emptied, and the point of the catheter feels as if it pressed against a solid substance within the bladder. When this is suspected, the best treatment is to cut into the bladder from the vagina.

The *treatment* of cystitis in the female is easier and more surely successful than in the male, because it is so easy to explore the bladder and remove foreign bodies by a vaginal incision. Exploration may be effected by dilating the urethra until it is sufficiently large to admit a small finger; if carried further, much risk of permanent incontinence of urine is entailed. To extract a stone, a growth, or a foreign body, an incision should be made in the middle line from the vagina. This can be closed with sutures, when what is

required has been done. Even if not closed, it will often heal. In cystitis that has resisted all other treatment, and especially in painful cystitis (supposed to be due to ulceration of the neck of the bladder) a cure may be effected by maintaining the vesico-vaginal opening patent for two or three months. It can then be closed by an easy operation, and usually the urine will then be found clear, and the function of the bladder free from pain.

G. E. HERMAN.

URINE.—EXAMINATION OF.

—The total amount of urine passed in twenty-four hours should be collected and measured.

COLOUR.—The healthy urine has a yellowish colour, which may vary in depth of tint at different times, according to the varying physiological states of the body. The depth of tint is diminished when the watery element is in excess. Thus the urine is limpid after profuse potations, after hysterical or other nervous attacks, in cases of simple anæmia, in both the forms of diabetes, and in granular kidney. The colour of the urine is increased in intensity when from any cause, such as excessive sweating, the urine is concentrated, also when pyrexia is present, and in certain wasting diseases, and in some cases of so-called pernicious anæmia. In the pathological states mentioned it is probable that the increased depth of colour is not due merely to a greater proportion of colouring matter being present, but also to the presence of a pathological pigment produced by the profound changes in the physiological processes. The normal colouring matter, urobilin, may be replaced, as Dr. McMunn has shown, by febrile urobilin, or by urohæmatoporphyrin, substances which are to be distinguished from the normal pigment by the spectra they exhibit on treatment with various re-agents, a matter which cannot be entered into here.

The pathological admixture with the urine, of certain normal fluids of the body, will alter its colour in a characteristic manner.

Bile is present in the urine in cases of jaundice and causes the urine to assume a brownish hue, which may in extreme cases appear almost black. On standing exposed to the air for some days such an urine occasionally becomes of a green colour.

Tests for Biliary Pigments.—Two reactions serve to detect the biliary

colouring matter in the urine and thus distinguish the brown colour due to the presence of bile, from that produced by other pigments.

Gmelin's Test is applied by placing side by side on a white porcelain slab a drop of the urine and a drop of strong nitric acid and allowing the two to come into contact, or by floating a layer of the urine on the surface of a little nitric acid in a test tube. At the point of contact of the two fluids a play of colours, green, violet, red, and yellow, will indicate the presence of bile. But the play of colours is not easily distinguished from the red colour which other matters in the urine give with nitric acid, and therefore the following test is to be preferred.

Maréchal's Test.—A test tube is filled to about one-third its depth with water and to this are added a few drops of tincture of iodine, so as to form a light brown liquid. This is then mixed with a little of the urine, when if bile be present a bright green colour is almost immediately developed. If the urine be very dark it is desirable to dilute it before applying the test.

Urobilin Icterus.—Gerhardt has drawn attention to a condition which he calls urobilin icterus. The skin and conjunctiva are coloured yellow, the urine is dark brown in colour, and it may be supposed that slight jaundice exists. Yet, when the tests for bile pigment are applied to the urine, none is found. The pigment which is present is an excess of urobilin, a normal constituent of the urine, and such excess is produced in the body by oxidation of bile-pigments. Gerhardt has applied to such urines the following test:—To a chloroform extract of the urine tincture of iodine and caustic potash are added, when a green fluorescence appears.

Tests for Biliary Acids.—The biliary acids are detected by *Pettenkofer's Test*, though this is not easily applied to urine. A little cane-sugar should be dissolved in the urine, and this poured gently on to the surface of sulphuric acid in a test tube. A purple colour at the junction of the two fluids indicates the presence of biliary acids.

Urine containing much bile occasionally deposits crystals of bilirubin.

Blood, according to its degree of admixture, causes the urine to assume either a smoky tint or a bright red colour, not easily confounded with any other condition. The blood-colouring matter alone may occur in the urine as

in hæmoglobinuria. In ordinary hæmaturia, blood corpuscles will be also found by microscopic examination. Hæmatoidin crystals are sometimes found as a urinary deposit.

Tests.—The blood-colouring matter is detected by its reaction with *Tincture of Guaiacum and Ozonic Ether*. A little of the urine to be tested is placed in a tube, and with it about two drops of tincture of guaiacum; then ozonic ether is added, and the whole well shaken, when, if blood-colouring matter be present, a bright blue colour is developed. Should this not appear at once, the test tube should be allowed to stand for a short time until the ether rises to the surface of the mixture. Such blue colour as has been produced will be absorbed by the ether, and will then be more easily seen. Should the urine contain iodide of potassium, as will happen when the patient is taking that drug, or saliva, a similar reaction will be shown, even though no blood be present.

Heller's Test.—If urine be boiled with liquor potassæ the phosphates contained in it are precipitated as a grey flocculent mass, but, if blood be present, the precipitate is coloured red or brown.

Chyle makes its appearance in the urine when there is leakage from the lymphatic vessels into the urinary passages. The urine is then of a milky colour, and is sometimes spontaneously coagulable. Under the microscope, granules and occasionally fat globules are seen; while the clot, if such has formed, will be seen to consist of threads of fibrin.

Pus causes the urine to be of a milky colour, but the greater part of the pus separates on standing, and its detection is easy with the aid of the microscope (see PYURIA).

Effects of certain Drugs upon the Colour of the Urine.—The administration of certain drugs causes the urine to assume characteristic colours. Carbolic acid and salol, which contains it, cause the urine to become black. It may happen that the black colour, which is due to oxidation products of hydrochinon, does not develop until the urine has been allowed to stand for a little time in contact with the air, and it rarely develops to a marked extent if the urine be highly acid in reaction. Resorcin, hydrochinon, pyrocatechin, tannic and gallic acids and tar, used externally or internally, may cause the same appearance. It occasionally happens that without any drug having been used, the urine

becomes of a black tint. Occasionally, as in one case observed by the writer, this is due to the presence of protocatechuic acid, and Dr. Kirk has also found in such urines a new body, which he has named uroleucic acid. When malignant tumours of a melanotic nature are present in any part of the body, but especially when they affect the skin, the urine may be dark in colour, and may deposit a black pigment. Here, again, the pigment only appears when the urine has stood for some time in contact with the air, or when the urine has been treated with an oxidizing agent such as hydrochloric acid and chlorate of potash or liquor ferri perchloridi. The dark pigment may also be demonstrated by the addition of bromine water, which gives a precipitate, at first yellow, afterwards black.

Rhubarb or chrysophanic acid produces a dark yellow colour of the urine, changing to red if ammonia be added. Senna causes a similar colour to appear. Santonin, when given internally, often causes the patient to pass a urine which is bright yellow if the urine be acid, orange red if it be alkaline. When logwood is administered internally hæmatoxylin is excreted in the urine, and gives a violet colour if the urine be alkaline or if ammonia be added. Large doses of quinine cause the urine to become dark in colour, kairin produces a brown, thallin a green, and antipyrin a deep red colour of the urine. Antifebrin is stated to produce no change in the urine, but in two cases which came under the notice of the writer this drug caused the urine to assume a deep red tint, due to the presence of hæmatoporphyrin, which was separated from the urine and examined by the spectroscope.

Indicanuria.—An alkaline urine after standing in contact with the air for some time may be covered by a blue scum. A few cases have been recorded where the blue colour had developed within the body and was seen in the urine as soon as it was voided, in the form of a general diffused blue tint and bluish particles. The colouring matter is indigo-blue derived by oxidation from indican which is a normal constituent of the urine. Indol, a product of pancreatic digestion is absorbed from the intestines and becomes changed in the body into indican, which is excreted in the urine as an ether-sulphuric acid.

Tests for Indican.—The urine is mixed with an equal quantity of strong hydrochloric acid, when a reddish-violet

colour is formed, caused by the production of indigo-red. If now a weak solution of bleaching powder be added drop by drop, the violet changes to a blue colour (indigo blue) which is quite bleached by excess of the chloride of lime. The blue colour may be extracted by shaking with ether, and the depth of colour in the ethereal extract shows roughly the amount of indican present in the urine. Indican is excreted in greater amounts when putrefactive processes are going on actively in the intestine, consequently greater quantities are found in cases of peritonitis and of obstruction of the small intestine. Other products of the decomposition of proteids, amongst which the most important are skatol and kresol, are absorbed from the intestine together with the indol, and are similarly excreted in the urine as ether-sulphuric acids. These bodies cause a deep red colour to develop in the urine when strong nitric acid is added and consequently interfere somewhat with the nitric-acid test for albumen and bile.

ODOUR.—Normal urine has a peculiar odour, which can only be styled urinous. When the urine is heated with a mineral acid the odour is intensified. Urine containing a fixed alkali has a sweetish smell like that of the urine of a horse. Ammoniacal decomposition of the urine can be detected by the sense of smell, since the presence of ammonia and also of sulphuretted hydrogen is at once perceived. A few cases have been recorded in which sulphuretted hydrogen gas was present in the urine before any decomposition had set in, indeed as soon as the urine was voided. In many cases of diabetes the urine has an odour resembling that of chloroform. The urine of a person who has imbibed turpentine in any way, either medicinally, or, for instance, by sleeping in a newly painted room, smells of violets. Asparagus imparts a very disagreeable and intense odour to the urine. Copaiba and cubebs similarly impart a peculiar smell to the urine.

SPECIFIC GRAVITY.—The specific gravity of the urine is determined by the urinometer, the form of which is well-known. In using it, it is necessary to make sure that the test-glass is sufficiently wide to allow of a moderate quantity of urine remaining between the sides of the glass and the urinometer, and also that sufficient urine is present to float the urinometer free from the bottom of the glass. If there is not sufficient urine obtainable for this purpose, two courses

are available, either the urine may be diluted with an equal quantity of distilled water, and when the specific gravity of the mixture is obtained by the urinometer, the decimal points be doubled; or beads of different degrees of gravity, which are sold for the purpose, may be used, the bead which will float in the urine determining the specific gravity of the fluid. For more accurate determinations it is well to weigh a known quantity of the urine and compare it with that of the same quantity of distilled water.

The specific gravity of the urine is expressed in its proportion to that of water taken as 1, the comparison being made to the third decimal place, or more frequently, for convenience, the specific gravity of water is taken as 1000.

The specific gravity of urine is a measure of the amount of solid matter dissolved in it. If the two last figures of the specific gravity be multiplied by 2 (Trapp), or, more accurately by 2.33 (Haeser) the amount of solid matter per 1000 parts of urine is approximately obtained.

The urine in health has a specific gravity ranging between 1015 and 1025. Abundant potations on an empty stomach will lower the specific gravity to a figure very nearly that of distilled water. In disease, the lowest specific gravities are met with in hysteria, diabetes insipidus, and albuminuria. In regard to the latter affection it must, however, be remembered that it is not the presence of albuminuria which produces the low specific gravity. Gouty urine, for instance, may contain albumen and yet be of high gravity. In the majority of cases, nevertheless, albuminuria is the result of some disease of the kidneys which diminishes the secretion of solids, and is accompanied by high arterial tension which increases the amount of water. The disease, *par excellence*, which increases the specific gravity of the urine, is diabetes mellitus. On the other hand, the writer has met with sugar in an urine having a specific gravity of only 1013.

REACTION.—The reaction of the urine is ascertained by dipping into it a strip of litmus paper coloured red or blue. If alkaline, the red paper becomes of a blue colour, if acid, the blue paper becomes red. For practical purposes it is well to use litmus paper, coloured purple, since this is tinted red by an acid, and blue by an alkaline fluid. The normal urine, as usually examined, is of an acid reaction, by reason, mainly, of

the presence in it of acid salts. Yet if passed at frequent intervals, it is found that the urine varies in its reaction at different times of the day. Food has a marked effect upon the reaction of the urine. Shortly after a meal, the urine begins gradually to lose its acid reaction, and may actually become alkaline. After a time, the reaction gradually returns to its acid character, indeed, the meal, finally, to a certain extent, increases the acidity of the urine. This phenomenon of the "alkaline tide" has been variously explained. According to Dr. Bence Jones it is due to the withdrawal of acid gastric juices from the blood, for the purpose of digestion, while Sir William Roberts has suggested that it is produced by the accession to the blood of the alkaline bases contained in the food. The matter, however, is not so simple as would appear from what has been said above. Thus the urine of the forenoon is specially prone to be alkaline. The writer observed this when, after fasting for many hours, he took as his sole meal the raw whites of a dozen eggs diluted with water. Again, at other times of the day and without any relation to food, the urine may lose its acid reaction. The reasons for these phenomena are not yet known.

It is important to notice, when the urine is alkaline, whether the alkalinity is due to fixed or volatile alkali. The volatile alkali is ammonia, and, if present in considerable quantity, its vapour alone will cause a moistened litmus paper to turn blue, when the latter is held close over the urine. The question is conveniently determined by dipping a red litmus paper into the urine and then allowing it to dry slowly in the air. If the blue colour has been produced by fixed alkali it will remain after the paper has dried; if by ammonia, it will disappear when the alkali has evaporated.

The urine is easily rendered alkaline by drugs, especially by the carbonates of the alkalies, or by the alkaline salts of the vegetable acids, which appear in the urine as carbonates. It is important to bear this in mind when testing for albumen by boiling, since the albumen will be changed into alkali albumen and is then not coagulable by heat. The urine is also liable to become alkaline from fixed alkali in many diseases, especially in those of a debilitating character; alkalinity from ammonia is in almost every instance the result of putrefactive changes in the urine, an effect of the action of micro-organisms, which change

the urea of the urine into carbonate of ammonia. The chief of these organisms is the micrococcus ureæ first described by Pasteur.

The acidity of the urine can be also increased by drugs, but only to a limited extent. The most efficacious drug for this purpose is the benzoate of ammonia, which is excreted in the urine as hippuric acid.

Estimation of the Degree of Acidity.

—The acidity of the urine can be estimated by neutralizing it with a solution of caustic soda of known strength. The strength of this solution is determined by a standard solution of oxalic acid, and is conveniently such that 1 cubic centimetre neutralizes 0.063 gramme of oxalic acid. A burette is filled with the soda solution, best diluted to $\frac{1}{10}$ or $\frac{1}{5}$, and the solution is then gradually added to the urine until complete neutralisation is attained. From the number of cubic centimetres of the alkali solution used, the acidity of the urine, reckoned in milligrammes of oxalic acid, can be easily calculated. The attainment of the neutralization is ascertained by the reaction of the urine on litmus or rosolic acid.

DEPOSITS.—The normal urine is perfectly clear when it is first passed from the bladder, but is prone to become turbid, and to deposit a faint hazy cloud, consisting of mucus and epithelial cells, after it has stood for a little time, but before ammoniacal fermentation has set in. In diseased conditions, many other deposits are found in the urine, and they may be conveniently discussed under two heads, the inorganic and the organic.

In order to examine the deposit from urine, it should be allowed to stand in a conical glass, when the deposit will fall into the apex of the cone, and can then be examined by the microscope. The most useful glasses are those made by Mottershead & Co., of Exchange Street, Manchester, after a pattern furnished by Sir William Roberts.

Inorganic Deposits.—*Urates.*—The most common deposit from the urine is that composed of the amorphous urates. These fall from acid urines, and form a mass more or less dense, having no appearance of crystallization, which usually soon settles to the bottom of the glass. The amorphous urate deposit may be pale grey in colour, but most frequently it carries down with it some of the colouring matter of the urine, and thus assumes varied tints, which may, however, be classified as pink and red. The

surface of the urine which has deposited urates is commonly covered by a faint purplish bloom. Under the microscope the deposit is seen to consist of amorphous finely granular matter. The deposit re-dissolves on warming the urine, and also when alkalis or their carbonates are added. Acids, however, first increase the amount of the precipitate, and will even cause it to appear in a urine in which no deposit has previously occurred. In a little time acids decompose the deposit, and cause the appearance of crystals of uric acid.

The *Amorphous Urate* deposit is a quadrurate containing one atom of alkali and three of hydrogen, combined with two molecules of uric acid. Sir William Roberts has shown that it is very easily decomposed, and is, in fact, always decomposed after standing for a time in contact with the urine, being transformed into bi-urate and uric acid. The bi-urate is again changed into quadrurate, and again decomposed until, in this way, the whole of the uric acid of the urine, whether combined or uncombined, is at last thrown down. The decomposition is hindered by the presence of the salts and the pigments of the urine.

This deposit is produced by a low temperature, an acid re-action, and concentration of the urine. It is hence common in cold weather and after profuse sweating, without the presence of any pathological condition. Amongst the diseased states which are associated with it, the most important are digestive troubles and pyrexia. The dark-red coloured urate deposit is significant of very serious organic disease, commonly the presence of malignant tumours of the abdomen, while the pale pink urates are of little clinical importance.

Urate of Soda is sometimes deposited from the urine, and frequently before the urine has left the bladder. It occurs as "hedge-hog" crystals, globes with spiny projections. It forms a white or grey deposit in acid urines, and is associated especially with the gouty state and with the pyrexial attacks of children. The rough crystals are prone to cause severe vesical irritation.

Urate of Ammonia is sometimes found, together with a deposit of phosphates, in urine which has undergone ammoniacal decomposition. It occurs in the form of spheres and dumb-bells.

Uric Acid.—Uric acid is also a very common urinary deposit. The uric-acid deposit occurs in acid urines, and gene-

rally, but not invariably, in those of high density. It may, for instance, occur in the limpid urine of low specific gravity, which is passed in chronic Bright's disease. The deposit is almost always coloured red or brown, whence its common name of "urinary sand." It is even to the naked eye crystalline, and while it falls for the greater part to the bottom of the glass, some of the crystals arrange themselves in lines on the sides of the glass, others form a slight scum on the surface. Under the microscope the crystals are seen to assume the most varied forms, of which perhaps the most common are flat, elliptical plates. Cubes, prisms and rhomboids are also met with, and these may collect into groups so as to assume most fantastic forms. Even under the microscope the uric-acid crystals usually retain a little of the colour, which is evident in the microscopic deposit.

The uric acid deposit is soluble in alkalis, insoluble in acids, but is decomposed with effervescence by strong nitric acid. The *Murexide Test* is most delicate, and at once decides the nature of the deposit, if this is in doubt. A little of the deposit should be placed in a porcelain evaporating dish, and on it poured a drop or two of strong nitric acid. Gentle heat is now to be applied, preferably by means of a water bath, until the nitric acid is evaporated and an orange-yellow deposit remains. To this is now to be added a drop of liquor ammoniæ, when, if uric acid be present, a beautiful purple colour will be immediately developed. The quantitative estimation of uric acid will be discussed later in this article.

The deposit of uric acid from the urine relates rather to the reaction of the urine than to the absolute quantity of uric acid contained therein. A perfectly healthy urine will deposit uric-acid crystals if allowed to stand sufficiently long (*see* RENAL CALCULUS). Yet when the urine habitually deposits uric acid within a short time of its emission this is distinctly a pathological phenomenon.

Oxalate of Lime forms a white deposit, which falls to the bottom of the glass, and is limited above by a wavy, film-like layer. On the sides of the glass, too, it forms lines of crystals, in the same manner as does uric acid, but without the colour of the latter. Under the microscope the deposit is seen to be constituted by crystals, which have the forms of small octahedra, dumb-bells, or

ovoids. The deposit does not disappear when the urine is heated, and is insoluble in acetic acid, alcohol and ether, but soluble in the mineral acids. The conditions of its formation will be found in the article upon OXALURIA, to which the reader is referred.

Cystine.—This is one of the rare urinary deposits. The urine depositing it is generally turbid when first passed, showing the great tendency of such an urine to form calculi within the urinary passages. It is usually faintly acid, and is said to have sometimes a yellow colour and an oily appearance. The deposit, which settles on standing, is light grey in colour, and under the microscope its nature is readily recognised by the shape of the crystals composing it, hexagonal plates. Further, it can be recognised easily by its chemical reactions. It is soluble in ammonia, in solutions of carbonate of potassium or sodium, and in the mineral acids, but it is insoluble in a solution of carbonate of ammonium and in vegetable acids, water and alcohol. It is not dissolved by heat. From its solution in ammonia it crystallizes in the form of hexagonal plates and square prisms. When the deposit is heated to incandescence it gives off thick white fumes having an odour of garlic. The urine containing it decomposes very easily, and Dr. Golding Bird found that in doing so it changed colour from yellow to green.

The occurrence of cystine as a deposit in the urine is specially interesting, by reason of its liability to form urinary calculi. The tendency to excrete cystine may last for years without any deterioration of the general health, beyond that which the irritation of urinary calculi may cause. It is more common in the young and in males, and shows a decided tendency to run in families.

Cystine contains a large percentage of sulphur, and therefore it is assumed that the liver is the seat of its formation, but no more than this is known of its origin.

Xanthine has been found in very rare instances as a constituent of urinary calculi, and has been said to have constituted a urinary deposit. Its identity, however, was not perfectly proved. It is soluble when heated and dissolves without effervescence in strong nitric acid. When evaporated, a bright yellow deposit is left, which is changed to violet red on the addition of liquor potassæ (Stecker). Its crystals have the shape

of pointed ovals resembling those of uric acid.

Leucin and Tyrosin.—The urine of patients suffering from acute yellow atrophy of the liver contains both leucin and tyrosin. The latter is deposited in the form of bunches of acicular crystals. Leucin, however, usually remains in solution, but is occasionally thrown down in spherical crystals.

Phosphates.—Phosphates of lime, magnesia, and ammonia are very frequently deposited from the urine. As a rule, when these salts are precipitated the urine is alkaline, but two of them, the stellar and the triple phosphates, are occasionally thrown down from urines which are neutral or even faintly acid. Again, an urine which has deposited phosphates will usually give a further precipitate when heated, a reaction due, as Sir William Roberts has shown, to the fact that phosphate of lime is less soluble at high than at low temperatures.

Amorphous Phosphates have the chemical composition of $\text{Ca}_3(\text{PO}_4)_2$, and are invariably deposited when the urine becomes alkaline. They form a white, flocculent precipitate, which is not dissolved by heat, but disappears instantly when acetic acid is added to the urine. Under the microscope it consists of amorphous granules.

Stellar Phosphate has the composition $\text{CaHPO}_4 + 2\text{H}_2\text{O}$ and is of somewhat rarer occurrence. It forms a white deposit, composed of rod-like crystals, arranged in rosettes or stars, whence its name. Other forms, resembling Indian clubs, are also met with. From the observations of Sir William Roberts we know that the occurrence of this body as a deposit is usually a sign of some grave disease. Albeit, the same deposit may occur in the urine of a healthy person, if it be rich in lime and of low acidity.

Triple Phosphate has the composition $\text{MgNH}_4\text{PO}_4 + 6\text{H}_2\text{O}$, and usually occurs together with the amorphous phosphate in urine which has undergone ammoniacal decomposition. Under the microscope, the deposit is seen to be composed of large crystals, whose predominant form is a triangular prism with bevelled ends, and they are further characterized by their high refracting power.

Magnesium Phosphate, having the composition $\text{Mg}_3(\text{PO}_4)_2$, has been found in a strongly alkaline urine in the form of highly refractile rhomboid plates.

Carbonate of Lime.—This substance does not often form an urinary deposit in

man, but does occasionally compose a urinary calculus. It has been found as a rare deposit in sphere-like crystals.

Sulphate of Lime is sometimes found as a deposit, either as crystals which assume the form of long needles, plates, or prisms, or as dumb-bells.

Hippuric Acid is a rare urinary deposit, but may be found when a patient is taking benzoic acid or salicylic acid internally. It forms rhombic prisms resembling one of the varieties of uric acid crystals, but distinguished from these by not giving the murexide reaction.

Fat occurs in the urine of chronic Bright's disease and in chylous urine, as small, highly refracting globules.

Fatty Acids.—Von Jaksch has described a deposit which he believed to be composed of the lime and magnesia salts of the fatty acids. It consisted of crystals resembling those of tyrosin, but not giving the chemical re-actions of that body.

Cholesterine.—Plates of this substance are sometimes, but rarely, met with as an urinary deposit.

Indigo, as already mentioned, may form in decomposing urines. It may then occur as a deposit, as blue crystals, or amorphous masses.

Organic Deposits.—(1) *Tube-Casts* (see CASTS, URINARY).

(2) *Epithelium*.—In cases of nephritis the epithelial lining of the renal tube is liable to become separated from its attachments, and the individual cells find their way into the urine. They present themselves as a round nucleus, enclosed by a variable amount of granular protoplasm. The whole is irregular in form, but is more or less rounded. The nucleus may sometimes be divided, and the protoplasm also may show degenerative changes, amounting sometimes to atrophy of the cell.

Other epithelial cells which may find their way into the urine, are (a) those of the pelvis of the kidney, also of the ureter and bladder; these are irregular in form, many of them "tailed," and the dovetailing of the irregular epithelium characteristic of the mucous membrane of these parts is frequently obvious when patches of cells are discharged. The presence of such cells indicates inflammation of the mucous membrane. (b) Urethral cells; these are rounded flat epithelial plates, frequently found adhering in the form of a layer. (c) Vaginal epithelium—large flat scales. (d) Cells from the mucous membrane of the mouth;

these also are large flat scales, which are found in urine when the saliva has been mixed with it.

(3) *Pus*.—Urine containing pus is usually cloudy when passed from the bladder, and, on standing, deposits a greyish layer at the bottom of the glass. The supernatant urine invariably contains albumen. When the deposit is examined under the microscope it is seen to consist of leucocytes, and when treated with liquor potassæ it becomes thick and ropy. This condition of the pus is assumed spontaneously if the urine has undergone the ammoniacal decomposition. The leucocytes appear as small, round, granular bodies, which, when treated with dilute acetic acid, become clear and show a horseshoe-shaped or divided nucleus (see also PYURIA).

(4) *Blood Corpuscles*.—These appear in the urine, either in their usual form as bi-concave discs, or, more frequently, shrivelled, crenated, or swollen, from the action upon them of the water and salts of the urine. The chemical reactions of blood have already been described above.

(5) *Hæmoglobin*.—In cases of hæmoglobinuria dark brown granular masses of hæmoglobin are found as an urinary deposit.

(6) *Spermatozoa*.—These form a deposit in the urine resembling mucus, but its nature is at once evident on microscopic examination, when the characteristic filaments are seen.

(7) *Mucus*.—Mucus forms a white glairy sediment in the urine, which may be mistaken for pus. Under the microscope, however, it shows merely amorphous granules, threads, or flakes, and is soluble in liquor potassæ.

(8) *Fungi*.—Many forms of the lower vegetables may be found in the urine. Amongst these may be mentioned varieties of torulæ, which grow in acid urine and will be recognized by their spores and thallus, sarcinæ, distinguished by their characteristic dice-like shape, and bacteria of different kinds. In by far the majority of cases these plants are extraneous additions to the urine after it has been voided, and are associated with its decomposition. This is not always the case. A few instances have been recorded in which organisms, either micrococci or bacilli, were present in the urine as soon as it was passed, and the condition has been named idiopathic bacteruria. Pathogenic germs, too, may be found in the urine. Of these, the more important are tubercle and typhoid bacilli and the micrococci of

erysipelas and pyæmia. Most of these germs can easily be detected by staining them with methylene blue and examining with an oil immersion lens and an Abbé's condenser. For the tubercle bacillus a special method is required. A little of the pus or cheesy matter, which is always present in such cases as give rise to a suspicion of the presence of tubercle in the urinary tract, is to be spread upon a cover-slip and allowed to dry in the air. It is advisable, when examining for tubercle bacilli in the urine, to take a somewhat thick layer of pus, not a thin layer, as is the custom in examining sputum. After drying, the cover-slip is drawn through a flame three times in order to fix the albumen. Then the slip is to be floated on a small quantity of Ziehl's fuchsin solution, consisting of 100 parts of water, 5 parts of carbolic acid, 10 parts of alcohol, and 1 part of fuchsin. The solution is to be gently warmed and the cover-glass allowed to remain floating on it for a quarter of an hour. Then it is washed in a 25 per cent. solution of nitric acid for a few moments until most of the colour seems to have disappeared. It is further washed in water, and stained again by being floated for five minutes on the surface of a saturated watery solution of methylene blue. Again it is washed in water, dried and mounted in Canada balsam, when the tubercle bacilli will be seen as red rods on a blue ground.

(9) *Animal Parasites*.—The embryos of the filaria sanguinis, hydatid hooklets and cysts, the eggs of bilharzia hæmatobia, rhabditis genitalis, and ascarides are occasionally found in the urine.

(10) *Portions of Neoplasms*.—Tumours which ulcerate into the urinary passages will discharge portions of their tissue into the urine. Nevertheless, tumours of the kidney cannot be diagnosed by examination of the urine. The separated cells of a tumour cannot be distinguished from those of the urinary passages. Where, however, not merely separated cells, but actual portions of a tumour, are discharged into the urine, as happens, for instance, in the case of villous tumours of the bladder, important aid to diagnosis is afforded by their recognition.

(11) *Foreign Bodies*.—Lastly, an observer must be prepared for the presence in the urine of various foreign matters, such as hair, the fibres of flax, cotton and silk, wool, feathers, portions of vegetable matter, and muscle fibre.

DISSOLVED MATTERS.—Space will not

allow of more than a sketch being given here of the methods employed in detecting and estimating the various substances which may be in solution in the urine. For fuller details, works on urinary analysis must be consulted.

(1) **Albumen** (*see* ALBUMINURIA).

(2) **Sugar** (*see* GLYCOSURIA).

(3) **Urea**.—The amount of urea daily excreted in the urine is a measure of the nitrogenous waste of the economy, and is therefore of considerable clinical interest. The average amount excreted by a healthy man in twenty-four hours is about 500 grains or 32 grammes. It is diminished during exercise, increased in the period of rest which follows exercise. It is increased also by nitrogenous food. Generally speaking, it is increased during pyrexia, diminished during convalescence from pyrexia. In organic diseases of the kidneys it is markedly diminished, while in both diabetes mellitus and diabetes insipidus, the daily excretion is increased in amount.

Quantitative Estimation of Urea.—It is important in estimating the amount of urea in a specimen of urine to perform the analysis before any decomposition has set in, since the urea is readily decomposed, as already stated, into carbonate of ammonia.

The Hypobromite Method.—This is the most ready means of estimating urea for clinical needs. Several kinds of apparatus for this purpose are in use, of which the writer has found Dupré's to be the most convenient. The principle of the method is that urea is decomposed by hypobromite of soda, and its nitrogen is discharged as free gas, which can then be measured in a graduated tube. Dupré's apparatus consists of a small flask closed with a caoutchouc stopper, in which the hypobromite solution is placed, and from this an india-rubber tube leads to a long graduated tube, the mouth of which is under water in a large wide jar. Since solution of sodium hypobromite is quickly decomposed on standing, it is well to make it fresh for each estimation, by adding 5 c.c. of bromine to 45 c.c. of a 40 per cent. solution of caustic soda. Of this solution 25 c.c. are placed in the small flask, and 5 c.c. of urine are poured into a narrow tube, which is then placed in the flask in such a manner that none of the urine is mixed with the hypobromite solution until the flask is inclined. The stopper being now replaced, the graduated tube is lowered until the water in it reaches the zero mark, and by means

of the opening at the top of the graduated tube the pressure inside and outside of it are equalized. The small flask is now tilted, and the urine allowed to gradually mix with the hypobromite solution, the mixture being finally shaken to ensure due discharge of the nitrogen. After waiting ten minutes, the amount of nitrogen collected in the graduated tube is read off, care being taken that the water inside and outside the tube are at the same level. The graduated tube may be marked merely in divisions of cubic centimetres, when the quantity of urea in the five cubic centimetres of urine taken can be calculated from the fact that 37.3 c.c. of nitrogen correspond to 0.1 gramme of urea; or the tube may be graduated in percentages of urea. Uric acid, creatin and other nitrogenous bodies of the urine, also give off nitrogen by this manipulation, while urea only gives off 92 per cent. of its nitrogen. Thus about 4.5 per cent. must be subtracted from the total amount of nitrogen produced, to obtain the exact amount discharged by the urea of the urine.

Liebig's Method.—This is also in use, and depends upon the fact that urea is precipitated by a solution of mercurous nitrate. The phosphates and sulphates of the urine are first removed by baryta solution. Then a solution of the mercurous nitrate is added until all the urea is precipitated, which is known by the urine at this point giving a yellow colour with a solution of carbonate of soda. But a certain amount of the mercurous nitrate solution has to be added before precipitation of the urea commences. This amount must be noted and subtracted from the total quantity of solution used, since it is the amount necessary to change the chlorides of the urine into bichloride of mercury, and until this is done no urea will be thrown down. From the quantity of mercurous nitrate solution used, the amount of urea in the quantity of urine taken can be calculated. It is convenient that the mercurous nitrate solution should be of such a strength that 1 cubic centimetre corresponds to 10 milligrammes of urea. For greater accuracy it is desirable to first estimate the chlorides present by a solution of nitrate of silver. Further details cannot be given here.

(4) **Uric Acid.**—The murexide test for the detection of uric acid has already been given. For an estimation of its quantity either gravimetric or volumetric methods may be made use of. Employing the gravimetric method 5 c.c. of hydro-

chloric acid are added to 100 c.c. of filtered urine, and the mixture allowed to stand for twenty-four hours, when the uric acid will have separated out and can be weighed. Of the volumetric methods that of Haycraft is most employed. It is based on the fact that nitrate of silver forms a urate of silver, when brought into contact with uric acid, and the silver contained in the latter salt can be estimated by titration. Details of the method will be found in the *British Medical Journal*, December 1885.

(5) **Sulphates.**—These occur in the urine as simple sulphates and as salts of the ether-sulphuric acids. The simple sulphates are precipitated by the addition of a solution of barium chloride to the urine slightly acidified with acetic acid, the compound sulphate, not until the urine has been boiled with hydrochloric acid. The method for estimating these two forms of sulphates will be found in Von Jaksch's "Clinical Diagnosis," Dr. Cagney's translation, p. 245.

(6) **Phosphates.**—Phosphates are estimated in the urine by the uranium process. The solutions required are: (1) Uranium acetate solution having such a strength that 1 c.c. corresponds to 5 milligrammes of phosphoric acid. (2) A saturated solution of ferrocyanide of potassium. (3) A solution of sodium acetate containing 100 grammes in the litre together with 100 c.c. of acetic acid. The strength of the uranium solution is determined by a standard solution of sodium phosphate.

Fifty c.c. of the urine are mixed with 5 c.c. of the acetate solution and heated to near the boiling point. The uranium solution is then run in until the mixture gives a brown colour with a drop or two of the ferrocyanide solution, when the wished-for point of the total precipitation of the phosphates is reached. The quantity of uranium solution then gives the amount of phosphoric acid in the quantity of urine employed.

(7) **Chlorides.**—The chlorides of the urine are precipitated by nitrate of silver in the presence of nitric acid. This can be used as a rough test of their presence or absence by adding only a drop of a nitrate-of-silver solution. The chlorides are estimated by means of a solution of nitrate of silver of such a strength that 1 c.c. corresponds to 10 mgr. of sodium chloride. For details of the process, Sutton's "Volumetric Analysis" may be consulted.

(8) **Acetone.**—Acetone has been found in the urine in a great variety of condi-

tions, of which the most important is diabetes. It has also been found in the urine of patients suffering from fever, inanition, and cerebral disorders. Further, a certain amount of acetone can be detected in healthy urine. For its detection the urine should be distilled, and one of two tests applied to the distillate. These are:

(1) *Lieber's Test*.—A few drops of a mixture containing caustic potash, iodine and iodide of potassium are added to a small quantity of the distillate, when, if acetone be present, a precipitate of crystalline iodoform is produced. (2) *Legal's Test*.—To the distillate are added a few drops of a concentrated solution of sodium nitroprusside and also a little solution of caustic potash. A red colour is produced which rapidly disappears, and if acetone be present, gives place, on the addition of acetic acid, to a purple colour.

(9) *Diacetic Acid*.—The urine of diabetics often gives, with a solution of perchloride of iron, a burgundy-red colour, which was believed to indicate the presence of diacetic acid. Certain precautions, however, must be taken before this test can be accepted. In the first place, the presence of acetone must be ascertained as above, since its reactions always occur when diacetic acid is found. Then a strong solution of perchloride of iron is added to the urine; any phosphates which are precipitated are filtered off and more iron solution is added. When the red colour appears, a portion of the mixture is boiled, and, if due to diacetic acid, the colour should still remain. To another portion of urine is to be added sulphuric acid and ether. The ethereal extract should give the perchloride reaction after standing twenty-four to forty-eight hours (Von Jaksch).

For Ehrlich's diazo reaction, see TYPHOID FEVER, p. 871.

ROBERT MAGUIRE.

URINE, RETENTION OF, IN THE FEMALE.—Retention of urine may arise from the following conditions:—

(1) Retroversion of the gravid uterus, which is mentioned first as being the most common cause of retention sufficiently prolonged to lead to serious ill consequences (see PREGNANCY, DISEASES OF).

(2) Retroversion of an uterus enlarged by a fibroid. This is much rarer, but may produce the same results as retroversion of a pregnant uterus.

(3) Impaction of a tumour, either uterine or ovarian, in the pelvis, causing pressure upon the urethra.

(4) Pressure upon the urethra by a pelvic abscess, hæmatocele, or an extra-uterine gestation cyst. The urethra may either be directly compressed on, or the uterus may be pushed forwards against it. The latter is the more common condition.

(5) Hysterical retention of urine. This is the commonest kind of retention in young unmarried girls of a neurotic type.

(6) Atony of the bladder from overdistension.

(7) Stricture of the urethra—rare in women.

(8) Congestion or abscess of the urethro-vaginal septum.

(9) Urethral caruncle: retention being *quasi* voluntary, due to the patient's shrinking from the pain of micturition.

(10) So-called "lupus" of the vulva: the fibrous overgrowths blocking the urethra.

(11) Cancer involving the urethro-vaginal septum.

(12) In the first few days after delivery retention is common, partly from swelling of the urethra from contusion during labour, partly from the laxity of the abdominal parietes, which renders the patient unable, in the recumbent position, to make the necessary expulsive effort.

(13) Spasmodic stricture of the urethra, from drink, exposure, sexual excess, &c., has been described, but is very rare.

(14) Reflex influences, as from hæmorrhoids, or fissure of the anus. Other causes, which occur equally in both sexes, do not need enumeration here.

The obvious *treatment* is to draw off the urine with a catheter. In hysterical retention this should be postponed as long as possible, and should be done by a nurse.

G. E. HERMAN.

URINE, SUPPRESSION OF.—

By suppression of urine is understood that condition in which no urine reaches the bladder, as opposed to retention of urine where the bladder is full but no urine passes from the urethra. Suppression of urine may arise from total abolition of the secreting power of the kidneys, due directly to some disorder of the organs themselves, or on the other hand, from some obstruction in the pelvis or ureter of both kidneys, which, while at first causing retention of urine in the pelvis and calyces, afterwards produces abolition of secretion. The first of these conditions is known as non-obstructive, the second as obstructive, suppression of urine. The symptoms

of the two conditions are different and will require separate description.

I. Non-obstructive Suppression.—This is prone to arise in the course of the specific fevers and especially in the algid stage of Asiatic cholera. Organic disease of the kidneys of any kind may be the cause of little or no urine being secreted, and this is specially seen in cases of acute nephritis, and in the later stages of chronic Bright's disease. It must be remembered too that a dose of opium may cause almost absolute suppression of urine if the kidneys are in a damaged state. Mere exposure to cold and shock of all kinds, but especially that following major operations, act similarly. Operations on the urethra are specially liable, if the kidneys are diseased, to produce suppression of urine, preceded by rigors and pyrexia. Hysterical patients occasionally suffer not merely from retention, but also from true suppression of urine, which may last for days and yet ultimately be followed by recovery.

The *symptoms* of non-obstructive suppression are those of ordinary uræmia (see URÆMIA). Vomiting, dyspnoea, delirium, and convulsions usher in the attack, and the patient usually dies comatose, if the condition be unrelieved. Those cases due to hysteria are, however, characterized by almost entire absence of these distressing symptoms. Such patients suffer from vomiting, and the vomit may contain a certain amount of urea, but for days, until the renal secretion is again established, the patient may remain in an apparently comfortable condition.

The actual *pathology* of non-obstructive suppression is still obscure. The kidney itself has in such cases been found congested. Probably the suppression is brought about through the agency of the nervous system, and in those cases which arise from catheterization presumably the irritation of the urethra exerts a reflex effect upon the sympathetic nerves of the kidney, and thereby abolishes secretion.

Treatment.—The treatment adopted for other forms of uræmia should be made use of here. Hot baths, and especially the blanket bath, are most efficacious. The patient should be encouraged to drink copiously of barley water and other diluents. Perspiration may be induced by subcutaneous injection of pilocarpin, when internal medication is prohibited by the vomiting.

II. Obstructive Suppression.—The most common cause of obstructive sup-

pression is blocking of the ureter, generally at its entrance into the bladder, by a small calculus formed in the pelvis of the kidney, the opposite kidney having been destroyed at some previous time by this or some other cause, or being congenitally absent. Again, both ureters may be involved in the growth of carcinoma or tubercle of the bladder. Congenital malformations, of the renal arteries or of the ureters are among the rarer causes of obstructive suppression.

Symptoms.—In most cases the exciting cause of the suppression acts suddenly. After an attack of renal colic, the painful symptoms gradually subside, but no stone is passed, and the excretion of urine is abolished. Yet other symptoms do not appear rapidly. The patient feels fairly comfortable even for a few days, and it is difficult to persuade either him or his friends of the serious nature of his condition. Yet he is not free from symptoms which are suggestive to the observer. Great weakness and twitching of the muscles gradually develop. The patient becomes restless, and although he is at times drowsy yet he gets little or no real sleep. The urine may be entirely suppressed, but more frequently small quantities are passed at irregular intervals. Such urine is limpid and of low specific gravity, containing sometimes a little albumen. The respirations are panting. The pupils, normal at first, become contracted. Very rarely is there any gastric disturbance or diarrhoea; still more rarely, dropsy of any part of the body. There is no odour of ammonia perceptible in the breath. The drowsiness increases, and with it the muscular weakness, yet the mind is normally active when the patient is roused, until near the end of the case, when low muttering delirium, coma, and rarely convulsions, may precede death. The longest period known during which life was prolonged without any urine being passed is twenty days, but usually eight or nine days is the limit.

When the obstruction is due to renal calculus a *diagnosis* of its situation can generally be made from the localization of the renal colic which preceded the suppression. Usually, too, the history will indicate a former attack of renal colic on the opposite side, after which no stone was passed.

The *prognosis* is most unfavourable, unless the obstruction in the ureter can be overcome.

Treatment.—Medicinal measures are

of no use whatever. All treatment must be directed to a removal of the obstruction. Sir William Roberts has recommended kneading of the abdomen, in the direction of the obstructed ureter, changes of posture and succussion of the patient with a view to displacing the stone. It might be advisable, seeing that the stone is often impacted near the bladder, to attempt its dislodgment by catheterizing the ureter. Should all these measures fail, the ureter must be opened from the loin, above the obstruction, and a permanent ureteral fistula established.

ROBERT MAGUIRE.

URTICARIA (Nettlerash ; Hives ; Cnidosis).—An acute or chronic affection of the skin, and sometimes of mucous membranes, characterized by the development of wheals of ephemeral existence, accompanied by severe pruritus.

Symptoms.—Wheals (*pomphi*), which are pathognomonic of the disease, vary greatly in their characters; they may be as small as a pea, but usually are about the size of a finger-nail. They form with great rapidity, and seldom last more than a few hours, but they may appear in successive crops extending without interval over months or years. In their most typical form wheals are distinctly raised above the general surface, flat on the top, pale in the centre, bright pink at the periphery, and slightly harder than the surrounding skin. In shape they are usually circular, but sometimes oval, irregular or in streaks; they exhibit no grouping. In tissues which are lax (*e.g.*, eyelids, scrotum) and on mucous membranes the pale centre is not present, and vivid patches of erythematous redness are formed by the coalescence of large numbers of them. If the amount of serous effusion into the centre of the wheals be excessive vesicles result, but probably most cases of so-called *U. vesicans* are in reality examples of hydroa. Occasionally, too, the rupture of the extremely congested capillaries results in hæmorrhage, constituting *U. hæmorrhagica* or *Purpura urticans*. In children there is a special tendency for the migration of leucocytes in addition to the transudation of serum, and on the subsidence of the wheals inflammatory papules are left behind. Various clinical types meriting separate description are recognized, but these merge one into the other.

Acute Urticaria is often febrile; it is preceded by rigors and malaise, and the temperature may rise to 103° or

104° F. before the appearance of the rash. It frequently results from irritating ingesta (*vide* *Ætiology*), and may be accompanied by severe gastric catarrh and vomiting. The rash is usually very copious, and distributed with rough symmetry more or less over the whole body surface; the lesions are not grouped, and on the face they coalesce to form a sheet of vivid redness comparable to an erysipelas, while on the chest they may be mistaken for the rash of scarlatina. Œdema of the eyelids occurs, and the buccal, faucial, pharyngeal or even the laryngeal mucous membranes are often involved, causing dysphagia and threatening suffocation. In one case of frequently recurring attacks reported by the writer, the gastric mucosa appeared to be involved, as large quantities of blood were vomited with each recurrence. Temporary albuminuria has also been noted. The sensation of itching, burning or tingling is always intense and constitutes an important diagnostic feature. Fortunately, the duration of such cases is generally short, extending only over a few days, but occasionally they may be succeeded by a more or less **Chronic Urticaria**, which may last for months or years and prove a source of great annoyance, especially by causing sleeplessness, as the crops have a tendency to develop when the patient gets warm in bed. In other cases exposure to cold, even to the most trifling draughts, determines an attack. The outbreaks are not attended with appreciable fever, and the lesions present the ephemeral characters already described.

Papular Urticaria (*U. Papulosa*; *Lichen Urticatus*) is a variety which occurs only in children, and represents the link which connects urticaria with prurigo (*q.v.*). After the subsidence of the wheals persistent, hard, small, acuminate, inflammatory papules remain, the tops of which are crowned with blood-crusts as the result of scratching. These lesions are most common and persistent about the outer sides of the legs and thighs, on the buttocks and, generally speaking, on extensor surfaces. They not infrequently become vesicular, pustular or, on the palms and soles, even bullous, probably as the result of inoculation of pyogenic micrococci. From time to time acute crops of typical urticarial wheals occur, but these become gradually less and less frequent. The disease almost always occurs in the neglected children of the lower classes, and is often in the first instance the result of pediculosis or flea-

bites. It is very apt to be mistaken for scabies, but a careful study of its distribution, and the absence of burrows generally, render its differential diagnosis easy.

Urticaria Pigmentosa is a much rarer form, the relationships of which are not so manifest. It has been chiefly described by English dermatologists. The affection always begins in early infancy, and its course is very protracted, although it tends to spontaneous recovery at or about puberty. The lesions are permanent and pigmented; they are commonest on the trunk and neck, and consist of large, wheal-like tubercles, at first reddish in colour, but soon becoming dull yellow or buff. They are surrounded by a pink areola at first, and develop very rapidly. Small successive crops appear every few days, and ordinary urticarial wheals or factitious urticaria may be present. Occasionally they vesicate or become ecthymatous, probably as the result of scratching. The deeply pigmented tubercles persist unchanged for years. Although most cases are accompanied by severe itching, a few are not so, and in them no secondary lesions develop. Their diagnosis from xanthoma may be a matter of difficulty.

Giant Urticaria.—This term has been somewhat inaptly applied to a group of cases characterized by the sudden appearance of large, soft, œdematous swellings of the skin and subcutaneous tissue, which may measure several inches in diameter. They are specially prone to develop on the face about the eyelids, occluding the eyes. They may also attack the trunk and the limbs, especially in the neighbourhood of joints. The skin over them is usually of normal colour; there is no itching, and only some sense of tension is generally complained of. When the mucous membrane of the mouth, throat or larynx is involved—as not infrequently happens—the symptoms are alarming, but they generally subside with rapidity in the course of a few hours or days. The usual exciting causes are exposure to cold and disorders of digestion, but a considerable number of cases are associated with chronic rheumatoid arthritis. The disease may in exceptional cases extend over months or years, relapses occurring with regular frequency.

Ætiology.—The ill-balanced state of the peripheral circulation which predisposes to urticaria is commoner in children than in adults, in women than in men. Many cases result from external irritants applied to the skin; among

such may be included those due to rough flannel clothing, coarse aniline dyes, the stings of nettles, the “bites” of all sorts of pediculi, fleas, bugs, gnats, &c., the personal factor entering largely into the production, and determination of the severity, of the resulting lesions. Scratching or rubbing of the originally affected parts, acting as a further irritant, produces extension of the mischief, the secondary lesions thus caused generally greatly predominating over the primary. In the same way and for the same reason urticaria usually complicates all forms of itchy eruption, notably eczema, scabies, acute lichen ruber, prurigo and pruritus. In susceptible individuals, who are generally said to have “an irritable skin,” exposure to cold is a common excitant, and in them wheals may result from poultices, the application of electricity, the pressure of articles of dress, or from passing the finger-nail or any blunt instrument firmly along the skin surface (*U. factitia*). In this manner elaborate patterns may sometimes be traced on the skin, especially of the back.

The more important cases are, however, generally symptomatic of other conditions, especially of disorders of the gastro-intestinal tract and of the presence of toxic matters in the circulation. Thus many kinds of food are notoriously prone to cause urticaria, chief among which may be mentioned crustaceans and molluscs; occasionally fish of any sort, whether fresh, dried, smoked or potted, produces the same disagreeable result. Pork (especially in sausage form), pickled meats, cheese (especially toasted), eggs, pastry, porridge, cucumbers, nuts, mushrooms and pickles are often noxious, and, among fresh fruits, strawberries, grapes, gooseberries and raspberries are perhaps those which most frequently disagree. The number of articles of diet which may provoke nettlerash, however, is very large, and individual idiosyncrasies manifest themselves in the most remarkable manner. It is a point worthy of note that in many instances the eruption appears to be the result, not of a toxic substance in the blood, but of a true reflex action from the stomach, as it immediately ensues upon the ingestion of the peccant and almost as quickly disappears when the stomach is emptied by an emetic. Sometimes, too, the direct application of the excitant to the skin produces the same immediate effect as its ingestion.

Other conditions to which nettlerash is apparently sometimes reflex are—

dentition, the presence of intestinal worms (especially in children), the puncture or rupture of hydatid cysts and the passage of gall-stones; it may also result from pregnancy, parturition, operative procedures on the generative organs, menstrual disorders (especially at the menopause) and violent mental or moral emotions. The gouty diathesis and acid dyspepsia underlie many persistent cases, and attacks of urticaria may alternate with those of asthma, neuralgia, megrim or ague, and may occur with the periodic regularity and definite course of the latter disease.

Urticaria is also of comparatively frequent occurrence in connection with chronic Bright's disease, jaundice, lithiasis, diabetes, rheumatism and enteric fever, probably from irritant matters in the blood, and in the same category must be placed those cases which result from the administration of certain drugs—*e.g.*, copaiva, cubebs, opium or its alkaloids, quinine, chloral, turpentine, santalin, salicylic acid and the salicylates. The fact must be accentuated that neither in the case of *U. ab ingestis* nor in *U. medicamentosa* is the severity of the affection present proportional to the amount of unsuitable food or of the drug taken, but to the personal susceptibility of the patient. The most severe case the writer has seen occurred in a lad suffering from influenza, and in which no other plausible explanation could be found other than that it formed an integral part of that disease. It remains only to be said that in many cases, especially of the more chronic forms, no ætiological factor can be discovered, and the continuance of the affection is attributed to the establishment of "the urticarial habit."

The treatment of every case of urticaria must be directed mainly against its cause, if that be ascertainable. It is, however, impossible here to enter into the management of the very extensive list of morbid conditions which may underlie the disease. In an urticaria *ab ingestis* an emetic of ipecacuan or sulphate of zinc, or a subcutaneous injection of apomorphine, may be administered if the patient be seen soon after taking the noxious substance. This may be followed by a brisk purge of sulphate of magnesia. In more chronic cases the greatest care must be exercised in the selection of food, dyspeptic troubles must be treated on the ordinary lines, alkalies, bismuth and vegetable bitters being perhaps the most generally useful drugs. Regular and free action of the bowels must be

maintained. Alcohol, tea and coffee are often specially harmful. The most perfect hygienic surroundings must be obtained, and pediculi, fleas or other causes of external irritation must, of course, be removed. The skin must be kept scrupulously clean, and soft silk or fine linen worn rather than flannel underclothing, which is often rendered extremely irritating by its impregnation with aniline dyes. In many cases a warm bath every night is decidedly beneficial, and sulphide of potassium (3ij) or bicarbonate of soda (3vj) may advantageously be added to an average bath of 30 gallons.

Lotions containing liquor carbonis detergens (3j–5j ad 3vj), carbolic acid (3j ad 3vj), naphthol (gr. x–xx ad 3j) or bicarbonate of soda (gr. xx or more ad 3j) are generally useful, but Crocker points out, with reason, that any "disinfectant" is useful as an antipruritic. In many cases, the ætiology of which is quite obscure, certain drugs appear to act as specifics. Thus, arsenic is often curative, but care must be taken that the digestive functions are in good order. The same precaution is, oddly enough, not necessary for the applicability of ichthyol, which the writer is inclined to consider as of great value, especially in the nettlerash of women at the menopause. Owing to its nauseous taste it must be given in capsules or in sandarach-coated pills, the dose being gradually raised from 10 to 30 grains daily. Belladonna or atropine, pilocarpin, sulphate of quinine, bromide of potassium and colchicum are all sometimes useful and merit careful trial in obstinate cases.

J. J. PRINGLE.

UTERUS, CANCER OF.—Cancer may affect either the cervix or the body of the uterus. It is much more common in the cervix.

SYMPTOMS.—The main symptoms of cancer of the uterus are hæmorrhage, pain and wasting. Of these, hæmorrhage is the earliest and most constant. It is not uncommon for hæmorrhage following coitus to be the first symptom noticed. After the hæmorrhage there comes leucorrhœal discharge in the intervals of hæmorrhage, which becomes very profuse as the disease advances. It may be watery or yellowish. Pain is usually later than hæmorrhage. Occasionally the disease runs its whole course without pain. Wasting to a degree which attracts the patient's attention does not occur till comparatively late in the dis-

ease. The symptoms of *Cancer of the Body of the Uterus* are much the same as those of cancer of the cervix. The pain is of a somewhat different character, being more paroxysmal, and due to uterine contractions. The discharge, when the cancer has begun to break down, contains fragments of dead and decomposing tissue, and smells offensively. There is nothing in this at all characteristic of cancer, for fœtor of discharge may be produced by many causes. As the disease progresses, the hæmorrhage may be so great as to directly kill the patient. This is rare. It may produce anæmia which leads to fatty degeneration of the heart, and this to sudden death. Venous thrombosis and pulmonary embolism resulting therefrom may carry off the patient. The cancer may involve the peritoneum, and set up fatal peritonitis. Secondary growths may set up fatal changes in the organs in which they grow. One of the most common ways in which uterine cancer leads to death is by occlusion of the ureters and consequent uræmia.

DIAGNOSIS.—No reliance can be placed upon the symptoms or the history for the purpose of diagnosis, which can only be made by physical examination. In the later stages of cancer of the cervix or vaginal portion the diagnosis is easy: it is based on the presence of new growth enlarging the cervix, invading all tissues, and therefore fixing the uterus, and breaking down in the central part, thus producing excavated ulceration. In the early stages diagnosis is very difficult, and it may be impossible to make it without removing a piece of the growth for microscopical examination. In judging of the characters of such a piece, only the opinion of a microscopist familiar with the examination of uterine structures is of value. The diagnosis of cancer rests upon the discovery of epithelial ingrowths into the uterine tissue. The presence of irregular enlargement of one part only of the cervix, marked off from the rest, or divided into lobes, by fissures which do not run centrifugally, as do lacerations; and of a sharply defined warty growth, ulcerating in the centre, are characteristic appearances; but cancer so advanced as to exhibit these features will often be beyond the reach of treatment. An early sign of importance is a peculiar feeling of the cervix, so that its examination suggests that the finger is passing over wet india-rubber. The behaviour of the cervix to a tent has been said to be diagnostic:

that a cancerous cervix will not dilate, while one not cancerous will. This is certainly not correct.

In cancer of the body of the uterus, on vaginal and bimanual examination, the cervix is found healthy, and the body of the uterus enlarged. The diagnosis can only be made early enough to admit of treatment either by scraping the body of uterus with the curette, and examining the piece removed microscopically, or by dilating the uterine cervix and examining the cavity with the finger. The diffuse growth will then be felt. In the circumscribed form of uterine cancer it will be necessary to remove the polypus and examine it with the microscope.

PATHOLOGY.—**Cancers of the Cervix** are divided into two classes: (1) *Cancer of the vaginal portion*, and (2) *Cancer of the cervix*. Cancer of the vaginal portion is cancer beginning on the surface which lies between the os uteri externum and the attachment of the vagina. The vaginal portion, defined as above, is covered with squamous epithelium. Cancer of the cervix is cancer beginning in the part which lies between the os uteri internum and the os uteri externum.

(1) *Cancer of the Vaginal Portion* begins in the epithelium. It may begin at one point, or at several points close together. The appearance of this form of cancer in the early stage presents different forms. It may be a papillary or villous growth. This kind grows down into the vagina, and forms the so-called "cauliflower excrescence," a soft spongy villous mass which collapses after removal. It may, on the other hand, present in the earliest stage nothing but an area of lividity, or it may be first visible as a finely granular patch, or as a red tuberculated surface. The essential and important peculiarity of this form of cancer is that it is superficial, and does not involve the substance of the uterus till a comparatively late period of the disease, and the parametric tissues not till later still. It extends superficially, and in so extending does not tend to spread up the cervical canal, but advances outwards and downwards towards the vagina.

(2) *Cancer of the Cervix* begins in the glands of that canal. These glands increase in number and in size, and their ramifications become more various in shape. Their epithelium proliferates, and with the multiplication of the cells their shape alters, so that the glands instead of being lined by a single layer of columnar epithelium, become filled with cells of various shapes, often with

several nuclei. Thus they form tubes, strings, clusters, and nests of cells. The growth may commence either near the surface or in the deeper parts of the glands. It may begin either high up or low down in the cervix. The forms assumed by cancer in this part in its early stages are various. It may be polypoid, hanging from one of the lips of the cervix, or it may be a papillary growth on the surface, or it may begin as a nodule in the substance of the cervix. But whatever its characters in the early stages, its tendency is to quickly involve the whole thickness of the cervix and the cellular tissue around. It often also grows downwards, forming an excrescence projecting into the vagina, but it seldom extends upwards above the os internum until late. Briefly, cancer of the vaginal portion creeps along the surface towards the vagina; cancer of the cervix grows outwards and downwards in the substance of the cervix.

Cancer of the Body of the Uterus may be diffuse or circumscribed. The *diffuse form* is the more common. In it the whole or the greater part of the mucous membrane of the body of the uterus is covered either with villous growths or with wart-like protuberances. The irritation of the new growth causes hypertrophy of the muscular wall, from which cause, combined with the enlargement of the cavity caused by the new growth, the body of the uterus becomes considerably enlarged. In the *circumscribed form* the cancer projects like a polypus into the uterine cavity. In its growth it extends deeper and deeper into the uterine wall, at the same time that its projection into the cavity increases.

The disease begins in the glands of the endometrium. There are two forms, adenoma and true cancer. In the former, while the glands greatly proliferate, they remain lined by a single layer of columnar epithelium. In the latter, beside the increase in the size and number of the glands, the epithelial cells become heaped up, and of various sizes and shapes. As the interior of the body of the uterus is not accessible to simple inspection, we really know very little of the appearance in the early stages of cancer of the body. Cancer of the body of the uterus seldom extends to the cervix, but not uncommonly to the Fallopian tubes.

Cancer of the uterus in its further history presents the same characters as cancer elsewhere. It invades all tissues,

and as its edge advances its older parts break down and ulcerate. The lumbar glands enlarge and secondary growths appear in other organs. In the case of the uterus they appear later than in cancer affecting most other parts.

ÆTIOLOGY.—Cancer of the cervix is rare in the virgin and occurs chiefly in women who have had children. Statistics shew that the more labours a woman has passed through the greater is the liability to cancer. It has been attributed to the lacerations of the cervix which occur in almost all women who have had children, but the only scientific investigation which has been made into this question shows that it seldom, if ever, begins in the lacerated part. Therefore the supposed prevention of cancer is no valid reason for doing the operation of trachelorrhaphy. Cancer of the body of the uterus occurs with equal frequency in virgins, the married, and in those who have had children. Beyond these facts nothing more is known as to the ætiology of cancer of the uterus than of that of cancer elsewhere.

TREATMENT.—The classification of cancer given above is a practical and important one, because it corresponds to important differences in the amount of success which follows treatment.

Cancer of the Vaginal Portion can be diagnosed early, because the growth can be well seen, and a bit of it, if necessary, easily removed for examination; and, until it is far advanced, so that it has extensively invaded the vaginal wall, it can be removed. The treatment, so long as the disease is not too extensive, is to amputate the cervix. This part should be removed as high as possible, so as to get quite clear of the disease. The cervix should be pulled down to the vulval orifice by seizing it with a vulsellum. The practicability of so pulling it down is an important guide to the possibility of complete removal, not only because (1) the operation is easier when the cervix is well pulled down, but because (2) if on vaginal examination we do not perceive any very definite induration around the uterus, yet on attempting to pull down the uterus we find that the upper part of the vagina seems rigid, and is not easily inverted so as to let the uterus come down, that is an indication that the cellular tissue is involved. If the disease has spread to a small extent over the vagina, but has not affected the cellular tissue, the vagina will come down with the uterus, and the diseased mucous membrane, with a surrounding

zone of healthy mucous membrane at least one-third of an inch wide, should be dissected off and removed with the cervix. The results of this operation are very good, its danger is slight, and patients may go for years after it without relapse.

Cancer of the Cervix is less frequently amenable to treatment. As the part in which it begins is not always accessible to sight or touch, it is often not recognized until the time has passed within which successful treatment was possible: and, as its tendency is to grow outwards, towards and into the cellular tissue, it comparatively soon oversteps the limits within which its removal is possible. Still, if we are so fortunate as to meet with a case of cancer of the cervix before the growth has reached the cellular tissue, the proper course is to amputate the cervix. In removing the cervix for this variety of cancer, it is still more important than in cancer of the vaginal portion to cut well above the internal os uteri, so as to be sure that the whole cervix has been removed.

Cancer of the Body of the Uterus.—The only radical treatment is the removal of the whole uterus. The collective mortality following this operation has until recently been not far off one in four, but modern improvements in operating (especially the use of pressure forceps) have reduced the mortality, in the hands of skilful operators, to about that of ovariectomy. For a full description of this operation works on surgery must be consulted.

If a case of cancer of the uterus be not seen until too far advanced for removal, all that can be done is to relieve symptoms by palliative treatment. Pain can be eased by morphine, and this may be given in doses as liberal as are required. Patients usually soon become tolerant of the nausea produced by it. It is best given in the form of hypodermic injections, for thus the least ill effect is produced. Fœtor of discharges can only be overcome by great cleanliness, frequent douching, and an unlimited supply of clean napkins. When hæmorrhage is great, it can be for a time arrested by scraping the surface of the growth with Simon's sharp spoon, so as to remove the part of the growth which is breaking down and get to a part where the cancer is mingled with healthy tissue. In cancer of the body this step often gives marked relief to pain as well as to hæmorrhage.

G. E. HERMAN.

UTERUS, CORRODING ULCER OF.—This is a rare disease, consisting in an ulcer which spreads, destroying as it does so all the tissues in its way. In this it resembles cancer. But it differs from cancer in that there is no induration, or evidence of new growth, in its edges or base; that on microscopic examination of its base or edge no evidence of cancer is found, but only the appearances of simple ulceration; that its progress is slower, and its course longer than that of cancer, some patients living ten years or more, and finally dying of some other disease; that it is not attended with such emaciation as is usual in cancer, nor with such severe pain; and that hæmorrhage is less frequent. It seldom occurs before the climacteric. It has been suggested that it may be analogous to lupus or to senile gangrene, but recorded cases are too few to establish its pathology. No successful treatment has yet been carried out.

G. E. HERMAN.

UTERUS, DISPLACEMENTS OF.—The displacements of the uterus are described in the following order:—

1. Lateriversion.
2. Ante flexion.
3. Anteversion.
4. Retro flexion.
5. Retroversion.
6. Descent of the Pelvic Floor.
7. Prolapse of the Uterus.
8. Inversion.

The uterus in healthy women has not always the same position and shape. The organ is not always in the middle line, and, if it originally occupy a nearly central position, it may be dragged towards one side by adhesions.

Much importance has of late been attached by German writers to the effect of perimetritic and parametritic adhesions in producing uterine displacements. There is no doubt that by adhesions the uterus may be displaced in the most various ways. But such displacements are of little clinical importance: first, because in the great majority of such cases the symptoms produced by the pelvic inflammation are not appreciably modified by the displacement of the uterus; and secondly, because in the rare cases in which the displacement appears to interfere with the uterine functions, it is quite irremediable by any justifiable treatment.

1. *Lateriversion.*—This term has been applied to the deviation of the uterus from the central position, and mechanical

appliances have been recommended for its treatment. It is quite consistent with health, and therefore requires no treatment. If it did, there is no means, mechanical or other, by which the position can be altered.

2. **Anteflexion.**—In the majority of unmarried women and in a large proportion of parous women the uterus is not straight, but is bent forward so as to be concave in front. To this condition many evil consequences were formerly attributed, and instruments devised for its alteration. It is now known that it interferes in no way with health, comfort, or fertility, and that, even were it necessary, it is not possible to permanently straighten an anteflexed uterus by any appliance. Childbearing generally makes the uterus more nearly straight than it was before.

3. **Anteversión.**—The position of the uterus varies according to the degree of fullness of the bladder. When the bladder is full, the uterus lies in or behind the axis of the pelvic inlet; when empty, the uterus falls forward, so that often its whole length can be felt through the anterior vaginal wall. This is called anteversion, and, like anteflexion and lateriversion, has been considered a disease, and treated as such. It is a normal state of things, requires no treatment, and cannot be altered by treatment.

4. **Retroflexion.**—In some women the uterus is bent backwards, so as to be concave behind. The above term is applied to this condition.

5. **Retroversion.**—The organ is sometimes turned backwards without being bent, so that the uterine body can be felt through the vagina. This is called retroversion.

Cases of retroversion and retroflexion may be divided into four classes:

(1) *Without Symptoms.*—Retroflexion and retroversion (which are generally combined) may be present without interfering in any way with health or with the uterine functions; they therefore do not always require treatment.

(2) *With Symptoms due to other Conditions.*—It is obvious that the existence of displacement of the uterus backwards does not protect the patient from other diseases, and that therefore, if symptoms referred to the pelvic organs exist along with backward displacement of the uterus, it does not follow that the latter condition is the cause of the symptoms. The displacement must only be blamed when every other morbid condition can be excluded, and the

symptoms are such as the displacement is known to cause.

(3) *With Symptoms of Prolapse only.*—In the early stage of prolapse as the uterus sinks it often becomes displaced backwards. In that case, while the symptoms of prolapse are present, the backward displacement may be the most distinct alteration in the position of the uterus.

The *symptoms* are pain, referred to the lower abdomen, sacral region, and thighs, the pain being of a dragging, bearing-down character; constant, not paroxysmal; aggravated by exertion, relieved at once, and soon entirely removed, by recumbency. There is irritability of the bladder, constipation is usual, and the straining which accompanies defæcation is painful to the patient. To strong robust women such symptoms are trifles, but these displacements are more common in nervous weakly women, who also suffer from atonic dyspepsia, sleeplessness, neuralgic pains, nervous exhaustion and hysteria. The train of morbid phenomena forms a vicious circle. Weakness of the nervous system favours the occurrence of functional failure of various kinds, and also makes the nervous system more sensitive to the painful sensations which such failure produces; the presence of local discomfort in its turn reacts upon, and further weakens, the exhausted nervous system.

(4) *With Symptoms of Prolapse and Congestion.*—In some women, the disposition of the peritoneum in the pelvis is such that two firm bands run from the uterus back to the sacrum. With this arrangement of parts, if the body of the uterus gets displaced backwards, and pressed down between these bands, the veins which run from the body of the organ outwards in the broad ligament are compressed, the return of blood is impeded, and congestion of the body of the uterus is the result. In these cases the pain is more severe, and is not relieved by recumbency until that position has been maintained for some days; the uterus is very tender to the touch; menstruation is often very profuse and prolonged. Pain and hæmorrhage in this affection are, as a rule, in inverse proportion to each other, copious hæmorrhage relieving congestion and therefore pain. There is not only irritable bladder, but some smarting on micturition, and leucorrhœal discharge.

Backward displacement of the uterus is often, but not always, associated with erosion of the cervix, as vessels run

vertically downwards from the body into the cervix and are therefore liable to be compressed if the uterus be bent, and with prolapse of the ovaries.

Prognosis.—This depends very much on the amount of prolapse. If this be great, the patient may need either to wear a support, or put up with the inconvenience of prolapse, for an indefinite time. If the descent of the uterus be only slight, it may be that after the uterus has been kept supported at its proper level for one, two, or three years, the pessary may be left off without return of the symptoms. The correction of the flexion is not of importance for the relief of symptoms; the falling downwards and backwards of the uterus is the essential condition, not the bending.

The *treatment* of retroversion and retroflexion, when treatment is necessary, is to support the uterus with a pessary. For complete relief it is desirable that the uterus be raised into a position of anteversion. In effecting this the pessary converts the uterus itself into a lever, the body of the uterus being the weight, the fulcrum the anterior attachment of the uterus to the bladder, and the power the traction of the posterior vaginal wall (pushed up by the pessary) on the cervix. This is most perfectly effected by Hodge's pessary, or one of its modifications. This pessary is made of pewter, vulcanite, or celluloid; pewter is more readily moulded, but sometimes causes pruritus. There is a useful form made of spring wire, covered with india-rubber, the anterior ends being separated by india-rubber only, so that the ends can be approximated for ease of introduction. Hodge's pessary is sometimes difficult to adjust, and sometimes, especially in cases of acute flexion, will fail to raise the uterus into a position of anteversion. If it fail to do this, and the uterus be congested, the pressure of the pessary will aggravate the pain. In such a case the best pessary is a thick ring made of a watch-spring covered with india-rubber. If prolapse of the ovaries be present, this pessary is indicated, as even if it should not antevert the uterus, its thickness and softness prevents the pressure from causing pain. Whatever pessary be used, it should fill the vagina, but not make its walls tense. A good practical guide to the size will be found in this rule:—Choose a ring in diameter one inch less than the posterior vaginal wall, measured from the posterior *cul-de-sac* to the vulva.

All india-rubber pessaries are apt to

cause vaginitis, with offensive discharge. The patient should therefore be instructed, while wearing one, to syringe the vagina with warm water night and morning. If there be pruritus, some borax may be added to the water. The pessary should be removed, and the parts examined to detect any ill effects that may have been produced, such as ulceration, at least once in three months.

Before considering prolapse, a condition must be described which accompanies it, and is indeed the first step in the process, viz.:—

(6) *Descent of the Pelvic Floor.*—This condition accompanies all the most pronounced cases of prolapse. But it may occur by itself, without any appreciable change in the relative position of the uterus. There is always in health some change in the pelvic floor. It descends with inspiration and during effort, and ascends with expiration and when effort ceases. The amount of descent in most healthy women does not exceed half an inch. It is greater in women who have borne children. In women in whom the pelvic floor has been weakened by childbearing, and the muscular tone lowered by debility, the descent may be much greater, and may be attended by symptoms much the same as those of uterine prolapse. These are relieved by a perineal support. They vary with the tone of the patient's nervous system, being a source of distress when the nervous system is depressed, but hardly felt at other times.

7. *Prolapse of the Uterus.*—This term is applied to those cases in which the uterus is distinctly lower than it should be. It is customary to distinguish three degrees of prolapse: the first degree when the uterus has not descended below the vulvar orifice; the second when the cervix has protruded externally, but not the whole uterus; the third degree, or *procidentia*, when the whole organ is outside.

This condition usually begins with descent of the anterior segment of the pelvic floor—i.e., the anterior vaginal wall and bladder. As the anterior vaginal wall sinks downwards, it drags the cervix after it. When the cervix is thus dragged down, while the body is held by its peritoneal and other attachments in or near its normal position, the effect is to stretch the part of the cervix above the vaginal insertion; and therefore, in prolapse of the second degree, it is the rule to find the uterine cavity measuring from 4 to 5 inches in length.

That this elongation is due to stretching, although it is sometimes spoken of as hypertrophy, is shown by the fact that when cases of prolapse of the second degree, with elongation of the cervix, advance to procidentia, as the traction of the cervix from the body which caused elongation no longer exists, the uterus resumes its normal length. The cervix uteri in descending drags the posterior vaginal wall after it. When the uterus is completely outside, it lies in a bag formed by the inverted vagina, which becomes dry and scaly. In prolapse of the second degree, the cervix being constricted by the vulvar orifice, the part outside becomes much congested and swollen. This change disappears when the case goes on to procidentia. The protruded parts, both cervix and vagina, are liable to ulceration, which is mainly the result of friction. These ulcers heal when the uterus is replaced and maintained in position. There are cases in which the descent of the parts does not take place in this order, but they are quite rare and exceptional.

The *symptoms* of prolapse have been already described. There is a dragging, bearing down pain, relieved by recumbency, and made worse by exertion. The bladder is irritable, and there is smarting pain on micturition. The act of defæcation is attended with discomfort; a leucorrhæal discharge is usually present.

Prolapse is a condition which is met with chiefly in the labouring class.

Treatment.—The best treatment is to keep up the uterus by one of the forms of cup and stem pessary. The cup receives the cervix, and the stem has attached to it elastic bands which are tied to a waist-belt. The pessary may be made of gutta-percha, vulcanite, earthenware, or india-rubber; of these, earthenware is the cleanest. An instrument 3 inches long, with a cup 2 inches wide, is of the size most generally useful.

In slight cases one of the forms of Hodge's pessary or a thick ring may be sufficient. But these can only be retained where there is not much dilatation of the vaginal orifice, and they are therefore ineffective in the extreme cases of prolapse.

If a pessary with external straps be objected to, a plastic operation to contract the vaginal orifice may be performed. But this will not do more than make it possible to keep the uterus up with a vaginal pessary.

Alexander's Operation, or the shortening of the round ligaments, has been recommended for backward displacements of the uterus and for prolapse. For prolapse it is useless; because in prolapse there is descent, not only of the uterus, but of the vagina, and this operation only alters the position of the uterus. Cases of backward displacement of the uterus without descent of the vagina, which cause symptoms enough to make the patient an invalid, and yet cannot be relieved by a vaginal pessary, may be completely cured by Alexander's operation. It is not free from risk, but this is less than that attending treatment with an intra-uterine pessary, and, if successful, it cures, which an intra-uterine pessary never does.

It has been recommended to open the abdomen, and stitch the uterus to the abdominal walls. This measure is no doubt for a short time efficient; but knowing how peritoneal adhesions may stretch and even disappear, it is hardly to be expected that the permanence of an adhesion so produced could be relied upon; and no cases have yet been published showing the duration of relief afforded in this way.

8. *Inversion*, or turning inside out, of the uterus, is fortunately rare. It most often occurs after delivery, and is due to contraction of the cervix coinciding with relaxation of the body of the uterus, so that while the latter is pushed or pulled downwards through the os uteri, the cervix contracts and prevents its returning. In the unimpregnated state it may occur from the traction of a fibroid, either during its spontaneous expulsion or as it is being pulled down for removal by the surgeon.

Cases of inversion of the uterus are divided into *acute* and *chronic*. Acute inversion is the form which follows delivery. It may be caused by traction on the cord either by the medical attendant in attempting to remove the placenta, or by the child in consequence of the cord being too short, or from its being twisted round its body. But it may also occur without any traction, if the uterine body be relaxed, and it is important to bear in mind that it may thus happen without any fault of the medical attendant.

The *symptoms* are collapse and hæmorrhage. On examination, a sensitive tumour, the size of the uterus, surrounded at its base by the cervix as by a collar, will be found projecting into the vagina. On examination of the

abdomen the body of the uterus is not to be felt in its proper place. The *treatment* is to push up the inverted uterus with the hand. This is most easily done by pressing somewhat laterally, so as to push up first one side, then the other. The sooner replacement is attempted after the inversion has occurred the easier is it. If long delayed it may be difficult even with chloroform, and the case may require to be treated as one of chronic inversion.

If acute inversion of the uterus be left unreduced, the organ undergoes involution just as is the case when it has not been inverted. When involution is complete the condition is called *chronic inversion*. The inverted uterus is sensitive to the touch, and bleeds almost continuously, watery or purulent discharge being present in the intervals of hæmorrhage.

The *treatment* of chronic inversion is to replace it by continuous elastic pressure. The best repositr is Aveling's. By this instrument reduction can almost always be effected within three days, and generally in a shorter time. No other treatment is at the present time justifiable.

G. E. HERMAN.

UTERUS, FIBROIDS OF (Fibroid Tumours; Fibro-myomata). — These are the commonest tumours which grow in the uterus. They are classified, according to their position, into *sub-mucous*, *interstitial* and *sub-serous*. They are all interstitial growths at first, and, as they enlarge, some come to project into the uterine cavity (sub-mucous), and others on the peritoneal surface of the uterus (sub-serous).

Fibroids are also classified according to their structure; some consist of concentrically arranged fibro-muscular tissue, or of several masses so formed, and appear as round, hard nodules distinctly encapsuled. They can easily be shelled out of their capsule, are less vascular than the other kind, and on section are pale in colour. These have been called *hard*, *white* or *nodular* fibroids. In them fibrous tissue is relatively more abundant; therefore some writers restrict to them the term "fibroma." Others are much softer, more vascular, redder on section, are not formed of concentrically arranged fibres, but of fibres which interlace in all directions; they are not encapsuled, but so closely blended with the surrounding tissue that they cannot be shelled out; and they do not form nodules, but a general enlargement of the uterus concentrically surrounding

the uterine cavity. These have been called *soft*, *red* or *concentric* fibroids, and in them muscular tissue is relatively more abundant; therefore they are by some writers called "myomata."

SYMPTOMS. — **Sub-serous Fibroids** cause trouble chiefly by their size. They may grow to be as large as any tumours met with in the body, reaching a weight of 50 or 60 lb., or even more. When they reach this great size they may cause much suffering and danger by their pressure on important parts. By enlarging the abdominal cavity, and so pressing the diaphragm upwards, they may cause dyspnœa. By pressing on the stomach they may cause vomiting. Intestinal obstruction may be the result of pressure on the bowel. Pressure on veins may cause œdema of the lower extremities, and pressure on the urethra may give rise to retention of urine and its consequences; or one or both ureters may be occluded by pressure. These tumours may produce the pressure results thus enumerated, not merely by their size when in the abdominal cavity above the pelvis, but, when no larger than a foetal head, they may get locked in the pelvis, and thus exert injurious pressure on parts within that cavity, or they may get so tightly incarcerated as to become gangrenous. The degeneration, softening, and escape of the products of degeneration of these fibroids may cause peritonitis. Such peritonitis may be fatal, but if not fatal it results in the production of adhesions. Such adhesions may enable a tumour to produce effects by its pressure which would not have happened had the tumour been free to move. It may even happen that the tumour comes to receive its blood-supply through an adhesion, and that the traction exerted by an adhesion may elongate, perhaps twist, and finally break off the connection between the fibroid and the uterus. Fibroids which are entirely sub-serous seldom have much effect upon menstruation.

Sub-mucous Fibroids (with which, for clinical purposes, the soft or "concentric" growths spoken of by some as "myomata," must be classed) are chiefly important because they produce hæmorrhage. When of the hard or nodular kind they are generally single, and seldom reach a great size. A sub-mucous fibroid larger than a foetal head is rare. By projecting into the uterine cavity they enlarge it, and the irritation of their presence causes the uterine mucous membrane to undergo thickening and

vascularization to such a degree that some have termed the condition endometritis. The vascularity of the mucous membrane and the increase in its area causes profuse, long-continued and often repeated hæmorrhages, with leucorrhœal discharge in the intervals of hæmorrhage. There is often dysmenorrhœa, often also irritability of the bladder and slight pelvic pain. But the hæmorrhage is the important symptom, for through it the patient is made an invalid. Death directly from hæmorrhage is rare, more commonly such patients, if not cured, die from some condition the result of the anæmia induced by the hæmorrhages.

As already stated, all fibroids are interstitial in the beginning, and, as they grow, bulge either towards the peritoneum or towards the uterine cavity. But they may enlarge in both directions, especially when multi-nodular, and may reach a considerable size while covered on each aspect by a layer of muscular tissue, altering the external shape of the uterus and enlarging and distorting the uterine cavity. In such cases there will be menstrual troubles, such as are produced by sub-mucous growths, and there may be also symptoms resulting from pressure or from peritonitis and subsequent adhesions.

CHANGES IN FIBROIDS.—Fibroids are liable to various changes. They *enlarge* slightly before each menstrual period, and very much during pregnancy, if it take place. They may become very *œdematous*, and the fluid exuded may separate the fibres and lie in interstices of irregular shape between them. Thus is formed the so-called "fibro-cystic" tumour. The term "fibro-cystic" is not quite appropriate, because in such tumours there are, as a rule, no true cysts, but merely irregular spaces between the fibres containing fluid, but having no epithelial lining. There may be more than œdema—viz., *myxomatous degeneration*. There may be *suppuration*, or, what is more common, *breaking down* of part of the tumour, and conversion into a granular detritus. This often takes place at parts of the tumour, and, by opening of such softened spots and escape of débris into the peritoneum, peritonitis may be produced. The writer has known a suppurating fibroid discharge pus copiously into the uterine cavity, but this is rare.

Fibrous tumours may undergo *calcification*—that is, there is a deposit of calcareous salts around the periphery of the tumour, or in streaks through its

centre, together with shrinking and hardening of the whole mass. This change occurs in the sub-serous fibroids of old women. *Gangrene* of the whole tumour may occur either from inflammation and suppuration of its capsule, or, in the case of a sub-serous growth, from twisting of its pedicle, or from a tumour getting wedged and compressed in the pelvis. Disintegration of uterine fibroids is often spoken of as *gangrene*. A natural mode of cure of sub-mucous tumours is by their *expulsion* through the cervix into the vagina, and the slow elongation, thinning and at last parting of the pedicle and separation.

Disintegration and expulsion of sub-mucous fibroids in the form of loose fibrous débris also occurs, though rarely. Such disintegration is not attended with grave symptoms until the disintegrated tissue reaches the lower part of the vagina, when putrefactive germs get access to it, and decomposition of the dead tissue and blood-poisoning from absorption of the products of putrefaction result. If the patient be seen before this has happened, timely treatment with antiseptic injections will prevent it. This form of degeneration is interesting clinically, because the loose fibrous débris presenting at the os uteri feels very like placenta, for which it has often been mistaken, thus giving rise to unfounded suspicions.

Lastly, many isolated cases have been published in which tumours diagnosed by competent observers as uterine fibroids have disappeared, and it has been believed that the tumours have been *absorbed*. In most such cases the absorption has taken place during the lying-in period.

DIAGNOSIS OF FIBROIDS.—This is made by physical examination. It is generally easy, but may be difficult, or impossible. The important signs are, first, that the tumour, on bimanual examination, is found to be continuous with the uterus, and to move with it. Next, that sub-peritoneal, multi-nodular tumours are very hard, and are made up of a number of masses, each having a rounded outline. Should a sub-peritoneal fibroid have a long pedicle, it may be impossible to distinguish it from a solid ovarian tumour. Sub-mucous fibroids produce uterine enlargements, which it may be difficult to distinguish from pregnancy. The diagnosis will be made from the fact that the enlargement due to a fibroid is seldom quite as regular in

shape as that of pregnancy, and also the softening of the cervix and the bluish tint of the genital mucous membrane are absent in the case of the fibroid. Between a small fibroid and cancer of the body the diagnosis may be difficult, and indeed impossible without a digital exploration of the uterine body after dilatation of the cervix. This proceeding will be necessary for treatment as well as diagnosis if there be copious hæmorrhage with slight uterine enlargement. A fibroid projecting from the uterus laterally may much resemble the swelling formed by a thickened and dilated Fallopian tube. If in addition there have been pelvic peritonitis matting the pelvic organs together, the diagnosis will be still more difficult, and may be only possible after abdominal section. The diagnosis (previous to that proceeding) depends mainly on the much more severe pain which accompanies disease of the tubes.

ÆTIOLOGY.—Nothing is known about the ætiology of fibroids. They occur chiefly in women between thirty-five and forty-five. It is rare to find them before twenty-five, and rare also for their growth to begin after the menopause. They occur alike in the virgin, the married and the parous.

TREATMENT.—As the majority of uterine fibroids (taking all classes together) produce no serious symptoms, they require no treatment. Sub-serous fibroids of such size as to cause grave pressure symptoms can only be effectively treated by removal. If locked in the pelvis, they should be pushed up either manually or by hydrostatic pressure.

Sub-mucous fibroids are spontaneously cured in two ways. First, by their disintegration and piecemeal expulsion. This is rare; and attempts to bring it about artificially such as have been advocated, are attended with more probability of harm than good. Secondly, by their gradual expulsion from the uterus, first into the cervical canal, then into the vagina. In this process the attachment of the tumour to the uterus gradually becomes thinner and longer, and it may be spontaneously severed, and thus the cure completed. This process may, however, take years to accomplish, but the most satisfactory treatment of sub-mucous fibroids is the acceleration by art of this natural process.

Fibrous Polypus.—A fibroid tumour lying in the cervix or vagina, attached to the body of the uterus by a thin stalk, is thus termed. If it be found *in the vagina*

the treatment is to cut through its stalk either with scissors or the écraseur. If the attachment of the tumour to the uterus be extensive and close, it may be that, instead of the neck of the tumour elongating and a polypus being formed, the tumour drags down the body of the uterus, and thus inversion of the uterus is produced. In the case of a seeming polypus, if it be about the size of the fundus uteri, it should be remembered that, to the vaginal touch, an inverted uterus and a polypus about the same size feel very much alike. In both there is a rounded swelling projecting into the vagina and surrounded at its base by the cervix uteri. The diagnosis is to be made either by bimanual rectal examination, by which, if the tumour be a polypus, the body of the uterus will be felt in its natural place above the cervix; or by the sound, which, in the case of a polypus, will pass $2\frac{1}{2}$ inches or more beyond the os externum, but in an inverted uterus will not pass more than about $\frac{1}{2}$ inch.

In the case of a tumour *in the cervical canal*, the lower part of the cervix being stretched over it and the external os dilated—if the tumour be small, that is, not larger than a walnut, it may be seized, pulled down and twisted off. If the os be not large enough to allow this, it may be enlarged by incision, or by waiting a few days and giving full doses of ergot, which will produce further dilatation of the cervix, but which has the disadvantage of being accompanied by further hæmorrhage. If the tumour be larger than the size of a Tangerine orange, and within the cervix, it should be removed by enucleation. It has been said that there is a secret in the enucleation of fibroids. The secret is to select cases in which the cervix is expanded and the os externum dilated to the size of a florin or larger, to use antiseptic precautions, and not to try to drag by force a large tumour through an undilated cervix, but to cut the tumour up into small pieces, removing a piece at a time, and dragging down a fresh piece as room is gained by removal of its predecessor. In this way the writer has enucleated a tumour weighing $2\frac{1}{2}$ lbs.

Sub-mucous fibroids *not expanding the cervical canal* and causing hæmorrhage can generally be effectively treated by ergot, which, by making the uterus contract and contracting the arterioles, reduces the hæmorrhage to limits consistent with health, and often diminishes the size of the tumour. The ergot

should be given in $\frac{1}{2}$ -drachm doses of the liquid extract, three times daily, continuously for at least three months, unless something else be needed before that time has expired. It has been given by hypodermic injection; but the advantages of this method are so slight as not to counterbalance the disadvantages. The beneficial results mentioned follow the use of ergot in three-fourths of the cases. If benefit accrue, the ergot may be continued without intermission for twelve months or more. If the uterine contractions from the ergot should be very painful, they may be obviated by the addition of gr. x of antipyrin to each dose. In some cases ergot fails to do good, and in a few it appears to increase the hæmorrhage. This latter result is sometimes due to the uterine contractions forcing down the tumour and rupturing veins running in its capsule. Fatal hæmorrhage has been known to occur from rupture of such veins. There is no drug besides ergot which has any definite effect upon uterine fibroids or the hæmorrhage they cause.

Lately, a method of treatment by electricity has been introduced. This consists essentially in passing a very strong continuous current (100–300 milliamperes) through the tumour, one electrode being placed in the uterus, the other on the abdomen. Injury to the abdominal wall from so strong a current is prevented by using as an electrode a large poultice-like sheet of potter's clay. The intra-uterine electrode exerts a cauterizing effect on the mucous membrane, and so checks hæmorrhage. It is said also that the current exerts what is called an "electrolytic" action on the tissue of the tumour through which it passes, and diminishes its size. No proof of this has yet been adduced. There is some danger attending this treatment, for it has been followed by death, but the sources of danger have not yet been defined. The published results show that this treatment is not so effective as that by ergot, and, in addition, it is less safe. But in cases in which ergot fails and operative treatment is unadvisable, electrical treatment may properly be tried.

If hæmorrhage be considerable enough to affect health, and ergot fail to lessen it, removal of the uterine appendages should next be considered. If the tumour be small and movable and the patient's health not much affected, this is, in competent hands, an easy and safe operation. If the tumour be large, the ovaries are

often displaced and the folds of the broad ligament are spread out, so that the uterine appendages cannot easily be pulled up and ligatured; if it be immovable, the appendages may be found imbedded in firm adhesions; and if the patient be extremely anæmic, there is danger from thrombosis after the operation: these conditions, therefore, much increase its danger. If the appendages are successfully removed, cessation of hæmorrhage and shrinking of the tumour follow in the great majority of cases.

If these methods fail, nothing remains but hysterectomy. But cases are exceedingly rare in which this is required.

G. E. HERMAN.

UTERUS, HYPERTROPHY OF.

—Increase in size of the Body of the Uterus sometimes remains after child-bearing, the condition has been called *hypertrophy*, but it is usually termed *sub-involution*, and is described under that name. The body of the uterus becomes increased in size and thickness whenever new growths are contained in its walls or cavity. This hypertrophy is secondary to the growths, and is in itself unimportant.

Hypertrophy of the Cervix Uteri.—

There are three kinds of enlargement of the Cervix to which the term hypertrophy has been applied. (1) Chronic inflammation of the cervix producing general thickening. When this thickening is great, good may come from amputation of the cervix. (2) In prolapse the traction on the cervix by the proeident vagina elongates that part of the cervix which is above the insertion of the vagina. By some this has been called hypertrophy; by others, elongation; by others again, *hypertrophic elongation*. Reasons for thinking that it is lengthening of the cervix by stretching rather than overgrowth are given in the section on Prolapse (p. 908). But, although usually so produced, it may be due to overgrowth. A specimen in the Hunterian Museum shows hypertrophy of the infra-vaginal part of the cervix in the anterior lip; of the supra-vaginal portion of the cervix, in the posterior lip. Here the supra-vaginal hypertrophy cannot have been due to stretching, and is not accompanied with thinning. (3) Hypertrophy of the vaginal portion of the cervix may be a congenital malformation. The writer has seen and published cases of its occurrence in two sisters. If slight descent of the uterus take place, the hypertrophied

cervix protrudes at the vulva, and the condition simulates the second degree of prolapse. The hypertrophy appears to favour the occurrence of prolapse. This form of hypertrophy is recognized on endeavouring to replace the apparent prolapse, when it is found that, when the uterus is pushed as high as possible, the distance between the vaginal insertion and the os externum is not diminished.

The *treatment* is to cut off the infra-vaginal portion of the cervix, either with knife or scissors, the mucous membrane of the cervical canal being sutured to that of the external surface of the cervix, or the galvano-cautery wire may be used.

G. E. HERMAN.

UTERUS, INFLAMMATION OF (Metritis).—**Acute Metritis** occurs in the puerperal state as a result of septic infection (*see* PUERPERAL FEVER). In the non-puerperal woman it is sometimes seen as a result of rough treatment of the uterus, as in the removal of tumours; from the use of tents without proper precautions, or from the wearing of intra-uterine pessaries. It is generally believed that it may result from suppression of menstruation, or from sexual excesses, but from such causes it is at least rare. It is associated with endometritis, and quickly leads to peritonitis.

The *symptoms* are that, in addition to the hæmorrhage or discharge which endometritis produces, the uterus is swollen and tender.

Treatment consists in absolute rest in bed, the administration of laxatives, leeches to the inguinal regions if the patient be full-blooded, counter-irritation to the abdomen in the form of poultices of linseed mixed with mustard or sprinkled with turpentine, potassium bromide if there be much reflex excitability, the removal of any pessary or tent, and discontinuance of any interference with the uterus.

Chronic Metritis is one of the most common, and yet ill-understood, diseases that occur in women.

Symptoms.—The affection is assumed to be present when the uterus is large and tender, and the patient, without any other morbid condition being present to account for it, suffers from chronic pelvic pain. The pain is not very severe, but lowers the tone of the nervous system by its continuance, and is increased at the menstrual period. It is generally stated that in the beginning of the disease the menstrual flow is in-

creased in quantity, while later on it is diminished; but if this be the rule, exceptions are numerous. There is usually some leucorrhœa, from accompanying vaginal catarrh and cervical endometritis. There is often irritability of the bladder and slight scalding in micturition. Dyspareunia is usual. The pelvic symptoms are usually accompanied by those of atonic dyspepsia—capricious appetite, fulness after meals, flatulence, constipation—and by such symptoms of nervous exhaustion as loss of energy, depression of spirits, muscular weakness, disturbed sleep, inability to sustain thought, frequent headaches, vertigo and hysterical seizures. This train of symptoms is generally of long standing, and is often dated back to a labour which was followed by a convalescence slower than usual or interrupted by illness. A similar group of morbid phenomena is sometimes seen in women who are sterile, or comes on during a period of sterility following a period of fertility; and in some at least of such cases is due to efforts to prevent conception. It has been attributed to laceration of the cervix, but without the slightest evidence, and there is abundant proof to the contrary. It may be produced by too much local treatment of the uterus. From the circumstances of its origin, its persistence and chronicity, and the kind of treatment that is found effectual, the increased size and tenderness of the uterus is believed to be due to chronic congestion and inflammation. It is suggested that in the earlier stage it is congested (hence the increased menstrual flow), and that later the inflammatory exudation has become organized into fibrous tissue, which thickens and hardens the uterus, compressing and even obliterating vessels, and hence making menstruation scanty. Some who think the evidence of inflammation insufficient, but nevertheless accept as a fact the presence of an excess of fibrous tissue in the uterus, call the disease "chronic areolar hyperplasia." But the morbid changes, whatever they may be, have never yet been demonstrated. Those that have been pointed out are not peculiar to this disease. There is no evidence that there is any more fibrous tissue in these large tender uteri than there is in uteri which, although large, are not tender. The strongest argument in favour of the disease being really due to congestion is the benefit that follows treatment which depletes the pelvic vessels.

The success of treatment depends upon

the stage at which the opportunity for it occurs. Recent cases can be quickly cured, but in those of long standing treatment is not followed by good results.

Treatment.—Rest is most important, but it may be difficult to induce the patient to keep her bed for a malady which does not seem to require it, but if she can be induced to do so the effects of treatment will be greatly helped. If the patient be florid and menstruation scanty, four or six leeches should be applied to the cervix uteri, when aggravation of pain indicates the approach of menstruation. A hot vaginal douche should be used night and morning. After the douche, a plug of cotton-wool saturated with glycerin, and tied to a piece of string to facilitate removal, or, better, a pessary of glycerin and gelatin (gelatin ʒj, glycerin ad ʒij), should be inserted. To the latter, if there be much soreness and irritation, gr. xx of boric acid may be added. Alcohol should be forbidden. The bowels should be regulated, it being better that they should be loose than confined. Disorders of digestion must be treated in appropriate ways, and tonics given, with draughts of ammonium bromide (ʒss) if there be sleeplessness. If the patient can be induced to keep her bed, and the case be recent, a month or two of this treatment will probably remove the symptoms. It has been proposed, and practised in intractable cases, to remove the ovaries; but in the cases which have come to the knowledge of the writer this has not proved beneficial. Treatment is likely to be more efficient if the patient can be taken from her home, and in some cases, but by no means in all, this is essential. G. E. HERMAN.

UTERUS, MALIGNANT ADENOMA OF.—A rare disease, consisting in a fungous overgrowth of the mucous membrane of the uterus.

Symptoms.—Quite in the beginning it may be difficult or impossible to distinguish this disease from fungous endometritis, for detached portions of the overgrown mucous membrane, when examined microscopically, only show overgrowth of the regular gland-tissue of the uterus, and not any malignant structures.

In course of time the case is distinguished from endometritis by the rapidity and extent of the growth, which may come to form great masses spreading down into the vagina and filling it.

The symptoms and course of the disease when advanced are practically

identical with those of cancer of the body of the uterus, from which it differs only in the histological characters.

The *treatment* is the same as that of cancer of the uterine body.

G. E. HERMAN.

UTERUS, POLYPUS OF.—The term “polypus” means a stalked growth. It has been applied to at least four different uterine products.

(1) *Fibroid Polypus*, a sub-mucous fibroid which has been expelled into the uterine cavity or beyond it, and has thus acquired a stalk.

(2) *Mucous Polypus*.—The simplest form of mucous polypus is that caused by an occluded cervical gland, which, being enlarged from retention of its secretion, first projects from the surface of the mucous membrane and then hangs down by a stalk. Such tumours have been called *Ovula Nabothi*. Sometimes several of these are aggregated together and form a larger tumour. Other mucous polypi are simply overgrowths of the mucous membrane, and consist chiefly of connective tissue. Polypi of these kinds seldom reach a size larger than a hazel nut. They only cause leucorrhœa, and perhaps hæmorrhage when touched. They are easily cured by seizing them with a pair of forceps and twisting them off. There is another kind of polypus, commonly classed under “mucous” polypi—viz., *follicular hypertrophy of the cervix*. This is formed of an overgrowth of all the cervical tissues, muscular tissue, vessels and glands, the overgrowth of the glands being the most conspicuous change. These have been called “channelled” polypi. They, and the polypi formed by blocked glands, are by some called “adenoma.” Such a polypus causes leucorrhœa, backache, and, it may be, slight hæmorrhage. The *treatment* is to twist it off, or, if the pedicle be thick, to remove it with an écraseur.

(3) *Placental Polypus*.—This is a retained portion of placenta with entangled clot, which still has some vascular connection with the uterus. For *treatment*, &c., see ABORTION.

(4) *Fibrinous Polypus*.—A clot retained in the uterine cavity and having some attachment to the uterine wall. *Treatment* as for placental polypus.

Cancer sometimes forms a polypoid tumour.

G. E. HERMAN.

UTERUS, SARCOMA OF.—Sarcomata of the uterus—i.e., tumours com-

posed of embryonic connective tissue—are rare. Before this name had been given to these growths they were described under the title of “recurrent fibroids.” They are usually of the rounded type, less often of the spindle-celled kind, sometimes of mixed types. They more often grow in the body of the uterus than in the cervix. They are met with in two forms—circumscribed and diffuse. When *circumscribed*, they form rounded tumours growing in the uterine wall, to the touch very much like uterine fibroids, but softer. Fibroids sometimes degenerate into sarcoma. At this stage they can be distinguished from fibroids only by microscopical examination. In the *diffuse* form, assumed when the growth begins in the mucous membrane, the interior of the uterus presents an irregular ulcerated surface with ragged fungous outgrowths, its walls being infiltrated with new growth. The circumscribed growths are often multiple; they may break down and ulcerate, and thus the transition can be traced between the circumscribed and the diffuse forms. The diffuse form can only be distinguished from cancer by the microscope. Late in the course of the disease secondary growths occur in other organs, although less often than in cancer.

The *symptoms* are much the same as in cancer—pain; hæmorrhage; watery, offensive discharge in the intervals of hæmorrhage; cachexia. Its course seems to be slower than that of cancer.

Nothing is known about the *etiology* of sarcoma. Unlike cancer of the cervix, its occurrence does not seem to be favoured by child-bearing.

The *treatment* is the same as that for cancer.

G. E. HERMAN.

UTERUS, SUB-INVOLUTION OF.—When, after delivery, the uterus does not return to the size it had before pregnancy, it is said to be in a condition of sub-involution. It is very common; so much so, that in anatomical works it is usually laid down that the uterus in women who have borne children is larger than in the virgin. The uterus does sometimes, after child-bearing, return to its former dimensions, so that the mere size of the organ affords no ground for giving an opinion as to whether there has been pregnancy or not.

Symptoms.—Sub-involution does not *per se* give rise to any symptoms, even though the uterus be of considerable size. But just as all damaged or degenerated

parts are more liable to inflammatory and other morbid changes than healthy parts, so a uterus which has not undergone perfect involution is more liable to become the subject of chronic metritis or endometritis and to menstrual irregularities than a well-involuted uterus. After the lying-in period has passed, the size of the uterus cannot be appreciably diminished by treatment. This effect has been claimed for many kinds of treatment, but the claim has never been supported by the evidence of cases so observed as to show that the observer was aware of the fallacies which make it difficult to draw conclusions on the point.

Etiology.—The main causes of sub-involution are the following:—(1) Deficient contraction of the uterus in the puerperal period; (2) Retention of placenta, membranes, or clot *in utero* during the early days of the puerperium. (3) Febrile conditions during the lying-in period.

Treatment.—Sub-involution is to be prevented by the use of antiseptics during labour and the lying-in: by proper management of the third stage of labour, so that the placenta and membranes may be completely separated and expelled; and, if uterine contractions be imperfect (indicated by after-pains, passage of clots and hæmorrhage), by the administration of ergot during the lying-in period.

G. E. HERMAN.

UTERUS, SUPER-INVOLUTION OR PUERPERAL ATROPHY OF.—This condition is produced when the puerperal involution of the uterus goes further than to restore it to the size that it had before delivery, the organ again becoming infantile in size, but it is rare. Nothing is known about its causation. It is not necessarily accompanied by any symptoms, except amenorrhœa, or, to use a more comprehensive term, premature menopause. The vaso-motor disturbances which often accompany the menopause, such as flushes, perspirations, headaches, &c., may be present with this condition. No serious impairment of health is produced by super-involution. There is no treatment which can restore the uterus to its former size. Intra-uterine stems, cauterization, galvanism, have been advised to stimulate, or rather irritate, the uterus. It is possible with them to make the uterus bleed, but this is not restoration of function, nor is it beneficial to the patient. Such treatment is moreover attended with

risk. Super-involution is of course attended with sterility.

G. E. HERMAN.

UVULA, DISEASES OF. — The uvula is the conical-shaped body depending from the centre of the free border of the soft palate. In its structure it resembles the soft palate, but it is especially rich in glands.

From its position the uvula naturally suffers when the soft palate and fauces are affected; hence it is liable to inflammatory conditions, and to be the seat of the local manifestations of measles, scarlet fever, diphtheria, syphilis, &c. Occasionally the uvula is the starting-point of the inflammation, and very rarely the mischief is confined to the uvula, the term *Uvulitis* being applied to this condition. In some cases the engorgement of the uvula may proceed to such a degree that it attains the size of the thumb, and causes an irritating cough, or even obstructs the passage of air.

Treatment. — When the uvula is acutely inflamed the application of a 20 per cent. solution of cocaine by the spray or laryngeal brush will often suffice to give relief, and pellets of ice in the mouth will assist. Should the swelling increase, scarification or amputation may be required.

Elongation of the Uvula. — By repeated inflammatory attacks, particularly in persons of lax fibre, the uvula may become permanently elongated. In one instance the uvula was so long that the patient could take it between his teeth; and, on removal, it was found to be 4 inches in length, its lower extremity being terminated with a knob. Elongation of the uvula generally gives rise to an irritating cough, especially when the patient is in the recumbent position; this fact should be borne in mind in investigating cases of nocturnal coughing. Schech states that an elongated uvula may cause spasm of the larynx, and quite recently A. Mantle (*Brit. Med. Journ.*, vol. i. 1890, p. 286) has described a case of laryngismus in a child cured by removal of the uvula. The elongated uvula may also give rise to the sensation of a foreign body in the throat or cause an inclination to vomit.

Treatment. — It is necessary, in the first place, to improve the general health. If there be constipation, a mixture containing the sulphates of iron and magnesium will usually diminish the relaxed condition of the uvula. Local astringents

may then be tried. A combination of the extract of krameria and cocaine, made up into a paste, is often very effectual. Or astringent gargles, such as alum or tannic acid, may be ordered. The application of nitrate of silver, fused on an aluminium probe, usually gives at all events temporary relief. Should these measures fail, the elongated organ must be amputated. This is best effected, after the application of a 20 per cent. solution of cocaine to the part, by means of Mackenzie's uvulotome. If this is not available, the extremity of the uvula may be seized with a pair of forceps, and part of the organ cut off with scissors. The indications for this operation as laid down by Semon are as follow:—“(1) Elongation to such a degree that the uvula, especially during sleep, is sucked into the larynx and produces attacks of suffocation. (2) The co-existence of a long, thick uvula, with a persistent feeling of irritation in the throat, and a constant tickling cough. It must be distinctly understood that this indication is only valid after careful examination of the pharynx, larynx and thorax, and after exclusion of all other possible causes. (3) The hindrance offered by a very long uvula to the performance of delicate endo-laryngeal operations. (4) Malignant disease starting from the uvula.” There can be no doubt that the uvula is frequently removed unnecessarily, as the reasons for its removal are but rarely met with. It should be borne in mind that the pain on swallowing which sometimes follows the operation is severe and persistent, and occasionally the hæmorrhage is excessive. In one or two cases the hæmorrhage, which was very trifling at the time of the operation, recurred with great violence some hours later. The most effectual way to arrest the hæmorrhage is to sip slowly a mixture of tannic and gallic acids, 360 grains of the former and 120 of the latter in an ounce of water as recommended by Mackenzie.

Abnormalities and Growths of the Uvula. — The uvula may be cleft, giving rise to a bifid uvula, or there may be two uvulas.

Apparent absence of the uvula is generally to be accounted for by destruction of this body through tertiary syphilitic ulceration.

Growths such as mucous polypus, papilloma, cavernous angioma, epithelioma, &c., occasionally take their origin from the uvula.

F. DE HAVILLAND HALL.

V

VACCINATION.—The inoculation of a human being with the contagium of vaccinia or cow-pox, with the object of protecting the person thus inoculated against small-pox—or, at least, against a severe or fatal attack of that disease.

The immediate effects of vaccination are chiefly local; they vary in character according as the person affected has, or has not, already been successfully vaccinated or undergone an attack or inoculation of small-pox.

Primary vaccination denotes the successful vaccination of a person previously unprotected as above; *secondary vaccination* is synonymous with *re-vaccination*.

I. PRIMARY VACCINATION.—(1) **Regular Course.**—When vaccine lymph of proper quality has been applied to the abraded skin of a previously unprotected person, or has been inoculated by a subcutaneous puncture, a couple of days pass without any observable result. In successful cases the order of subsequent events is as follows:—

End of second or beginning of third day, a small, hard, red *papule* appears at the site of inoculation; by the *fifth or sixth day,* the papule has become a distinct pearly *vesicle*, oval or circular in outline, with raised margin and depressed centre.

Eighth day, the vesicle is fully developed; it is plump and rounded, distended with clear lymph; its margin is firm and prominent, and the central depression very distinct. In the course of this day—sometimes by the evening of the seventh day—the vesicle begins to be surrounded by a circular rosy *areola* of inflammation.

Ninth and tenth days, both vesicle and areola continue to extend, with increased swelling and hardness of the subjacent subcutaneous tissue, which is generally somewhat painful. After the tenth day the areola begins to fade, and in another three or four days has usually quite disappeared, together with all swelling and hardness. With the fading of the areola the vesicle begins to dry in the centre, its contained lymph becomes opaque, contracts, and consolidates, so that by the

Fourteenth or fifteenth day the vesicle is converted into a hard brown scab, which gradually dries and blackens; and on about the

Twenty-first day—or, from the twentieth to the twenty-fifth day—the scab separates, leaving a *cicatrix*, which is circular, depressed, pitted, sometimes radiated, and generally permanent through after-life.

These events form a tri-weekly record, which may thus be summarized:—the *first week* is occupied by the formation and maturation of the *vesicle*; the *second week* witnesses the formation and decline of the *areola* and the drying of the vesicle into a *scab*; the end of the *third week* sees the separation of the scab with the discovery of the *cicatrix*.

The manner in which the lymph was inoculated—whether into one large abraded surface, or by several punctures, and these some distance apart, or set close together—will determine the development of one large vesicle, of several separate vesicles (one for each successful puncture or abrasion) or of one or more confluent vesicles, together with variations in the shape and extent of the resulting cicatrix or cicatrices.

The *constitutional symptoms* which attend these local phenomena are usually slight; they comprise slight rise of temperature, beginning about the fourth day, more marked during the areola stage, and often at that time attended with disorder of the bowels and stomach, but declining as the areola fades. At this period also, the axillary glands sometimes become greatly enlarged and painful, and occasionally—chiefly in hot weather—there develops in young children an eruption of *vaccine roseola* (chiefly confined to the limbs), or of the papules of *vaccine lichen*, or even of vesicles—which differ from true vaccine vesicles in possessing no central depression. These eruptions, when they do occur, generally disappear within a week.

(2) **Irregular Course.**—The order of events just related is in most cases followed very exactly. Sometimes, however, the development of the vesicle is either retarded by two or three days or slightly accelerated, but this variation from the normal course of events is not believed to impair the protective value of the result, provided that the phenomena be in all other respects regular and typical.

It is, however, important to recognize

a non-protecting and spurious form of vaccination distinguished by irregularity in the characters and course of the vesicle itself. Thus, papules, or even small vesicles, may appear early, and, beginning to decline about the fifth or sixth day, are marked only by a slight crust or scale by the end of the first week; or vesicles develop early after the inoculation, attended with much local itching (which is hardly ever noticed in a true vaccination), become conoid or acuminate, instead of flattened with a central cup-shaped depression, contain a straw-coloured opaque fluid in place of clear lymph, and soon develop an irregularly shaped areola, which rapidly fades after the sixth day.

(3) **Complicated Course.**—Friction or other injury and want of cleanliness may sometimes cause the vesicles to develop into ulcerating sores, more especially in strumous subjects.

Similarly, swollen axillary glands may suppurate, and erysipelas may supervene on vaccination. Such unfortunate accidents are rare in proportion as scrupulous care is taken in the selection and use of fresh lymph taken from a healthy vaccinifer, and strict attention paid to cleanliness as regards the instruments used and the place of vaccination, and provided that the healthiness and continued personal cleanliness of the person vaccinated be insured.

For a full account of three fatal cases of gangrenous ulceration of the arm after vaccination the reader is referred to the "Archives of Surgery" of Mr. Jonathan Hutchinson (vol. i. No. 2). In No. 3 of the same series reference will be found to a case of hæmorrhagic vaccinia (petechial eruption after vaccination) recorded by Dr. Gregory in *Med.-Chir. Trans.*, 1842, and to another of protracted ulceration of vaccination sores with keloid formation in the scars; also in vol. i. No. 2, an account of a case of vaccinia-prurigo.

II. SECONDARY VACCINATION (Re-vaccination).—Most persons can be re-vaccinated at least once during their lives; sometimes repeatedly, and at comparatively short intervals. Occasionally the resulting phenomena are exactly those of a regular primary vaccination, or differ only in the development of a smaller and more transient areola and the formation of a fainter cicatrix. More usually the result is only a *spurious vaccination* with the production of a small papule or acuminate vesicle, attended with great itching and

irritation, surrounded by an early and irregular areola which is at its height by the fifth or sixth day, and scabbing by the eighth day; but the general constitutional symptoms are often quite disproportionately severe. In some persons all attempts at re-vaccination are without effect.

PERFORMANCE OF VACCINATION.—Since it is undertaken as a protection against small-pox, which spares no age and is especially fatal to infants, vaccination should be performed as early in life as possible. If the child be healthy and well nourished, the age of from four to six weeks is appropriate; if the child be delicate, the operation may be postponed for another month or six weeks. If small-pox be epidemic in the immediate vicinity or have attacked other members of the household, the infant should be vaccinated at once, whatever its age and whatever its condition, acute and serious illness being the only exception to this rule. Under other and ordinary circumstances the existence of certain forms of ill-health or of disease in the child will render its vaccination inadvisable so long as this continues. Thus, a child suffering from any acute febrile disease, from diarrhœa, from disorders of dentition, from any cutaneous malady, and particularly from any form of herpes, eczema, or intertrigo (in view of which the scalp, and the skin-folds in the groins, the neck, and behind the ears should always be carefully examined)—one that has been lately exposed to the infection of measles or of scarlatina, or in whose neighbourhood erysipelas prevails at the time—should not be vaccinated so long as any one of these conditions persists.

The lymph employed for the purpose may be either "bovine" or "humanised;" in either case it must be taken from an animal which is both young (calf or infant), and in sound health and of healthy parentage, so as to avoid the possibility of transmitting other acquired disease as well. Since bovine lymph is apt to induce rather more severe local effects, humanized lymph should be preferred for the vaccination of delicate children.

The lymph should be used as fresh as possible; whenever practicable, it is best transferred directly from one subject to the other, as in "arm to arm vaccination;" but it may be stored for a reasonable time on clean flat "points" of ivory or bone, between glass plates, or in glass tubes of narrow bore, which are partly filled by capillary attraction with lymph

exuding from a punctured vesicle, and then sealed by melting first one end and then the other in the flame of a spirit lamp.

The lymph must be taken only from a perfectly formed, sound, uninjured vesicle, which has developed after the "regular" type and which has not yet developed any areola. Though lymph may exist in a regular vesicle as early as the fifth day, it is obtained more abundantly and more conveniently by the early part of the eighth day (*i.e.*, the day-week following the vaccination. Each vesicle is multi-cellular, and should be opened by delicately scratching or puncturing its surface, great caution being used not to draw blood, which must on no account be mixed with any lymph intended for vaccination. The lymph rapidly exudes from the punctures and collects on the surface of the vesicle, whence it may be collected for storage as above, or from which it may be taken on the point of a clean lancet or other instrument suitable for the performance of arm to arm vaccination.

The arm of the child that is to be vaccinated should be bared above the shoulders, and the skin of the deltoid region washed with warm water and rubbed dry with a clean cloth; this cleanses the skin, at the same time rendering it somewhat hyperæmic and more prone to absorption. The arm being then grasped so as to steady it and slightly stretch the skin, the lancet (charged with the fresh or stored lymph) is made to slightly puncture, scarify, or tattoo the skin over one or more surfaces, whose total or combined areas should equal about half a square inch. The procedure may be varied by first scratching the skin with a clean lancet and then rubbing lymph into the abraded surfaces. Where "points" are used, the dried lymph which they bear must be softened by holding them in the steam of hot water before inserting them into the punctures or firmly wiping them over the scarifications.

The lymph thus applied, together with any blood which may have appeared, should be allowed to dry before the child's clothing is re-adjusted. It is well to instruct the nurse not to wash the vaccinated spot for the first two or three days, and then to protect the surface by one or two loose folds of fine scorched linen. If, as the vesicles mature, local irritation become excessive, the frequent application of soft rags saturated with lead lotion affords much

relief, and a mild mercurial alternative may be given internally. All unguents and greasy applications should be interdicted, and the part must be kept clean and protected from friction.

The child should be seen again on the day week (eighth day) following the vaccination. If the development of the vesicle be then found to be retarded, it should be again inspected in another two or three days' time. Should the local condition still appear abnormal, the case must be carefully watched day by day to its termination. Only that vaccination in which the development and character of the vesicles conform to the normal type can be certified as successful and regarded as protective.

All instruments used for vaccination purposes should not only be kept scrupulously clean and bright, but should be thoroughly cleansed after each time of using, if employed for more than one vaccination at a time.

Re-vaccination is performed with the same precautions as regards the infancy of the vaccinator and the selection of the lymph employed. The resulting constitutional symptoms are apt to be more severe; and it is well to support the vaccinated arm in a sling, and to enjoin abstinence from its active use, so as to minimize the troublesome enlargement and irritation of the axillary glands. In the case of men and boys (in whom the position of the cicatrix is comparatively immaterial) it is useful to re-vaccinate on the inner and upper aspect of the left *forearm*; the vesicles are here less exposed to friction from the clothes, the movements of the shoulder are less hampered, and dressing and undressing become less painful.

Vaccination does not, in all cases, confer absolute immunity against small-pox; it does so, however, for the great majority of the successfully vaccinated; and such a person, if attacked with small-pox, suffers only the much milder "modified" form of the disease; while the probability of a fatal issue is even less than if the individual had undergone a prophylactic inoculation or a previous attack of small-pox itself. The necessity for re-vaccination depends upon the fact that in only a comparatively small number of persons does the effect of a successful primary vaccination in infancy persist throughout life; in other words most people become susceptible to vaccination (and, presumably, to the infection of small-pox) after the lapse of a period which differs in length in dif-

ferent cases. The immunity so commonly afforded by a successful primary vaccination seems to be more rapidly exhausted during the actively metabolic period of youth and adolescence; hence most individuals can be re-vaccinated successfully before the period of puberty, and very commonly at least once again—sometimes at comparatively frequent intervals—during adolescence or in later adult life. Certain diseases also—and enteric fever in particular—seem directly to impair or to neutralize the effects of vaccination. On the other hand, successful re-vaccination appears, equally with successful primary vaccination, to afford immunity against small-pox (or, at all events, against its more serious effects); and this, in each case, for a period which varies probably with the “physiological equation” of the individual operated on. Statistics show that small-pox is extremely rare, and a fatal result almost unknown, amongst adults who have undergone a successful re-vaccination.

Hence, if susceptibility to re-vaccination be coincident with susceptibility to small-pox (which appears a reasonable supposition); and if successful vaccination afford, in most cases and for some time at least, protection against small-pox (which the vast and increasing experience of all civilized communities affirms); then it is reasonable to urge the re-vaccination of all children at about the age of from 10 to 12 years, and to advise a second re-vaccination by the time that adolescence is completed, as well as after recovery from certain diseases, such as enteric fever in particular. Persons who are found to be thus again susceptible to the vaccine virus would do well to submit to another re-vaccination after a further lapse of years; and, in any case, to be re-vaccinated whenever they were likely to be exposed to the infection of small-pox, and during an epidemic of that malady.

C. E. SHELLY.

VACCINO-SYPHILIS (*Vaccination Syphilis*).—A term used to indicate the conditions—local and constitutional—which result from the introduction into the system of syphilitic infection along with the vaccine at the time of vaccination. It does not include that quite distinct class of cases in which the syphilitic poison has been subsequently inoculated on the site of abraded vaccine vesicles, nor those other cases in which symptoms of here-

ditary syphilis develop in the course of, or shortly after, vaccination; although an accurate distinction between these three groups may sometimes present very considerable difficulty. The syphilitic virus may be inoculated during vaccination by means of contaminated lymph, or by the contact of tainted instruments, with the freshly made punctures or scarifications.

In true Vaccino-Syphilis there is a double and contemporaneous inoculation of two distinct infections—the virus of vaccinia, and that of syphilis—but the incubation-period and the developmental phenomena of the latter overlap, without, as a rule, interfering with those of the former; so that in such cases the vaccination vesicles generally pursue their usual course and obtain their normal development (*see* VACCINATION), and it is not until after they have healed, and four or five weeks have elapsed since the date of the vaccination, that the local inflammation which constitutes a chancre begins. This is attended by the usual glandular enlargement (axillary bubo), and is followed, in due course, by the recognized secondary symptoms of constitutional infection. The occurrence of vaccino-syphilis—although, fortunately, an event of extreme rarity—is the most lamentable accident by which carelessness or misfortune can prejudice the performance of vaccination, and it is important by reason, first, of the care which is requisite for its prevention; and secondly, by reason of the necessity for discriminating between it and some other conditions which simulate it, and with which it is apt to be confounded (*see* VACCINATION).

Vaccination syphilis is to be avoided by the invariable and conscientious exercise of the following precautions:—Great care in the selection of a healthy vaccinifer; scrupulous cleanliness of all instruments, &c., used in obtaining lymph from the vaccinifer and in transferring it to the subject of the vaccination, together with effectual cleaning and drying of the instruments immediately after the performance of each separate operation; carefully avoiding to draw blood when opening vaccine vesicles for the purpose of obtaining lymph from them for vaccination, and the rejection of any lymph with which blood may have become mixed; and the refusal to take lymph for vaccination from any vesicles which are surrounded by an areola.

The various pathological conditions which are apt to be confounded with vaccino-syphilis, and from which it may have to be discriminated, include *Vaccinal Ulcers* (ulceration or gangrene at the site of the vaccination vesicles); and—if the concomitant symptoms suggest

evidence of general infection—*Vaccination Rashes* and *Hereditary Syphilis*. The principal points which differentiate these various groups are exhibited in the annexed tables, which have been compiled mainly from Professor Fournier's lectures on the subject.

<i>Vaccino-Syphilis.</i>	<i>Vaccination Ulcers.</i>
Chancre developed on the site of usually one or two only of the vaccination-punctures.	Ulceration affects all the punctures as a rule.
Inflammation is slight.	Inflammation and ulceration severe.
Loss of substance superficial only.	Ulcer deeply excavated.
Suppuration scanty or absent; scabs or crusts formed.	Much suppuration.
Border of chancre smooth, slightly elevated, gradually merging into floor.	Margin of ulcer irregular, as in "soft chancre."
Surface of floor smooth.	Floor of ulcer uneven, suppurating.
Induration "parchment-like" and specific, not merely inflammatory.	Induration inflammatory only.
Inflammatory areola very slight.	Areola inflammatory, and erysipelatous in character.
Gland swelling constant, indolent (syphilitic bubo).	Gland swelling often absent; if present, merely inflammatory.
Complications rare.	Complications—sloughing, erysipelas, &c.—often present.
Chancre never developed before the fifteenth day after vaccination; usually not until after three to five weeks; still in its earliest stage twenty days after vaccination.	Ulceration is present twelve or fifteen days after vaccination, and is fully developed by the twentieth day after vaccination.
<i>Secondary Syphilitic Eruption</i> due to true <i>Vaccino-Syphilis.</i>	<i>Vaccination Rashes</i> —(including roseola vaccinalis, miliaria vaccinalis, vaccina bullosa, vaccina hæmorrhagica); also accidental eruptions—rubeola, scarlatina, lichen, urticaria, &c.
Appears, at the earliest, nine or ten weeks after vaccination.	A true vaccinal rash appears between the ninth and fifteenth day after vaccination.
Requires, in every case, the pre-existence of a specific ulcer (chancre) at the site of vaccination.	Absence of inoculation chancre.
Exhibits the characters of a true specific eruption.	Eruption does not exhibit specific characters.
Fever often slight.	Fever always present.
Lasts for a long time.	Evanescence.
Usually accompanied by specific appearances on mucous membranes.	
<i>Vaccino-Syphilis.</i>	<i>Hereditary Syphilis</i> showing itself about the time of vaccination.
Begins with a local infection, chancre and indolent bubo.	No chancre; begins with general phenomena.
Typical development in four stages, viz.:—Incubation, chancre, second incubation, generalisation (secondary eruptions, &c.).	Has no typical development in connection with vaccination.
Never appears earlier than the ninth or tenth week after vaccination.	Time of development quite independent of vaccination.
	Is attended by the characteristic syphilitic bodily aspect.
	Other manifestations of hereditary syphilis may be present.
	The history may indicate syphilis.

In considering this subject it must be admitted that there are some few individuals and some constitutions in which the inoculation of vaccine virus—however pure the lymph—may evoke local and general phenomena strictly comparable with those erratic forms of blood-poisoning which occasionally appear as the sequelæ of other specific fevers:—compare—*e.g.*, the cancrum oris and noma of measles; hæmorrhagic and gangrenous varicella; the otitis of scarla-

tina; the necrotic periostitis of small-pox and enteric fever:—and, moreover, that all of these conditions may appear to be benefited by the exhibition of mercurials, although they have nothing to do with syphilis.

The *prognosis* of vaccination-syphilis is, with appropriate treatment, at least as good as that of severe cases of vaccinal (non-syphilitic) ulceration.

The *treatment* is essentially that of syphilis.

C. E. SHELLY.

VAGINA, DISEASES OF.—Malformations.—The vagina may be occluded by a transverse septum. Such septa are more common at its lower part, but may occur at any part. There may be more than a mere membranous septum. The vagina may be absent altogether, or be obliterated for part of its length.

The consequences and treatment of malformations of this kind are described in the article on AMENORRHOEA (*q.v.*).

The vagina may be *double*, a condition usually associated with duplicity of the uterus. This malformation gives rise *per se* to no inconvenience, and is usually discovered only when some other condition calls for local examination.

Unilateral Hemato- or Pyo-colpos.—One half of a double vagina may be imperforate, and in that case blood or pus may be retained in it. Such a distended half-vagina forms a tumour on one side of and partly in front of the pervious half. The tumour is elastic, and fixed, not displaceable; fluctuation may be obtained, although with difficulty.

The *diagnosis* will be finally made by puncture. Before opening such a tumour, and sometimes even after a free incision has been made, it is difficult to tell how far the fluid-containing cavity is formed by the vagina, and how far by the cervix uteri.

Treatment.—A piece of the septum should be cut out, so as to lay the two canals permanently into one.

Inflammation.—*Puerperal vaginitis* is the commonest form. Some degree of vaginitis during the involution of the uterus and vagina is very common, and this may last for months or years after, thus producing chronic leucorrhœa. If treated early, it is easily cured. The most acute form of vaginitis is *gonorrhœal* (see GONORRHOEA IN THE FEMALE). *Senile vaginitis* is not uncommon, especially in fat, constipated women with gouty tendencies, and in such is often associated with eczema or erythema of the labia.

Vaginitis may also be due to the irritation of pessaries, bits of sponge or wool left in the vagina, &c.; and it may also be due to irritating discharges from the uterus. *Granular or papular vaginitis* is a form met with along with pregnancy and gonorrhœa. Usually both these conditions are present, but there may be one without the other. This form is characterized by the presence in the vagina of hard papules, feeling like shot imbedded in the mucous membrane. The probability is that these papules are inflamed

and enlarged glands; but this has not yet been proved. Very rarely, instead of papules there are *pustules*. Only one case of this is known to the writer—viz., one which he himself observed and published. Another rare form has been observed in Germany, the *emphysematous*, in which there are vesicles containing gas. No such case has been observed in England, but one case of a similar condition affecting the cervix uteri has been published in this country. There is a form which may be described as *painful vaginitis*, in which the discharge is slight, but there is much heat and swelling of the mucous membrane. In this form pain and difficulty in sexual intercourse are prominent symptoms, and are described as varying in degree at different times. Another rare form is *dry vaginitis*, in which there is no discharge, but the mucous membrane is deep red and tender. The writer has observed two cases of vaginitis lasting for months, and peculiar in the profuse discharge of pus which was present, the quantity being in excess of that in gonorrhœa, but there being neither pain nor tenderness and the affection not disappearing after a course of a few weeks, as in gonorrhœa. Vaginitis is sometimes produced by the disease known as *lupus* of the vulva, or *esthiomène*. Lastly, just as by a chill nasal catarrh may be produced, so vaginal catarrh may own a similar origin.

In slight forms of vaginitis the only symptom is a mucous or purulent discharge. In severer forms there may be pain, and there may be also soreness or pruritus. Pain in micturition, from extension of the inflammation to the urethra, is frequent.

Treatment.—If rapid recovery be wished for, the patient should be kept in bed. The secretion should be washed away by a hot douche, as frequently as the patient can be got to use it, and after the douche a mild astringent lotion should be used. Mild astringents frequently repeated are more efficient than the occasional use of strong lotions. Tannic acid (gr. vj ad ʒj), or zinc sulphate (gr. ij ad ʒj) may be used. If there be pain or soreness, a saturated solution of borax or boric acid is best. In a chronic case in which treatment of this kind has been much used, some strong carbolic acid may be poured into a Fergusson's speculum, and then the vagina bathed with it. Care must be taken that it be mopped up before withdrawing the speculum, so that none may go in the

vulva. Laxatives should be given, and alcohol forbidden. If vaginitis be slight and of long duration, its inconveniences are so trivial, and the cure so difficult, that it is better to let it alone.

Cancer.—The vagina is very seldom the seat of primary cancer, although it is common for uterine cancer, as it extends, to involve the vagina. Primary cancer forms a warty growth on the mucous membrane.

Treatment.—If seen while it is yet movable, it should be excised, about $\frac{1}{4}$ inch of healthy mucous membrane round it being removed with it. After it has extended to the submucous tissue only palliative treatment is practicable.

Sarcoma of the vagina is rare. It may form rounded nodules, very much like fibroids, but softer, and unlike fibroids they have no connective tissue capsule. They can in their early stage only be distinguished from fibroids by microscopic examination. After they have begun to break down and ulcerate they clinically resemble cancer.

The only treatment is early removal when possible.

Fibroids of the vagina are rare. They seldom reach a great size. They commonly attract notice by the mechanical inconvenience which they cause, leading to a protrusion, or blocking of the canal. They are encapsuled, so that their removal is usually easy, and is the only treatment.

Prolapse of the anterior vaginal wall with the bladder is called *cystocele*; of the posterior wall with the rectum, *rectocele* (*q.v.*).

Cysts are sometimes seen in the vagina. They are rare, and their mode of origin is disputed. They only cause mechanical inconvenience by their presence if they reach some size. They are seldom larger than a hen's egg.

The treatment is to cut away as much of the cyst wall as possible.

G. E. HERMAN.

VAGINISMUS.—A nervous disease, which consists in hyperæsthesia of the mucous membrane of the vulva.

Symptoms.—In this affection the slightest contact with the mucous membrane provokes cries of pain, and uncontrollable movements having for their object to withdraw the part from contact; and this, although the patient is quite willing to be examined. The tenderness is not limited to one spot, and examination under anæsthesia fails to detect any disease of the vulva. Contact in some cases

provokes not only pain, but spasmodic contraction of the levator ani muscle and narrowing the vagina.

Certain *morbid conditions* of the vulva may cause symptoms like those of vaginismus. Urethral caruncle, fissures of the fourchette, follicular vulvitis, a peculiar disease in which very tender patches of a deep red or purple colour are seen on the mucous membrane of the nymphæ and around the meatus urinarius, lupus of the vulva, abscess in Bartholin's gland, painful vaginitis. These will be distinguished from vaginismus by ascertaining by physical examination the local cause of the trouble. These conditions—both vaginismus and the local conditions subsequently mentioned—although often discovered on marriage, may come on for the first time after years of married life, and after child-bearing.

Treatment.—Vaginismus is a nervous disease which cannot be cured. Even childbirth fails to remove it, but with time it may diminish in severity. It can, however, be greatly relieved, and, for the time, removed, by the local use of cocaine in the form of an ointment, applied to the vulva (gr. xx ad vaseline $\bar{3}$ j). Or as a pessary (cocaine hyd. gr. v, gelatin gr. xx, glycerin ad $\bar{3}$ ij). Cutting operations have been devised, but are quite useless.

G. E. HERMAN.

VENESECTION.—Abstraction of blood from the living body by incision of a superficial vein—a mode of general blood-letting or bleeding.

Although nowadays much less generally resorted to, venesection still deserves confidence as a remedial measure of extreme value in certain diseased conditions; for example—in the early stage of inflammation, such as acute pleuritis and pneumonia, occurring in the plethoric and robust, and when followed by remedies which maintain its immediately sedative effect on the circulation; in acute congestion of the lungs—as when this condition follows exposure during chronic bronchitis or emphysema; in some forms of cerebral congestion; in sunstroke; and in certain varieties of eclampsia; generally when there exists great venous congestion with over-distension and consequent enfeeblement of the right heart, as in poisoning by carbon dioxide; and, perhaps, in those cases where it is intended to abstract from the circulation a certain bulk of poisoned blood in order to substitute for this an equivalent of pure blood or of saline solution by intra-

venous injection. Small bleedings, repeated as required, are also practised to reduce excessive cardiac action and to relieve pain and dyspnoea in some cases of aneurysm, in particular thoracic. The chief general indications for venesection, as afforded by the condition of the circulation, are turgid veins, a small, tense pulse, and a labouring heart. It is not a measure suitable to childhood, old age, or in debilitated conditions of the system.

The operation may be performed, if necessary, upon any superficial vein—as on the dorsum of the foot or hand—but is most readily carried out on one of the veins at the bend of the elbow, preferably on the median cephalic; or, if this cannot be found, on the median basilic (which lies close over the brachial artery).

The patient being, as a rule, seated, a broad bandage is first fastened round the arm above the elbow, so tightly as to compress the superficial veins without stopping the arterial current in the limb. The vein selected is then steadied by the thumb and partly laid open by an oblique, transverse incision, care being taken to make the skin wound larger than that in the vein. The thumb is removed, and the escaping blood is caught and measured in a suitable vessel, none being allowed to fall on the dress or bedclothes of the patient. When a sufficient amount has been drawn, the operator places his thumb over the incision, removes the compressing fillet from above the elbow, and finally seals the wound with a small pledget of lint, which is retained in its place by a few turns of a narrow figure-of-eight bandage, the arm being then placed in a sling for a day or two.

If the jugular vein be opened, the incision should be made from above downwards and inwards, so as to cross the fibres of the platysma, but this form of the operation should be avoided in view of the risks of air entering the circulation, and of other serious complications.

The lancet or scalpel used must be sharp and perfectly clean. The limb should not be moved while the blood is flowing, lest the skin slide over the opening in the vein and thus induce hæmorrhage into the cellular tissue. Nervous patients, and those whose veins are small or ill-filled, should be made to grasp a book or walking-stick before and during the operation.

It is worth bearing in mind that in the case of acute inflammatory conditions of

the abdominal organs, a moderate bleeding from the arm is more effective than the abstraction of a much greater volume of blood from the veins of the abdominal wall, as by leeching; and that, similarly, acute prostatitis is better, more promptly, and more effectually treated by opening two or three veins in the wall of the rectum, by means of a narrow, sharp bistoury, and encouraging subsequent bleeding by tepid injections, than by the application of leeches to the anus.

C. E. SHELLY.

VERTIGO (Giddiness; Dizziness).—“A feeling of uncertainty of our position in space relative to surrounding objects . . . constantly associated with impaired equilibration” (Grainger Stewart).

The equilibrium of the body is believed to be controlled by a centre situated in the cerebellum, which is greatly under the influence of the impressions received by the senses of hearing and sight. The semicircular canals and labyrinth certainly play a most important part in maintaining the equilibrium of the body, and it is probable that the vertigo met with in dyspepsia is due to disturbance of their functions as the centres for the auditory and vagus nerves are in close proximity in the medulla. Vertigo is often associated with other disorders of sensation—*e.g.*, nausea, deafness, tinnitus aurium, dimness of sight, faintness, palpitations, hallucinations, and even loss of consciousness.

Symptoms.—An attack of vertigo may supervene quite suddenly whilst the patient is standing, sitting still, lying down, or walking; not infrequently it occurs during stooping, and it may be transient, persistent or recurrent. Some people complain of giddiness after looking fixedly at an object for some time, or when the eyes are closed. The patient either has a sense that objects are moving round him or that the objects are stationary whilst he is in motion; the direction of the movements being horizontal, vertical, lateral, rotatory, or there may be a sensation of sinking downwards, or the impressions are confused, and the patient feels as if impelled in several directions. The outward result is some degree of reeling, and, if no support be at hand, he may fall down.

Etiology.—The causes of vertigo are many and various. It may accompany almost any disease of the central nervous system, but is most constant in disease of the cerebellum or its peduncles, in which case it is direct and independent of any

ocular trouble; in disease of the pons, crura cerebri, corpora quadrigemina or cortex, it is also met with and may occur independently of any ocular lesion. Paralysis of one ocular muscle, notably the external rectus, is a frequent cause, and vertigo may also result from mere weakness of one of the muscles (muscular asthenopia), as when the eyes are over-tired in myopia. In disseminated sclerosis and locomotor ataxia it is often present and is due chiefly if not entirely to the strabismus. In epilepsy and migraine it is sometimes complained of, also in cases of exhaustion of the nervous system from over-study, mental anxiety, sexual excesses, or from too great indulgence in alcohol or tobacco. In miners' nystagmus vertigo is present, but not in the nystagmus which is congenital or comes on soon after birth, as the patient is then presumably accustomed to and disregards the contradictory impressions he receives. There are, however, other sources of visual giddiness besides strabismus and nystagmus; looking down from a great height causes it in a great many people, whilst some cannot be in a building with a lofty roof without feeling giddy, and in others a strong light will produce it (*see AGORAPHOBIA*). In certain forms of disease of the ear giddiness is the prominent symptom (*see MENIÈRE'S DISEASE*). Giddiness from waltzing is probably due to the disturbance produced in the semicircular canals by the rotation; giddiness from swinging is partly due to this cause and partly to the peculiar sensation caused by the body apparently descending faster than the viscera. In sea-sickness the impressions from the eye, the labyrinth and the muscular sense are all contradictory and combine to produce the vertigo. General anæmia and heart disease, especially aortic valvular disease, are amongst the causes. But in no inconsiderable proportion of cases, the stomach (and probably the liver also) is at fault, and *vertigo a stomacho leso* is a well-recognized condition. There may or may not be organic disease of the stomach, and the attacks vary much in severity; they may come on at any interval after a meal, and sometimes no connection can be traced between the ingestion of food and the onset of an attack, and indeed it may be induced by fasting.

As regards the *diagnosis* it is obvious that a great many of the causes above enumerated will be self-evident if present. The cases that remain would be due either to brain disease, to ear disease, or

to dyspepsia. It must be remembered that the last named is far the most likely cause, and that vomiting, even when persistent and accompanied by headache, is no proof of the existence of brain disease. The presence of tremor would be strongly suggestive of this, however, whilst optic neuritis would be almost conclusive of it. So, too, deafness does not by any means exclude the possibility of the symptoms being due to dyspepsia. Even when no signs of dyspepsia can be elicited the results of treatment will sometimes furnish proof that the stomach was after all the peccant organ.

Treatment.—Careful attention to diet and moderate exercise are the most important points, the bowels should from time to time be acted upon by aloes or an occasional dose of blue pill, and small doses of alkali with gentian, calumba or quassia administered, when the vertigo, if due to gastric disorder, will soon disappear. The treatment of the other forms will depend upon their causation.

JOHN ABERCROMBIE.

VICARIOUS MENSTRUATION

means that the menstrual flow does not take place from the uterus, but *vicariously*, hæmorrhage from some other part replacing that from the uterus. This may now be fairly described as an exploded superstition. No such thing has ever been accurately observed or described.

Cases recorded as examples of it fall into three groups:—(1) Cases in which the only evidence is a vague statement from a patient, unaccompanied by dates. Every case in which a patient making such a statement has been asked to keep a diary, has failed to show a coincidence between the supposed vicarious hæmorrhage and the menstrual period. (2) Cases in which patients lose blood from some diseased part—*e.g.*, lungs or stomach, and in consequence become anæmic and do not menstruate, and think the bleeding is the consequence of the amenorrhœa, instead of its cause. (3) Cases in which, as in purpura, the general vascular tension accompanying menstruation causes hæmorrhage from other parts beside the uterus; that is, menstruation is accompanied by hæmorrhage from other parts, not replaced by it.

Cases in which the menstrual flow is replaced by a flow from some other part do not exist.

G. E. HERMAN.

VOMITING (Emesis).—Forcible expulsion of the contents of the stomach through the œsophagus.

The act of vomiting is produced by the dilatation of the cardiac end of the stomach, immediately followed by a violent expiratory effort. The former is accomplished by the contraction of the longitudinal fibres of the stomach, which by the same means is drawn over towards the diaphragm. The pyloric orifice is at the same time contracted so that the food is expelled only from the cardiac end. In bilious vomiting the contents of the gall-bladder are driven into the duodenum, and find their way through the pylorus, which must be then imperfectly closed. The respiratory effort is performed by the contraction of the diaphragm and abdominal muscles, and is of itself powerless to cause vomiting, but produces only distressing retching when the cardiac end of the stomach is still unopened. On the other hand vomiting becomes impossible when the respiratory muscles are paralysed. Thus there are two necessary factors for the performance of vomiting—dilatation of the cardiac end of the stomach, and forcible contraction of the diaphragm and abdominal muscles. The co-ordinated action of these muscles is regulated by a centre, situated in the floor of the fourth ventricle, and closely related to the respiratory centre. Efferent impulses proceed by the vagi to the longitudinal muscular fibres of the stomach, the phrenics to the diaphragm, and by the intercostals to the abdominal muscles. The centre may be excited by afferent impulses from almost any part of the body, but especially by those originating in the abdominal viscera. It may also be stimulated in a quasi-reflex manner by certain emotional states, and directly by the action of such drugs as tartar emetic and apomorphine.

Most infants, and some adults, vomit with the greatest ease and on very slight provocation, but in others the act of vomiting is generally preceded by symptoms of nausea—*e.g.*, giddiness, pallor of the face and feelings of faintness, coldness of the extremities and a weak pulse. Ineffectual attempts to expel the food may then be made on the part of the respiratory muscles, and they add considerably to the patient's discomfort, which is, however, as a rule, immediately relieved by the occurrence of vomiting.

Clinical Indications.—The irritation of faucial and pharyngeal inflammations sometimes induces vomiting, especially in children, and all kinds of gastric disorder are occasionally attended with the same result. Vomiting frequently occurs in acute catarrhal conditions of the

stomach, and is then associated with a considerable degree of nausea. It generally follows immediately upon the ingestion of food in cases of cancer of the middle of the stomach, but after the space of three or four hours, when the disease is situated at the pylorus. In the latter case the ejected material is usually streaked with blood in different stages of decomposition. The pain caused by the presence of food in cases of gastric ulcer is often relieved by the occurrence of vomiting, which, as a rule, however, only takes place when the pain has reached a certain intensity. The vomit of dilatation of the stomach is characterized by its great abundance, consisting perhaps of three or four meals, and by the presence in it of the *torula cerevisiæ* and *sarcina ventriculi*. Vomiting sometimes happens from compression of the stomach, which may be the result of tight-lacing, the pressure of a tumour, or the frequent application of tools against the epigastrium in certain trades. All cases of strangulated hernia and intestinal obstruction are attended at one time or another with vomiting, which is the more severe and persistent as the disease is more acute. At first merely matters from the stomach are rejected, but very soon these are mixed with bile from the duodenum, and at last the contents of the intestines themselves are regurgitated, from as far down as the seat of obstruction, if this be in the jejunum or ileum. The vomit has then a distinctly faecal odour, and is called "stercoraceous." The occurrence of faecal vomiting was supposed to depend upon a reversal of the normal peristaltic wave, but Dr. Brinton has suggested that the usual peristaltic motion would in cases of obstruction naturally set up two currents within the intestine, an outer one downwards and an inner upwards, so that the feces would at length mix with the bile in the duodenum, and ultimately even with the food in the stomach.

Nausea and vomiting are some of the earliest symptoms of peritonitis, and are common in cases of hepatitis, biliary and renal colic. They are rarely absent in the course of Addison's disease. Combined with diarrhoea, vomiting is a common result of acute and chronic uræmia: or vomiting may alone be present, occurring at first perhaps only in the morning, but afterwards whenever food is taken. It is liable in these cases to prove very persistent and intractable. The ejected matters generally contain

some urea, which, when they are alkaline, is partially decomposed into carbonate of ammonia. The conjunction of these two symptoms, diarrhoea and vomiting, although common enough in infants, should in adults always raise the suspicion of irritant poisoning, when the presence of uræmia has been negatived. It is important to remember that the cough of early phthisis is sometimes attended with vomiting, which may also occur in cases of right-sided pleurisy. The latter has been ascribed to congestive changes in the liver secondary to the inflammation of the diaphragmatic pleura. Occurring in the early morning, vomiting is one of the commonest symptoms of pregnancy, but it occasionally happens in women without any very apparent reason. It is also one of the frequent symptoms of chronic alcoholism.

Vomiting often occurs in the course of certain fevers. It may be a premonitory symptom of scarlatina or variola, and may also occur in the course of typhus and the cold stage of ague. The well-known black vomit of yellow fever owes its colour to the presence of masses of decomposed blood corpuscles, but is only met with in the most severe cases. Choleraic vomiting is often sudden and coincident with or following upon the discharge of the rice-water evacuations, to which the ejected matters are very similar. Sudden pain, such as that resulting from a blow on the testicles, a severe sprain or dislocation, usually causes a feeling of faintness, sometimes followed by vomiting.

Cerebral Vomiting.—As a symptom of brain disease, vomiting is of the greatest importance. It occurs in cases of tumour, meningitis, abscess, increased intra-cranial pressure, at the onset of apoplexy and more especially when the cerebellum is the seat of the lesion. There are no associated symptoms of gastric derangement and usually no preceding sensations of nausea, though these are in rare cases severe. As a rule the food is rejected soon after it has been taken, and it is decidedly uncommon for cerebral vomiting to occur on an empty stomach. It is an early symptom of tumour and meningitis and combined with headache may anticipate by a considerable time the development of further symptoms. Paroxysms of vomiting (gastric crises) sometimes occur in the course of tabes dorsalis. They are generally accompanied with severe pain in the epigastrium and sometimes with nausea. The vomiting may be incessant,

lasting for an hour or two or for two or three days. Recurrences are usually frequent and at irregular intervals, but in the interim there are no gastric symptoms whatever. Vomiting is a frequent result of vertiginous sensations, whether they result from Menière's disease or an injudicious meal; and to the same cause the writer would ascribe the symptoms of sea-sickness. Paroxysms of migraine are sometimes relieved by the occurrence of vomiting, which frequently also follows attacks of convulsions in children. Cases of habitual vomiting, lasting for years, are sometimes met with, in which no efficient cause can be discovered. Food may inevitably be rejected a few minutes after it has been taken, and yet no decided emaciation may be apparent. Such a condition usually occurs in young women in whom there is some evidence of an hysterical tendency and menstrual irregularity. Vomiting frequently occurs during the administration of chloroform, especially when the stomach is full, but it may also take place afterwards, and sometimes proves extremely intractable and alarming.

Treatment.—Vomiting is a symptom rather than a substantive disease, and its treatment is therefore first directed towards relieving the causal affection. This generally consists of some gastric disorder, the vomiting is then amenable to treatment, and the end is attained by the exhibition of remedies which act locally upon the *prima via*. But it is possible to depress the excitability of the vomiting centre by means of such drugs as opium, morphine, bromide of potassium, chloral, and probably hydrocyanic acid and strychnine; most of these exercise also a sedative influence upon the stomach, and should consequently be given by the mouth, when possible. In cases, however, in which the stomach is so irritable as to reject everything swallowed recourse must be made to hypodermic injection and rectal medication. The diet will have to be carefully regulated and it will be often found in severe cases that milk will be tolerated, when administered frequently and in small doses of a tea- to a table-spoonful. Sometimes even this is rejected, and it becomes necessary to give the stomach a complete rest for two or three weeks by the employment of nutritive enemata. The sucking of ice often proves soothing to the patient, and milk and other nutritious fluids are best retained when cool. Counter-irritation or the application of

leeches over the epigastrium is sometimes of value. When the stomach becomes more tolerant, the internal administration of subnitrate of bismuth and bicarbonate of soda, combined perhaps with hydrochlorate of morphine or hydrocyanic acid, tends to diminish the irritability. The action of the bowels should in every case be attended to and carbonate of lime may be added to the bismuth mixture if the motions are loose, and magnesia if there is a tendency to constipation. When the vomiting is accompanied with much flatulence, foul breath and other evidence of putrefactive fermentation, antiseptics are indicated and best administered in the form of creosote or sulphocarbolate of soda. Pepsine, by reason of its digestive power, is a valuable adjunct in some cases and acids, alkalies or bitters are all serviceable at times. Minute doses of tinct. iodi. or ipecacuanha occasionally succeed where other means have failed; and cocaine would probably prove useful sometimes. The vomiting so frequently occurring in infants generally responds to a rectification of the diet, which is commonly at fault, and the administration of bismuth with soda. If the child is not at the breast, the milk should be boiled during the hot summer months and mixed with lime water. The gastro-enteritis of infants is generally attended with such irritability of the stomach that everything swallowed is rejected. These cases are extremely difficult to deal with, but should be treated on the general lines mentioned above; especially is it important to give milk in very small quantities, frequently repeated. The vomiting of organic cerebral disease is little amenable to treatment, but any stomachic trouble should be remedied, as it may tend to stimulate an over-excitable centre. Counter-irritation to the nape of the neck, or ice applied to the same region, sometimes relieves not only the vomiting but also the headache of cerebral tumour. Several modes of treatment will have to be tried in those protracted cases of vomiting occurring in hysterical women, but the shower bath, valerian, and other antispasmodics seem to afford the best means of success. The vomiting of peritonitis, strangulated hernia, intestinal obstruction, renal and hepatic colic must be treated with opium, but in these cases the treatment of the cause is of much more importance than that of a mere symptom. The vomiting of pregnancy usually occurs only in the early

morning and is of little importance, but occasionally it is so severe as to seriously endanger the life of the patient. In severe cases a careful vaginal examination is necessary and an endeavour should be made to rectify any flexion of the uterus that may happen to be present. The local application of nitrate of silver has been recommended when the cervix is inflamed and covered with granular erosions. Besides the ordinary medicinal methods of treatment, oxalate of cerium may be tried, and Chapman's spinal icebag is sometimes of decided value. Stimulants may be urgently called for and none is so good as iced champagne, which is also easily tolerated by the stomach. In certain very rare cases, the induction of abortion becomes necessary, and this expedient is generally followed by an almost immediate relief to the symptoms. Uræmic vomiting must be treated by means of diuretics and sudorifics. The treatment of vomiting dependent upon the action of irritant poisons will be found discussed in the article upon that subject. Vomiting arising from other causes demands no special line of treatment, and must be conducted on general principles.

WM. GAY.

VULVA, DISEASES OF.—**Vulvitis** is common in children from gonorrhœa and from diabetes (see LEUCORRHOEA).

Follicular Vulvitis consists in inflammation of the mucous follicles which are scattered over the vestibule around the urethra, and on the inner surface of the nymphæ. The symptoms are soreness and itching of the parts. On inspection, the inflamed follicles are seen as dark red spots the size of pins' heads, dotting the mucous membrane. It is not common. Nothing is known of its ætiology.

The treatment consists in cleanliness and sedative applications, such as ointments of lead (ung. plumbi subacet. co.), bismuth (3j ad 3j), calomel (P.B.). Under treatment, especially in young subjects, it gets well; but we do not yet know enough of its clinical history to assign any definite period as that within which improvement may be expected. Sometimes it is very obstinate. Alcohol should be forbidden, and laxatives prescribed.

Gangrene of the Vulva, that is, rapid sloughing of the external genitals, is rare, but sometimes occurs. The gangrene is usually symmetrical. It differs from noma, in that it is not a progressive

process preceded by induration. There is death of a portion of the skin and subcutaneous tissues, and this dead part is cast off. It is different also from the creeping molecular disintegration which takes place in phagedæna or hospital gangrene, or the terribly rapid spreading inflammation of gangrenous erysipelas. The causes of this rare event are quite unknown. It may, although it is not usual, appear inclined to spread, and if so, the slough should be separated, and the surface freely cauterized with nitric acid or the actual cautery.

The treatment otherwise consists in supporting the patient's strength, relieving pain, and applying poultices till the slough has separated; afterwards zinc ointment may be used.

Tender Red Patches are sometimes seen on the mucous membrane of the vulva. Their usual situation is just around the anterior half of the vaginal orifice. They vary in colour from a pale brick red to a deep purple. They are extremely tender, and are sometimes, especially in women past the climacteric, accompanied by some contraction of the vaginal orifice, or at least what appears to the patient to be such. The morbid change seems to be closely allied to urethral caruncle, and to the red patches, associated with pain on micturition, that are sometimes seen extending along the urethra. It is important on account of the pain and difficulty, amounting sometimes to impossibility, attending sexual intercourse: and is one of those conditions which are sometimes included under the term vaginismus. In young women it sometimes gets well without treatment. In women past the climacteric it is very obstinate. Nothing is known about its ætiology.

Treatment.—The best treatment is the application of iodoform to the spots.

Various skin diseases: lichen, eczema, erythema, acne, syphilides may affect the skin of the labia. They present no essential differences either as to character or treatment from similar changes in the skin of other parts.

Warts are common on the vulva. They do not occur in clean and chaste women, but they may occur without unchastity in those who are not careful as to cleanliness. From their condition of origin, they often are seen with gonorrhœa. Attempts to communicate them by inoculation have failed. Warts of this kind are acuminate, broadest at the base, pointed at the free surface. They produce discharge and itching of the

parts. If quite small, dusting the parts with a powder of equal parts of calomel and oxide of zinc will make them dry up. If a little larger they may be rubbed with nitrate of silver. If too large to be thus destroyed, they must be cut off with scissors, or if associated with pregnancy, or of such a size that cutting them is likely to cause grave hæmorrhage, the Paquelin cautery knife may be used.

Syphilitic Condylomata are flat, not acuminate, and the free surface often slightly overhangs the base. These should be dusted with calomel, and mercury given internally.

G. E. HERMAN.

VULVA, LUPUS OF (Esthiomène).—Two opinions are held as to the nature of this disease—one, that it is lupus vulgaris, modified by the local conditions of warmth, moisture and vascularity under which it develops. The other, that it is a form of tertiary syphilis. The latter view is supported by the facts that in many cases there is a history of syphilis, and that antisymphilitic treatment is admitted to be the most effective in this disease. Against it is urged, that often no history of syphilis can be obtained, and that with it there is seldom if ever found tertiary syphilitic disease of other parts, or of the bones and periosteum underlying the diseased tissues, and that it sometimes co-exists with lupus vulgaris. As there is this difference of opinion as to the pathology of the disease, it would be better if the French term *Esthiomène*, which implies no theory, were adopted. But "lupus," being more generally used, is employed here.

Symptoms.—The disease begins mostly during the years of menstrual life, between twenty and forty. It is a form of ulceration accompanied by the production of fibrous overgrowths of the surrounding and adjacent tissues. It is very chronic, and whilst in progress at one part it heals at another, producing hard, thick, cicatricial tissue. The presence of healing and the absence of wasting of the body, and, as a rule, of glandular enlargement, mark the essential difference from cancer. It attacks the labia, clitoris, hymen, vestibule, vagina, uterus, groins, perinaeum, anus, and adjacent inner side of the thighs. It progresses by imperceptible disintegration of tissue, not by sloughing. The tissues may be deeply excavated. Ulceration and hypertrophy are not invariably combined; slight degrees of one may

occur without the other, but when either morbid change is extensive, the other is found also. The hypertrophies are hard, fibrous overgrowths: and they may surround a canal so as to form strictures; stricture of the rectum, of the urethra, and of the vagina, may be thus produced. Of these the first is the most common, the last the least so. The disease also renders the mucous membrane adjacent to the disease, but not affected by it, liable to inflammation; and this inflammation, the character of which is marked by its persistence and tendency to recur, may precede the ulceration and the overgrowths. The disease may cause death by hæmorrhage from vessels opened by the ulceration, but this is quite rare. It may also cause death by perforation: thus, when affecting the

uterus it may eat through into the peritoneum; or vaginal lupus may perforate the bladder. These are also rare events. Stricture of the rectum, by the incidents secondary to it, may also cause death.

The *treatment* is to cut off the hypertrophic masses with Paquelin's cautery, and to apply black wash or iodoform to the ulcerations. This is usually followed by improvement: and in slight cases may lead to cure. But in cases of long standing, where the disease is extensive, cure is seldom attained; treatment ameliorates the condition, the advance towards recovery goes a certain distance and then comes to a standstill. This is partly because from the chronic nature of the disease patients do not persevere with treatment.

G. E. HERMAN.

W

WART (Verruca).—Warts are excrescences on the skin formed by circumscribed hypertrophy of its papillary layer covered by thickened epidermis. They vary in size from a pin's head to a large bean, and are always acquired, so-called congenital warts being, indeed, nævi. Warts are flat, rounded or pointed, sessile or pedunculated, coloured like the normal skin or deeply pigmented; they may be smooth on the surface or rough, or split up in a digitate, brush-like manner. They may be solitary, but are generally multiple and sometimes very numerous. They develop chiefly on the fingers and hands in children, on the scalp or about the genitals in adults. Occasionally they arise from the mucous membrane of the mouth or anus, and may extend a considerable distance up the rectum. There is some reason to believe that all forms are more or less contagious, venereal warts being conspicuously so, but individual susceptibility to wart development varies within very wide limits.

Various clinical types are recognized, of which *V. Vulgaris* is by far the commonest, the usual subjects being children, and the seat the hands. They are certainly predisposed to, and aggravated by, personal uncleanness. At first they consist of a small, smooth, hard lump in the skin, the surface of which is unbroken and semi-translucent; soon they become rounded, button-like prominences. As the papillæ continue to hypertrophy, the

cuticle ultimately yields, the surface of the wart becomes rough, irregular, villous and dark in colour, mainly owing to the closely adherent atmospheric impurities. Frequently warts of this class disappear with an altogether inexplicable suddenness, leaving perfectly normal skin. As a rule, they are more obstinate, tending to disappear spontaneously about puberty, but they do not by any means always do so.

V. Digitata is the commoner form in adults. The essential characters are the same as those of *V. vulgaris*, but they usually attack the scalp, especially of women, where they cause great annoyance, as they "catch" the comb, and, being very vascular, often bleed freely. They are usually numerous, soft and very ragged at the extremity.

V. Senilis, Plana vel Sebacea represents the type usually met with in old age, especially in persons of seborrhœic tendency and uncleanly habits. They are commonest over the scalp, back and chest, then on the arms and face, in which latter situation they may closely resemble freckles. They are flat and greasy, always pigmented, and often markedly so, their tint varying from a pale yellow to dark greenish-brown; they are easily detached with the finger-nail, leaving a slight superficial erosion. The papillary hypertrophy is not nearly so marked as in *V. vulgaris* and *V. digitata*. Senile warts, although they give rise to no subjective symptoms, may prove the

starting-point of malignant epitheliomatous growths.

V. Acuminata is the form usually found about the genitals. They develop with great rapidity, and, if uninterfered with, persist indefinitely. They are not syphilitic manifestations, although often associated with them, but result from gonorrhœal, leucorrhœal or other irritating discharges, which accumulate as the consequence of neglect of cleanly precautions. In the male they are generally on or under the prepuce; in the female they are commonest on the inner side of the labia, but usually spread to surrounding regions (clitoris, vagina, perinæum, anus). They are at first soft, bright red in colour, long and pointed; they may be present in very great numbers and attain immense dimensions, becoming cauliflower-like excrescences, which secrete a copious, thin, very offensive, acrid, highly infective, muco-purulent fluid.

Treatment.—Warts in children often disappear rapidly when sulphate of magnesia is given in doses sufficiently large to cause three or four copious motions daily. If the treatment does not prove efficacious in the course of a few days, it may be discontinued, as being useless. Salicylic acid is the most useful local application, and, dissolved in collodion or alcohol (3ss-3j ad 3j), applied night and morning, is generally successful for common, senile and digitate warts. In obstinate cases the acid nitrate of mercury, caustic potash, or glacial acetic acid may be applied with caution. Very pointed warts may be destroyed by electrolysis, which obviates the risk of bleeding, or by the galvanocautery. Warts about the genitals are best treated by rigid cleanliness, constant washing with disinfectant lotions of carbolic acid, alum, or tannin, followed by dusting powders of borax, salicylic acid, talc or calomel. When very large they should be snipped off, the base being cauterized so as to prevent all danger of bleeding.

J. J. PRINGLE.

WHOOPIING COUGH (Pertussis).

—A contagious disease due to the presence of a specific poison, which is probably contained in the mucus discharges from the respiratory tract.

Symptoms.—The period of incubation is usually rather prolonged, lasting about two weeks, but in some instances it has seemed much shorter than this.

The disease may be divided into two stages: The catarrhal or prodromal stage, in which it may be difficult to recognize

anything specific or different from a mere "feverish cold," and a paroxysmal stage.

The Catarrhal or Prodromal Stage.

—The first period is usually of about seven to ten days' duration, but may be much longer, and sometimes lasts only a day or two.

The chief phenomena observed are:—languor or irritability, seldom drowsiness, a temperature not usually rising above 101°, a dry hacking, clanging, or aphonic cough, with a little thickness of the voice. These symptoms are usually worse towards night-time, and even thus early the cough may be more frequent and more spasmodic than the cough of a simple catarrh, and also more liable to be most troublesome in the night-time, waking the patient, especially in the early hours of the morning. The physical signs are simply those of catarrh of the respiratory tract: râles and rhonchi. At the end of a week in well-marked cases the face presents some puffiness, especially about the eyelids, but the urine is very seldom albuminous, and the facial fulness is doubtless the effect of simple congestion from the suffocative character of the cough. At this period also ulcers, of which the base is often covered with a white exudation, may sometimes be seen on or near the frænum, though usually they only appear after the establishment of the paroxysmal stage. These ulcers are of very frequent occurrence, but their correspondence with any projecting tooth and the time of their appearance go to prove that their association with the disease is accidental—not ætiological.

Sometimes the cough is the only sign of the catarrh, but in other cases there may be running from the nose and sneezing. In a typical case the fever subsides in about a week, but not so the cough, which becomes more explosive and more liable to run together into paroxysms, the daily number of which may be very numerous in severe cases.

Paroxysmal Stage.—As these fits of coughing become more pronounced, the mental distress accompanying them increases. The long-drawn inspiration, which always succeeds and occasionally precedes the series of spasmodic expiratory efforts which make up the paroxysm of coughing, becomes audible as the "whooping" or "crowing" sound, from which the disease takes its name. During the early part of the paroxysmal stage, the total duration of which may be four or more weeks, hæmorrhages may

arise from the nose and mouth, from the ears, and, more commonly, into the subconjunctival tissues. A peculiarity of the paroxysm is the ejection of a large quantity of pearly-looking mucus at the end of the fit of coughing; this is expectorated as far as the pharynx, but the quantity is sometimes so large, that even infants, without vomiting, eject the discharge on to the floor. Vomiting is more prone to occur from a whooping paroxysm than from any other species of acute cough. Facts go to prove, not only that hæmorrhages may occur as the result of the paroxysms of coughing, but also that widespread or intense explosions of nervous energy may take place. Convulsions of serious import—squinting, loss of sight, the passage of water and fæces, curious chilly sensations, and sensations of tingling—may attend or follow the fits. The rapid development of a drowsy state is almost as much to be feared as the convulsions. Besides coma and convulsions, sudden collapse may occur, in which the pulse and heart may resemble that found in the algide stage of cholera, but this is rare. That some of these symptoms are due to hæmorrhages into the nervous tissues cannot be doubted, the occurrence of hemiplegia and monoplegia has been recorded. The mental state after the convulsions is variable, even in the same case; instead of listlessness there may rarely be unwonted gaiety, recalling that occasionally noted after true epilepsy.

The face may become much swollen and have a slight mulberry tint; the conjunctivæ may be dingy and suffused, and cutaneous petechiæ may be noted. A whoop by no means always follows each paroxysm, and sometimes only a few whoops may occur throughout the long course of an undoubted case. All children who "whoop" are not suffering from pertussis, as some nervous subjects whoop on the least occasion, as on waking from sleep, in beginning to cry, or during crying. If the lung mischief be marked—*e.g.*, broncho-pneumonia—the whoop may be in abeyance. The precise set of conditions on which whooping depends is not always present, probably a certain force of inspiration and a certain degree of openness of the laryngeal aperture are necessary for its production.

Hæmoptysis is frequent; hæmorrhage from the bowels and emaciation are among the other symptoms in severe cases. Sometimes there is marked wasting from an early period and

independently of the occurrence of vomiting.

Other complications chiefly concern the lungs and pleura. Broncho-pneumonia and pleurisy are very common; pericarditis and laryngitis occur rarely.

The broncho-pneumonia is generally of the disseminated variety, and post-mortem examinations show that it probably originates in collapse. The consolidation has a tendency to persist and pass into fibrotic and caseous conditions, but even after lasting some weeks it may pass away.

Whooping cough often leaves behind it a tendency to the development of the peculiar paroxysmal and whooping character in a subsequent cough, even if due to an ordinary catarrh. It appears certain that this is not a genuine relapse. This habit of body is most easily established in members of neurotic families. Probably, long after the pertussis has subsided the whooping paroxysm may remain as a non-contagious habit.

Diagnosis.—In the first days this may not be possible, as influenza, measles and other catarrhal affections may present identical symptoms; occasionally it appears as though the pertussis were engrafted on an ordinary cold. Mediastinal tumours, including cheesy bronchial glands and pent-up empyemata, may produce a paroxysmal cough indistinguishable from that of whooping cough.

Prognosis depends on so many factors that each case must be considered on its merits. All are agreed that infants only a few months old are bad subjects for the disease. Convulsions and stupor are of grave omen; broncho-pneumonia adds to the seriousness of the case and so does rickets. In very severe cases the voice, whoop and cough may be almost suppressed, as in laryngeal diphtheria, and these signs are of exceedingly grave significance, being often followed by death from asphyxial convulsions. The season of the year exercises considerable influence, the winter being the most unfavourable period, then the spring; but this is chiefly noted in the children of the poor, and arises from the accompanying defective hygiene—vitiating atmosphere and want of warmth.

Pathology and Morbid Anatomy.—In fatal cases collapse and broncho-pneumonia are commonly present. In the latter event the parts about the root of the lung and the middle lobe of the right lung will generally be found to be most severely affected. There may be col-

lapse of the greater part of a lobe or the lesion may occur in scattered patches; emphysema being present elsewhere. Subcutaneous and mediastinal emphysema are also observed in some cases. Besides atelectasis of the lungs, bronchiectasis sometimes occurs, and these two conditions are sometimes associated. The glands about the trachea and roots of the lungs may enlarge and become cheesy and tubercular, the latter affection being a not uncommon sequel of pertussis. Sometimes, though less frequently than after measles, the mucosa of the intestines suffers from catarrh, the abdominal glands swell and tabes mesenterica may result.

Ætiology.—The exact cause of the disease still remains to be discovered, as although fungi and bacteria have been found in the sputa none have yet been proved to be pathogenic. The disease is especially common during the first four years of life, and is much less frequent after the seventh year, but it may occur at any period, the aged not being completely exempt. Female children are much more often attacked than male. A second attack is rare. Although, as a rule, the virus does not travel far, it may probably be conveyed by the clothes of persons not themselves suffering from the disease, although this is doubted by some observers and is certainly of rare occurrence. A child should not mix with others until at least six weeks from the commencement of the whooping, and not then unless the paroxysmal cough has ceased.

Treatment.—Cases presenting a noticeable degree of bronchitis must be kept in bed in a warm room (temp. 60° F.), ventilated without draughts. The treatment of the catarrhal stage is simply that of an ordinary catarrh, modified by the degree of lung complication, which, however, is seldom severe during the prodromal stage. The fresh air in autumn, or at any other season, is better than close confinement, if the child is strong and there are no pulmonary complications. Woollen clothing next the skin is most desirable. During the simple catarrhal stage the chest should be rubbed—front and back and under the arms—with turpentine liniment, night and morning, and a mixture containing carbonate of ammonia and ipecacuanha with some nitrate of potash may be given three or four times a day. A steam spray of carbolie acid appears to be useful in diminishing the frequency of the cough. On the theory that the disease is due to an

organism which first settles on the nasal mucous membrane, various germicide preparations have been used to that part and to the naso-pharynx. A 1 per cent. solution of resorcin may be applied by means of a brush to all parts of the nose and throat every two hours during the day, and even at night if possible, for the first ten days of the case. After this period it would be useless; and other antiseptics should be tried. Finely powdered boric acid, sulphate of quinine, powdered benzoin, salicylic acid and iodoform may be used separately or combined in equal parts, diluted if necessary with fine starch powder; a few grains being used every two or three hours as an insufflation.

During the paroxysmal stage, or after it has passed its first period, there can be but little use in persevering with germicide medicaments. What remains is the nervous element of the disease. Belladonna, prussic acid and bromides are the best nerve restorers or sedatives; small doses should be first prescribed and the dose gradually increased; each remedy should be tried separately; but sometimes the following combination is most successful:—℞ Tinct. belladonna ℥x, potassii cyanidi gr. ʒi, ammonii bromidi gr. ii, spt. amm. arom. ℥v, syr. simpl. ℥xv. aq. ad ʒij; t.d.s.; for a child three years old.

Mopping the pharynx and adjacent parts of the larynx with a 10 per cent. solution of hydrochlorate of cocain, care being used not to overcharge the brush, is sometimes useful. And the fumes from nitre paper and those produced by burning the compound lobelia powder or Himrod's powder appear to diminish the tendency to the paroxysmal attacks. A blister to the back of the neck may be sometimes applied with good effect. Arsenic and change of air are also valuable measures during convalescence.

ANGEL MONEY.

WRITER'S CRAMP (Scrivener's Palsy).—Writer's cramp is the most important member of a large class of diseases called "occupation neuroses." These most usually affect people whose employment consists in the frequent performance of highly specialized coordinated movements, which become impossible on account of the supervention of spasm whenever they are attempted. All other delicate movements may be executed with impunity, but in the later stages of these affections they too may become implicated, especially if

the required muscular combination form part of that primarily affected. The most frequent symptom is spasm, and hence the particular neurosis is generally expressed by affixing the word cramp to the occupation which has given rise to the disease—*e.g.*, “telegraphist’s cramp,” “violinist’s and piano-player’s cramp,” and “writer’s cramp.” There are many others, but the last mentioned is by far the most important member of the group, and will be taken as a type of the family. Several varieties of the affection are met with, in one of which spasm is the most marked feature, and in another pain, which may be referred to the muscles, bones, joints, or to the nerves themselves. Both these symptoms, however, are often present in the same case. Sometimes there is a weakness of some muscle or group of muscles underlying the affection, which at other times is simulated by some organic disease, such as progressive muscular atrophy.

Symptoms.—These are, as a rule, gradually developed. It is perhaps noticed that an unusual feeling of fatigue is experienced in writing, and that a certain amount of effort is necessary to form the letters, which were before formed almost unconsciously. The index finger is apt to slip off the penholder, which is held more tightly than it used to be, and the hand may lie flat upon the paper instead of being held, as normally, three-quarters prone. The fingers feel clumsy, and, with the increasing effort to guide the pen properly, a great amount of unnecessary strength is expended. Spasm of the flexors or extensors soon ensues and, gradually extends, so that after writing a few words the pen makes a splutter and falls from the grasp. Various devices are indulged in to overcome the difficulty. The chief movements may be relegated to the forearm, upper arm and shoulder, and, as they also become involved, to the trunk muscles. The penholder may be grasped between the index and middle, middle and ring fingers, or with the closed fist. The patient is driven from one resource to another, and at length all fail, and he may not be able to form even a single letter. Some, with infinite labour, teach the left hand to write, but that also is often overtaken with the spasm. In some cases it is not so, and the rest thus afforded results in complete recovery of the right hand. In the early stage delicate movements, other than those of writing, may be performed with ease, but with the spread of spasm they also become involved. The muscles

may not be decreased in size, but frequently they are distinctly flabby and the grasp is weak. It is often found that some of them respond less readily to the faradic current than those of the healthy arm, and sometimes too readily to the galvanic. The spasm is usually tonic in character, and comes on during the act of writing or the performance of some movement in which the grouping of muscles is somewhat similar. Spontaneous spasm, not only of the muscles engaged in writing, but of the shoulder and head, has been described in advanced cases. Tremor is sometimes a prominent symptom, and may itself cause the difficulty in writing or be associated with tonic spasm. In some cases the inability to write depends almost entirely upon a feeling of muscular fatigue; in others, upon actual pain, which may be referred to the course of the nerve, where tender points may sometimes be found. The pain, which is distinctly neuralgic in type, may at length come on independently of the act of writing, and in some cases tends to spread. Feelings of “numbness” and “pins-and-needles” are sometimes experienced, and anæsthesia was present in some cases described by Solly. The general health is sometimes good, but very often the patient is neurotic, irritable, and may become so despondent as to attempt suicide.

Diagnosis.—Since the act of writing is one of the most complicated man is called upon to perform, requiring a nice adjustment of nearly all the muscles of the arm, it is one of the first to be disturbed by any incipient disease specially affecting the upper extremity. Hence it is necessary to eliminate disseminated sclerosis, progressive muscular atrophy, neuritis, and even a gradually developing hemiplegia, before making a positive diagnosis in the early course of the disease. In the later stages the condition is quite unmistakable. Another difficulty arises from the fact that people are sometimes conscious of a feeling of fatigue and other sensations after prolonged writing, and, having heard, or probably read, of the affection, fear that it is about to develop. In such cases there is never any spasm, and a few days’ rest relieves the symptoms.

Prognosis.—This is favourable under two conditions—that the disease is treated in an early stage, and that a prolonged rest is possible. Unfortunately, neither condition is fulfilled in most cases, for men whose livelihood depends entirely upon their power of

writing are particularly affected. They refuse, therefore, to give in until absolutely compelled to do so, and hasten back to work as soon as the symptoms are sufficiently alleviated to permit it. Although the prognosis in such cases is extremely bad, recovery sometimes ensues under the most disadvantageous circumstances.

Pathology.—This must be a matter of speculation, for no anatomical changes have yet been discovered. Many observers believe that the starting-point of the affection is a lesion of some muscle or group of muscles, or of the peripheral nerve terminations in them. The act of writing demands a most delicate adjustment of the muscles, especially of the hand and forearm, and the failure of a single muscle, therefore, to respond to the appropriate stimulus causes a want of harmony in the movements, whilst the over-action of the antagonists results in spasm. The exponents of this view point out that there is never any evidence of central change, and assert that, as compared with the healthy side, there is always a diminution of faradic excitability in some one or other of the intrinsic muscles of the hand engaged in grasping the pen, and that, as these are placed *hors de combat*, their functions are performed by others in the forearm, which in their turn fail and are replaced by upper arm, shoulder, and trunk muscles, which also at length succumb to chronic fatigue. Other observers have been unable to subscribe to this theory, because they find that spasm is in many cases the initial symptom, and often at last involves the very muscles which have ultimately become weak. According to their theory, the disease is of central origin, and arises in the following manner:—The education of centres (which may be widely separated from each other) for the performance of any delicate movement is mainly accomplished by lessening the lines of resistance between them, so that the movement, which was at first produced by a considerable mental effort, is at last executed almost unconsciously. If, therefore, through prolonged excitation, this lessened resistance be carried too far, there is an increased and irregular discharge of nerve energy, which gives rise to spasm and disordered movement. According to this view, the muscular weakness is explained by an impairment of nutrition accompanying that of function, and the diminished faradic excitability by the nutritional disturbance

descending the motor nerves. This seems by far the more plausible theory, and is now perhaps most generally accepted.

Ætiology.—There is often a neurotic predisposition, and the disease itself is sometimes inherited, as is illustrated by an instance recorded by Dr. Poore, in which three generations in a direct line were affected. Many patients also have a highly strung nervous temperament, and the onset of the disease can often be traced to some great anxiety or worry. Those are particularly affected whose occupations require prolonged and frequently repeated efforts at writing. Dr. Gowers considers that writing a "cramped hand" is one of the most frequent causes, and accounts for the frequency of the disease among lawyers' clerks. The extremes of life are little liable to writer's cramp, which is most common between the age of twenty and fifty. Males are much more frequently affected than females.

Treatment.—Of all suggested methods of treatment, rest is by far the most important. This does not mean that all movements of the arm must be prohibited, but only those which tend to induce the spasm. Dr. Gowers strongly recommends that patients should be encouraged to cultivate a "running hand," and asserts that, if this were universally adopted, writers' cramp would become almost unknown. Quill nibs or pencils must also be employed instead of hard steel pens. The various devices invented by the patient should not be countenanced, for, although they certainly put off the evil day, they conduce to the spread of the spasm. The left arm may be educated to write, and, for those whose position allows it, a type-writer is of great service, for it affords rest to the affected group of muscles and at the same time enables the patient to write. Internally, nerve tonics, such as strychnine, are useful when a condition of nervousness and irritability seems to underlie the affection, and bromide of potassium is indicated in cases of great restlessness and insomnia. The neuralgic type should be treated with sedatives, both locally and internally, and counter-irritants may be applied over the painful points in the course of the nerves. The application of the galvanic current, short of that which causes muscular contraction, combined with rhythmical movements of the affected muscles, has proved of the greatest service in the hands of Dr. Poore. Massage has also been recom-

mended, and forms the principal feature in a highly successful mode of treatment practised by a non-professional man in

London whose method has been approved by leading physicians in Germany.

WM. GAY.

X

XANTHOMA (*Xanthelasma*; *Vitiligoidea*).—A rare chronic disease of the skin characterized by the presence of flat plates or raised tubercles of a yellowish colour, and due to the development of a new fibro-cellular and fatty growth in the corium.

Two principal clinical varieties are usually recognized, but, as they frequently co-exist, and as there is no essential difference in their pathological characters, they are here described separately merely in accordance with custom.

X. Planum is much the commoner form. Its usual site is the eyelids, beginning in the great majority upon the left side, on the upper lid, and near the inner canthus. From this point it extends outwards along the upper eyelid, downwards to the inner side of the lower lid, then outwards along it, so that in an exaggerated case the eye is surrounded by a ring of disease. The mischief pursues a similar course on the right side, the condition being after a time always bilateral and symmetrical. The initial patches vary in size from a pin's head to a finger nail; they are imbedded in the skin, which is scarcely, if at all, raised by them, and retains its normal suppleness and softness. Their colour varies from a pale lemon-yellow to a deep buff or bright orange, and they have been aptly likened to chamois leather let into the skin. Sometimes the colour of the lesions is so faint that it is necessary to empty them of their blood by stretching before the yellow tinge can be verified. Their margin is well defined and either regular or serrated. No subjective symptoms are produced by the condition, unless it be so extensive as to cause some *gêne* in the movements of the eyelids. Patches have very rarely been observed upon the concha of the ear, the neck, chest, and prepuce. The plane variety is generally found in women of middle or advanced age, especially in those of dark complexion; it is very frequently associated with megrim, various neuralgiæ, menstrual disorders, or "any conditions capable of producing dark areolæ round the eyes" (Hutchinson).

X. Tuberosum vel Multiplex is a rarer condition, more extensive in distribution, and more serious in character than *X. palpebrarum*. It may occur independently, but usually develops in persons suffering from the former variety. Often the extension of the malady is first evidenced by the appearance on the face of plane lesions in regions other than the eyelids, especially round the nostrils, mouth or external auditory meatus. A few sparse and slightly elevated lesions may be present over the trunk, but the most numerous and most characteristically tubercular appear upon the extremities, especially upon their extensor surfaces, and on parts exposed to pressure. The seats of election are the tips of the elbows and knees, the shoulders, the buttocks, the backs of the fingers and toes, the palms and soles. In the two latter situations, as well as round the anus, where the natural lines are deep, the tubercles are arranged along, and exaggerate them. The symmetry of the eruption is generally remarkable. The lesions usually vary in size from a hemp-seed to a pea; they are deeply set in the skin, and project prominently from it; the epidermis over them is smooth and unbroken; they are a little hard to the touch. Sometimes they coalesce to form veritable tumours as large as a hen's egg or small apple. When the case is a severe one, flat xanthoma patches often develop on the mucous membrane of lips, palate, gums, tongue, or fauces, on the œsophagus, stomach, bile ducts, or intestine, on the trachea and bronchi, on the conjunctiva or cornea, on the peritoneum or pleura, or even on the endothelium of the heart and arteries. The development of the disease is usually slow, and the lesions once formed persist permanently without undergoing retrogressive changes. They do not as a rule cause subjective symptoms, but occasionally some pain is evoked by pressure.

X. Multiplex, like *X. planum*, is commoner in women than in men, especially about middle life; sometimes, however, it occurs in early childhood, and it is frequently hereditary, affecting several

members of the same family. The most interesting point in its ætiology is its association with jaundice, which has been noted in at least four-fifths of the published cases, although the exact relationship between the two conditions has not been definitely made out; and mere surmises on the point would here be out of place. In the majority of cases the jaundice precedes the xanthoma by a considerable time—generally by a year or more—but is still present on its development. In a not inconsiderable proportion of cases, however, jaundice has disappeared before the xanthoma lesions appear, while in others a persistent condition of yellow skin—*xanthochromia*—resembling, but not identical with, jaundice is present. The definite hepatic diseases which have been observed in this association are in order of relative frequency, chronic catarrhal obstruction of the biliary ducts, hypertrophic cirrhosis, gall stones, atrophic cirrhosis, and carcinoma; while gout, lithiasis, dyspepsia and similar conditions attributable, perhaps, to functional derangements of the liver are common concomitants. The disease is usually benign, but the internal lesions, especially of the heart and arteries, may occasionally prove fatal.

The *pathological anatomy* of the two varieties differs merely in degree. In both the epidermis and upper layer of the derma is healthy, while the middle and lower layers of the latter are involved by a new growth of connective tissue, the amount of which is small in the flat variety and great in the tuberous. In the meshes of the fibres are numerous multinuclear epithelioid cells, containing much fat, along with crystals of tyrosin and cholesterin, as well as granular pigment which is not confined to the cells.

Treatment is seldom resorted to, as the disease is, in the majority of cases, absolutely benign, but occasionally it is desirable to take away patches from the eyelids, either to remove disfigurement, or to restore impaired movement. Excision is the most suitable procedure, great care being taken that no ectropion results. Painful outgrowths about the elbows have been removed by painting with a 10 per-cent. solution of corrosive sublimate in collodion; and Kaposi states that the troublesome condition of the palms and soles may be greatly benefited by vigorous rubbing with soft soap and by wearing india-rubber gloves and socks.

The disease described as **Xanthoma Diabeticorum** occupies a position as yet unsettled, but its closest affinities are certainly with the foregoing. It differs in the following respects: (1) it is always associated with diabetes mellitus; (2) it develops rapidly and sometimes intermittently; (3) it afterwards diminishes, or even entirely disappears without leaving any trace of its existence; (4) the lesions are denser and firmer than those of true xanthoma; (5) there is sometimes a bright congestive zone round their base, and at the apex they present a yellowish point like pus, but in reality are solid; (6) the tubercles are not generally bright yellow, while some are quite colourless; (7) they are abundant on the elbows and knees, common on the scalp and face, but never exist on the eyelids; (8) there is never jaundice present; (9) itching and tingling are always troublesome symptoms, and sometimes there is great tenderness; (10) although there is fibro-cellular infiltration of the corium, somewhat like that of xanthoma, it is more obviously in connection with the blood-vessels and sweat and sebaceous glands, and the fat and cholesterin characteristic of true xanthoma are absent.

While admitting that the condition presents some analogies to an inflammatory one, the designation of *lichen diabeticorum* suggested by some recent writers seemed peculiarly unhappy, as the disease presents no resemblance or relationship to the strictly demarcated and limited group of lichens.

Treatment must be directed towards the accompanying diabetes, and is often successful in removing or diminishing the growth.

J. J. PRINGLE.

XERODERMA.—A name still unfortunately employed in this country to designate the mildest form of ichthyosis, to which reference may be made. It bears no relation to the disease first described by Kaposi, which is discussed in the following article.

XERODERMA PIGMENTOSUM (*Atrophoderma vel Angioma Atrophicum; Melanosis Lenticularis Progressiva; Kaposi's Disease*).—A very rare condition of the skin, of which only between forty and fifty cases are on record. It usually affects more than one member of a family, or the various members of one sex in the same family, and generally begins in summer.

Symptoms.—In most cases the first

signs observed are minute, measly, erythematous blotches upon parts exposed to the sun (face, neck, arms, legs). These soon disappear, leaving pigment spots like ordinary freckles, but attention is often attracted to these by their depth of colour, close aggregation, and especially by their persistence during winter. The intermediate skin becomes dry, scaly, cracked or slightly eczematous, and capillary dilatations (telangiectases) rapidly form, and heighten the colour of the skin. Gradually the pigment disappears in places, the skin undergoing a spontaneous atrophy, which results in the formation of non-pigmented, glistening scar-tissue. This change usually begins and is most marked on the face, especially about the nose and cheeks, and the ectropion thereby produced is characteristic, materially adding to the disfigurement. Possibly the tears have infective properties; at all events, those parts of the face over which they run, owing to the ectropion, or are wiped by the patient's mopping, undergo most rapid shrinkage, and form the favourite seats for the first development of the malignant, epitheliomatous growths which mark the commencement of the last stage of the disease. These begin

as brownish, warty growths, which even from the first present the microscopic characters of epithelioma. They increase with varying rapidity to form growths of any size, and invade all tissues encountered in their onward march. Ultimately they soften, discharge and fungate.

The disease begins in the first or second years of life, and is often apparently attributable to undue exposure to the sun; it is progressive despite all treatment, and generally causes death from marasmus about puberty; but a considerable proportion of cases have succumbed within a few years, or, on the other hand, have lived to middle age.

Treatment.—Careful attention to the maintenance of cleanliness contributes to the comfort of the patient, and probably the use of white precipitate ointment, to the face especially, retards the advance of the atrophic, cicatricial and ulcerative lesions there. The epithelial growths should be excised or scooped out as soon as they appear, and the wounds thus caused heal kindly. Even large growths may be removed with advantage. Internal remedies exert no influence upon the disease.

J. J. PRINGLE.

Y

YAWNING.—Yawning is a co-ordinated act of considerable complexity, consisting fundamentally of three parts—(1) A prolonged and deep inspiration, accompanied with elevation of the soft palate and uvula, depression of the lower jaw, opening of the mouth, it may be to the fullest extent, and slight retraction of the head; (2) a brief tonic spasm of the muscles concerned in these movements; and (3) a prolonged expiration sometimes combined with a vocal sound. The depressed jaw and open mouth are not essential factors in the act, as those will have discovered, who, in the exigencies of social life, have endeavoured to suppress their yawns. There are several occasional associations, *e.g.*, a click may be heard in the ears, a shiver felt down the back, or, indeed, all over the body, or there may be an almost irresistible impulse to stretch the limbs.

Yawning generally indicates a condition of fatigue and a necessity for rest. It is thus most common at night, but

when sleep is deficient either in quality or quantity, it may actually be most frequent immediately after getting up. It results as readily from mental as from physical fatigue, and is a well-known expression of ennui. One of the strangest characters of yawning is its infectiousness, which is sometimes very striking. As an indication of anxiety it may not infrequently be noticed, and it is then only one of many other evidences of the influence exercised by various emotions upon the respiratory centres. Yawning is one of the earliest of the premonitory symptoms of fainting, and may often be observed in the operating theatre at the commencement of the session. It is very common as a symptom of sea-sickness, and frequently occurs in cases of dyspepsia after the ingestion of food. In a few cases of tetanus persistent yawning has been one of the earliest features of the disease. It is an old observation that the act of yawning is accompanied with extension of the fingers in certain cases of hemiplegia in which

there is absolute paralysis and a strong flexor contracture. No altogether conclusive explanation of the nature of yawning has yet been put forward. Poore has suggested that it is practically a reflex spasm of the depressors of the lower jaw, induced by fatigue of the elevators—a spasm commencing in the region of the fifth nerve and spreading thence into the other territories involved. Such a view is clearly only applicable to yawning as a result of fatigue. The theory enunciated by Hughlings Jackson in regard to the functions of the cerebellum affords a ready explanation of the nature of yawning. He believes, briefly, that the motor functions of the cerebellum are complementary to those of the cerebrum, in such a way that the former represents movements in the order from the general, or most automatic, to the special, or most voluntary, and the latter in the inverse order. Generally speaking then, the peripheral groups of muscles are chiefly subserved by the cerebrum, the central muscular groups by the cerebellum, and the extensors are far more under the influence of the cerebellum than are the more highly specialised flexors. The movements of the lower jaw are looked upon as examples of those belonging to the general rather than to the special type, and are therefore represented in the cerebellum. The extension of the head, the gape, the deep inspiration, and the stretching of the limbs, which is essentially a movement of extension, may all, according to this view, be regarded as of cerebellar origin, and the whole series of events be explained by “a wave of cerebellar influence.”

It must be rare, indeed, that yawning has to be treated *per se*. When too easily induced, however, it may be considered that the recuperative power of the individual is below par; an inquiry should then be made into the method and habits of life of the individual and any irregularity corrected. There is frequently some gastric derangement, which has to be treated on general lines and appropriate tonics may afterwards be prescribed.

WM. GAY.

YELLOW FEVER.—An acute disease, accompanied by jaundice and hæmorrhages, occurring only in certain sub-tropical regions, and due to the action of a specific poison of a nature at present undetermined.

Symptoms.—The incubation period is

stated to vary between one and fourteen days; it is probably usually from one to four days. The onset is sudden, with a sense of chilliness, the temperature rising rapidly to 103° F., or even 105° F.; headache, sacral and lumbar neuralgic pains are frequently complained of, and delirium is not uncommon. Sometimes there is spontaneous vomiting. The bowels are usually sluggish; the urine tends to become scanty or is suppressed, and is often albuminous and contains casts. In the mildest cases the fever may attain its maximum in twelve hours, and recovery may commence at once; in others the maximum temperature may not be attained until the third or fourth day. The pulse is compressible, and not, as a rule, very frequent; perspiration is often a marked feature. After the paroxysm, in all but the mildest cases, a tendency to hæmorrhage is developed, either from the nose, mouth, vagina, kidneys or stomach. About the third day, but it may be the fourth or fifth, the skin and conjunctivæ become of a yellow tint, which will vary in depth according to the severity of the attack, the skin sometimes assuming a deep-olive or mahogany hue. The fæces are not usually clay-coloured. The previous state of health exerts much influence on the course of the disease. The mortality is always rather high, but varies in different epidemics, the percentage of fatal cases being sometimes as low as fifteen, and in other epidemics as high as seventy-five. Fatigue, anxiety, grief, &c., diminish the patient's chances of recovery.

Prognosis.—The gravity of the case will be directly proportionate to the degree of hæmorrhage.

Post-mortem Appearances.—The body is deeply jaundiced, the heart pale and soft, the pleuræ ecchymosed, the lungs may contain infarcts, there may be congestion of the lining membrane of the alimentary canal throughout with hæmorrhagic erosions of the mucous membrane of the stomach, the liver is of a *café-au-lait* colour, and the hepatic cells under the microscope show granular disintegration; the kidneys are enlarged.

Ætiology.—The disease is certainly due to a specific poison, but the organism peculiar to it has not yet been isolated. It is believed by some writers to be allied to the malarial poison which is now known to be due to a micro-organism. It is met with only in epidemics in certain sub-tropical countries, and especially on the West Coast of Africa, America and

the West Indies. The disease is transmissible by the air for a short distance, but may be arrested by a high wall or a running stream; it is transportable by fomites to any distance, and is often borne by vessels from one port to another. Some writers, however, do not admit the contagious nature of the disease. Very few Europeans who are exposed to it escape infection, but the Negroes are much less liable to be attacked. One attack protects against subsequent seizures.

Treatment.—An emetic and a purge of castor oil may be given at the outset. Perspiration should be encouraged by warm drinks and clothing. There is no specific remedy, but quinine may be

given, and, if there be hæmorrhage, perchloride of iron. Until the paroxysm is over, nothing but effervescing drinks should be allowed, and, after that, only milk and barley-water. No solid food should be allowed for at least ten days after an attack, and even then caution is necessary, as fatal relapses have often been induced by indiscretion in the matter of food at a more remote period than this. Where there is much vomiting, ice may be given and the patient be fed by nutrient enemata. The patient must be kept absolutely quiet, and the bedroom be well ventilated. Stimulants, such as iced soda and brandy or iced champagne, may be given freely.

JOHN ABERCROMBIE.

Z

ZINC, Poisoning by.—There are only two salts of zinc of any importance—the sulphate, which is much used as an emetic and is a mild irritant poison, and the chloride. The latter is an irritant and corrosive poison, producing burning and pain in the mouth, throat and epigastrium; vomiting and purging, the vomit and stools sometimes containing blood; cramps, collapse and coma. Perforation of the stomach has been known to occur. In cases that do not prove immediately fatal, the patient may die at a later period from stricture of the œsophagus.

Post-mortem Appearances.—The mucous membrane of the mouth and œsophagus is white and tough, whilst that of the stomach and intestines shows more or less congestion or inflammation.

Treatment.—Vomiting should be encouraged by the administration of warm water, milk and albuminous fluids. The stomach-pump must not be used; carbonate of soda in large quantities is the proper antidote. Milk and eggs may be given freely with tepid water; astringents and morphine are also useful.

ZYMOTIC (from ζυμω, *I ferment*; "zymosis" and the verb from which it is derived occur in Hippocrates).—A word introduced into general use by Dr. William Farr to include the epidemic, endemic, and contagious diseases, and to express their "property of communicating their action, and affecting analogous transformations in other bodies." He included in this class of diseases "all

the principal diseases which have prevailed as epidemics or endemics, and all those which are communicable either by human contact or by animals in a state of disease, as well as the diseases that result from the scarcity and deterioration of the necessary kinds of food or from parasitic animals."

Dr. Farr divided the class of zymotic diseases into four groups or orders—(1) **Miasmatic**, diffusible through air or water and attended by fever; the matter by which they are communicable is derived from the human body (small-pox), or the earth (ague). (2) **Ænthetic**, which may be properly called contagious, as they are communicated by contact, puncture, or inoculation (syphilis, glanders). (3) **Dietetic**, which arise when the blood is supplied with improper food (scurvy, ergotism). (4) **Parasitic**, which may infest the skin, the intestinal canal, or all the tissues of the body.

This classification was, however, to a large extent non-natural, and has passed out of use, the term zymotic disease being now limited in the returns of the Registrar-General to Dr. Farr's first two groups. The diseases now placed under the head of zymotic diseases, and their classification are as follows:—*Miasmatic Diseases*—Small-pox, chicken-pox, measles, epidemic rose rash, scarlet fever, typhus, relapsing fever, influenza, whooping-cough, mumps, diphtheria, cerebrospinal fever, simple and ill-defined fever, enteric fever. *Diarrhæal Diseases*—Cholera, diarrhœa, dysentery. *Malarial*

Diseases—Remittent fever, ague. *Zoögenous Diseases*—Hydrophobia, glanders, splenic fever, cow-pox, and other effects of vaccination. *Veneral Diseases*—Syphilis, gonorrhœa, stricture of urethra. *Septic Diseases*—Phagedæna, erysipelas, pyæmia, septicæmia, puerperal fever.

The term "zymotic diseases" is also taken by the Registrar-General to be an equivalent for the term "specific febrile diseases," and it is in this sense that it is generally understood.

The analogy between fermentation and the infective process was noted by Hippocrates, and the discovery that certain fermentations (as the butyric) and certain diseases (as splenic fever) are due to the growth of bacteria has tended to

increase the force of the analogy. Certain pathogenic microbes (*e.g.*, the bacilli of anthrax and of diphtheria) produce, when grown outside the body, a decomposition of albumen, resulting in the formation of poisonous bodies (alkaloids, and poisonous albumoses). That this action of the bacilli is of the nature of ferment action is generally recognized, and it would therefore appear that in certain febrile diseases the symptoms are due to a form of toxæmia, the toxic bodies being the results of the growth of an organized ferment in the tissues or fluids of the body; in this limited sense then the analogy between the specific febrile process and fermentation holds good.

DAWSON WILLIAMS.

CATALOGUE
OF
MEDICAL, DENTAL,
PHARMACEUTICAL AND SCIENTIFIC PUBLICATIONS,
WITH A SUBJECT INDEX,
PUBLISHED BY
P. BLAKISTON, SON & CO.,
(SUCCESSORS TO LINDSAY & BLAKISTON)
PUBLISHERS, IMPORTERS AND BOOKSELLERS,
1012 WALNUT ST., PHILADELPHIA.

THE FOLLOWING CATALOGUES WILL BE SENT FREE TO ANY ADDRESS,
UPON APPLICATION.

- This Catalogue, No. 1, including all of our own publications.
A Catalogue of Books for Dental Students and Practitioners.
A Catalogue of Books on Chemistry, Technology, Pharmacy, Microscopy, Hygiene, Sanitary Science, etc.
Students' Catalogue, including the "Quiz-Compend" and the most prominent Text-books and Manuals for medical students.
A Complete Classified Catalogue (68 pages) of all Books on Medicine, Dentistry, Pharmacy and Collateral Branches. English and American.
A Monthly Bulletin containing lists of all new Medical Books issued by various publishers.

P. Blakiston, Son & Co.'s publications may be had through Booksellers in all the principal cities of the United States and Canada, or any book will be sent by them, postpaid, upon receipt of the price. They will forward parcels by express, C. O. D., upon receiving a remittance of 25 per cent. of the amount ordered, to cover express charges. Money should be remitted by Express, money order, registered letter, or bank draft.

 All new books received as soon as published. Special facilities for importing books from England, Germany and France.

Gould's New Medical Dictionary now ready. See page 4.

CLASSIFIED LIST, WITH PRICES,

OF ALL BOOKS PUBLISHED BY

P. BLAKISTON, SON & CO., PHILADELPHIA.

When the price is not given below, the book is out of print or about to be published.

Cloth binding, unless otherwise specified. For full descriptions of each book, see following Catalogue.

FROM PROF. J. M. DACOSTA.

"I find it an excellent work, doing credit to the learning and discrimination of the author."

A NEW MEDICAL DICTIONARY.

Small 8vo, Half Morocco, as above, with
Thumb Index, \$4.25
Plain Dark Leather, without Thumb Index, 3.25

A compact, concise Vocabulary, including all the Words and Phrases used in medicine, with their proper Pronunciation and Definitions.

BASED ON RECENT MEDICAL LITERATURE.

BY

GEORGE M. GOULD, A.B., M.D.,

*Ophthalmic Surgeon to the Philadelphia Hospital, Clinical
Chief Ophthalmological Dept. German Hos-
pital, Philadelphia.*

It is not a mere compilation from other dictionaries. The definitions have been made by the aid of the most recent standard text-books in the various branches of medicine. It includes

SEVERAL THOUSAND NEW WORDS NOT CONTAINED IN ANY SIMILAR WORK.

IT CONTAINS TABLES of the ABBREVIATIONS used in Medicine, of the ARTERIES, of the BACILLI, giving the Name, Habitat, Characteristics, etc.; of GANGLIA, LEUCOMAÎNES, MICROCOCCI, MUSCLES, NERVES, PLEXUSES, PTOMAÎNES, with the Name, Formula, Physiological Action, etc.; and the COMPARISON OF THERMOMETERS, of all the most used WEIGHTS AND MEASURES of the world, of the MINERAL SPRINGS OF THE U. S., VITAL STATISTICS, etc. Much of the material thus classified is not obtainable by English readers in any other work.

OPINIONS OF PROMINENT MEDICAL TEACHERS.

"The compact size of this dictionary, its clear type, and its accuracy are unfailing pointers to its coming popularity."—*John B. Hamilton, Supervising Surgeon-General U. S. Marine Hospital Service, Washington.*

"It is certainly as convenient and as useful a volume as can be found, regarding contents as well as arrangement."—*Julius Pohlman, Prof. of Physiology, Medical Dept., Univ. of Buffalo.*

"I have examined it with considerable care, and am very much pleased with it. It is a handy book for reference, and so far as I have examined it, it is accurate in every particular."—*E. H. Bartlev, Prof. of Chemistry, Long Island College Hospital, Brooklyn.*

"I consider this the dictionary of all others for the medical student, and shall see that it is placed on our list of text-books."—*A. R. Thomas, M.D., Dean Hahnemann Medl. Col., Philadelphia.*

"It will be recommended among our text-books in our new catalogue."—*S. E. Chaillé, M.D., Dean Medl. Dept., Tulane Univ., New Orleans.*

"Compact, exact, up to date, and the tables are most excellent and instructive. I prefer it to the larger and older books."—*Prof. C. B. Parker, Medl. Dept., Western Reserve Univ., Cleveland.*

"I have given your 'New Medical Dictionary' a critical examination. Its size has made it convenient to the study table and handy for frequent use. At the same time it is comprehensive as to the number of words, including those of the latest coinage, and concise in its definitions. The etymology and accentuation materially enhance its value, and help to make it worthy a place with the classical books of reference for medical students."—*J. W. Holland, M.D., Dean Jefferson Medl. Col., Phila.*

May be obtained through all Booksellers. Sample pages free.

P. BLAKISTON, SON & CO.'S

Medical and Scientific Publications,

No. 1012 WALNUT ST., PHILADELPHIA.

- ACTON.** *The Functions and Disorders of the Reproductive Organs* in Childhood, Youth, Adult Age and Advanced Life, considered in their Physiological, Social and Moral Relations. By WM. ACTON, M.D., M.R.C.S. 7th Edition. Cloth, \$2.00
- AITKEN.** *Animal Alkaloids, the Ptomaines, Leucomaines and Extractives* in their Pathological Relations. A short summary of recent researches as to the origin of some diseases by or through the physiological processes going on during life. By WILLIAM AITKEN, M.D., F.R.S., Professor of Pathology in the Army Medical School, Netley, England. 2nd Ed. Enlarged. Cloth, \$1.25
- ALLEN.** *Commercial Organic Analysis.* A Treatise on the Modes of Assaying the Various Organic Chemicals and Products employed in the Arts, Manufactures, Medicine, etc., with Concise Methods for the Detection of Impurities, Adulterations, etc. Second Edition. - Vol. I. Alcohols, Ethers, Vegetable Acids, Starch and its Isomers. etc. *Out of Print.*
- Vol. II. Fixed Oils and Fats, Hydrocarbons and Mineral Oils, Phenols and their Derivatives, Coloring Matters, etc. *Out of Print.*
- Vol. III.—Part I. Acid Derivatives of Phenols, Aromatic Acids, Tannins, Dyes, and Coloring Matters. 8vo. Cloth, \$4.50
- ANDERSON.** *A Treatise on Skin Diseases.* With special reference to Diagnosis and Treatment, and including an Analysis of 11,000 consecutive cases. By T. MCCALL ANDERSON, M.D., Professor of Clinical Medicine, University of Glasgow. With several Full-page Plates, two of which are Colored Lithographs, and numerous Wood Engravings. Octavo. 650 pages. Cloth, \$4.50; Leather, \$5.50
- ARCHIVES OF SURGERY.** Edited by JONATHAN HUTCHINSON, F.R.S. Colored Illustrations. Published Quarterly. Per Vol., \$3.00
- ARLT.** *Diseases of the Eye.* Clinical Studies on Diseases of the Eye. Including the Conjunctiva, Cornea and Sclerotic, Iris and Ciliary Body. By Dr. FERD. RITTER VON ARLT, University of Vienna. Authorized Translation by LYMAN WARE, M.D., Surgeon to the Illinois Charitable Eye and Ear Infirmary, Chicago. Illustrated. 8vo. Cloth, \$2.50
- BALLOU.** *Veterinary Anatomy and Physiology.* By WM. R. BALLOU, M.D., Prof. of Equine Anatomy, New York College of Veterinary Surgeons, Physician to Bellevue Dispensary, and Lecturer on Genito-Urinary Surgery, New York Polyclinic, etc. With 29 Graphic Illustrations. 12mo. *No. 12 ? Quiz-Compend Series. ?* Cloth, \$1.00. Interleaved, for the addition of notes, \$1.25
- BAR.** *Antiseptic Midwifery.* The Principles of Antiseptic Methods Applied to Obstetric Practice. By Dr. PAUL BAR, Obstetrician to, formerly Interne in, the Maternity Hospital, Paris. Authorized Translation by HENRY D. FRY, M.D. with an Appendix by the author. Octavo. Cloth, 1.75
- BARNES.** *Lectures on Obstetric Operations,* including the Treatment of Hemorrhage, and forming a Guide to Difficult Labor. By ROBERT BARNES, M.D., F.R.C.P. Fourth Edition. Illustrated. 8vo. Cloth, \$3.75
- BARRETT.** *Dental Surgery* for General Practitioners and Students of Medicine and Dentistry. Extraction of Teeth, etc. By A. W. BARRETT, M.D. Second Edition. Illustrated *Practical Series.* [See page 19.] Cloth, \$1.25
- BARTLEY.** *Medical Chemistry.* Second Edition. A Text-book for Medical and Pharmaceutical Students. By E. H. BARTLEY, M.D., Professor of Chemistry and Toxicology at the Long Island College Hospital; President of the American Society of Public Analysts; Chief Chemist, Board of Health, of Brooklyn, N.Y. Revised and enlarged. With 62 Illustrations. Glossary and Complete Index. 423 pages. 12mo. Cloth, \$2.50

- BEALE.** *On Slight Ailments; their Nature and Treatment.* By LIONEL S. BEALE, M.D., F.R.S., Professor of Practice, King's Medical College, London. Second Edition. Enlarged and Illustrated. 8vo. Cloth, \$1.25
- Urinary and Renal Diseases and Calculous Disorders.** Hints on Diagnosis and Treatment. Demi-8vo. 356 pages. Cloth, \$1.75
- The Use of the Microscope in Practical Medicine.** For Students and Practitioners, with full directions for examining the various secretions, etc., in the Microscope. Fourth Edition. 500 Illustrations. 8vo. Cloth, \$7.50
- How to Work with the Microscope.** A Complete Manual of Microscopical Manipulation, containing a full description of many new processes of investigation, with directions for examining objects under the highest powers, and for taking photographs of microscopic objects. Fifth Edition. Containing over 400 Illustrations, many of them colored. 8vo. Cloth, \$7.50
- Bioplasm.** A Contribution to the Physiology of Life, or an Introduction to the Study of Physiology and Medicine, for Students. Illus. Cloth, \$2.25
- Life Theories and Religious Thought.** Six Colored Plates. Cloth, \$2.00
- On Life and Vital Action in Health and Disease.** 12mo. Cloth, \$2.00
- One Hundred Urinary Deposits,** on eight sheets, for the Hospital, Laboratory, or Surgery. New Edition. 4to. Paper, \$2.00
- BEASLEY'S Book of Prescriptions.** Containing over 3100 Prescriptions, collected from the Practice of the most Eminent Physicians and Surgeons—English, French and American; a Compendious History of the *Materia Medica*, Lists of the Doses of all Official and Established Preparations, and an Index of Diseases and their Remedies. By HENRY BEASLEY. Sixth Edition. Cloth, \$2.25
- Druggists' General Receipt Book.** Comprising a copious Veterinary Formulary; Recipes in Patent and Proprietary Medicines, Druggists' Nostrums, etc.; Perfumery and Cosmetics; Beverages, Dietetic Articles and Condiments; Trade Chemicals, Scientific Processes, and an Appendix of Useful Tables. Ninth Edition. Revised. Cloth, \$2.25
- Pocket Formulary and Synopsis of the British and Foreign Pharmacopœias.** Comprising Standard and Approved Formulæ for the Preparations and Compounds Employed in Medical Practice. Eleventh Edition. Cloth, \$2.25
- BIDDLE'S Materia Medica and Therapeutics.** Eleventh Edition. For the Use of Students and Physicians. By Prof. JOHN B. BIDDLE, M.D., Professor of *Materia Medica* in Jefferson Medical College, Philadelphia. The Eleventh Edition, thoroughly revised, and in many parts rewritten, by his son, CLEMENT BIDDLE, M.D., Assistant Surgeon, U. S. Navy, and HENRY MORRIS, M.D., Demonstrator of Obstetrics in Jefferson Medical College, Fellow of the College of Physicians, of Philadelphia, etc. Cloth, \$4.25; Sheep, \$5.00
- BLACK.** *Micro-Organisms.* The Formation of Poisons by Micro-Organisms. A Biological study of the Germ Theory of Disease. By G. V. BLACK, M.D., D.D.S. Cloth, \$1.50
- BLODGETT'S Dental Pathology.** By ALBERT N. BLODGETT, M.D., Late Professor of Pathology and Therapeutics, Boston Dental College. 33 Illustrations. 12mo. Cloth, \$1.75
- BLOXAM.** *Chemistry, Inorganic and Organic.* With Experiments. By CHARLES L. BLOXAM. Edited by J. M. THOMPSON, Professor of Chemistry in King's College, London, and A. G. BLOXAM, Dem. of Chem., Royal Agricultural College, Cirencester. Seventh Edition. Revised and Enlarged. With 330 Engravings. 8vo. Cloth, \$4.50; Leather, \$5.50
- BOWLBY.** *Injuries and Diseases of the Nerves,* and their surgical treatment. By ANTHONY A. BOWLBY, F.R.C.S., Surgical Registrar and Demonstrator of Practical Surgery at St. Bartholomew's Hospital. Illustrated by 4 Colored and 20 other full-page plates. 8vo. Cloth, \$4.50
- Surgical Pathology and Morbid Anatomy.** 135 Illustrations. Cloth, \$2.00

- BOWMAN.** *Practical Chemistry*, including analysis, with about 100 Illustrations. By Prof. JOHN E. BOWMAN. Eighth English Edition. Revised by Prof. BLOXAM, Professor of Chemistry, King's College, London. Cloth, \$2.00
- BRUBAKER.** *Physiology.* A Compend of Physiology, specially adapted for the use of Students and Physicians. By A. P. BRUBAKER, M.D., Demonstrator of Physiology at Jefferson Medical College, Prof. of Physiology, Penn'a College of Dental Surgery, Philadelphia. Fifth Edition. Revised, Enlarged and Illustrated. *No. 4, Quiz-Compend Series?* 12mo. Cloth, \$1.00
Interleaved for the addition of notes, \$1.25
- BUCKNILL AND TUKE'S Manual of Psychological Medicine:** containing the Lunacy Laws, the Nosology, Ætiology, Statistics, Description, Diagnosis, Pathology (including morbid Histology) and Treatment of Insanity. By JOHN CHARLES BUCKNILL, M.D., F.R.S., and DANIEL HACK TUKE, M.D., F.R.C.P. Fourth Edition. Numerous illustrations. 8vo. Cloth, \$8.00
- BULKLEY.** *The Skin in Health and Disease.* By L. DUNCAN BULKLEY, M.D., Attending Physician at the New York Hospital. Illustrated. Cloth, .50
- BUXTON.** *On Anæsthetics.* A Manual. By DUDLEY WILMOT BUXTON, M.R.C.S., M.R.C.P., Asst. to Prof. of Med., and Administrator of Anæsthetics, University College Hospital, London. *Practical Series.* [See page 19.] Cloth, \$1.25
- BURNETT.** *Hearing, and How to Keep It.* By CHAS. H. BURNETT, M.D., Prof. of Diseases of the Ear, at the Philadelphia Polyclinic. Illustrated. Cloth, .50
- BYFORD.** *Diseases of Women.* The Practice of Medicine and Surgery, as applied to the Diseases and Accidents Incident to Women. By W. H. BYFORD, A.M., M.D., Professor of Gynæcology in Rush Medical College and of Obstetrics in the Woman's Medical College; Surgeon to the Woman's Hospital; Ex-President American Gynæcological Society, etc., and HENRY T. BYFORD, M.D., Surgeon to the Woman's Hospital of Chicago; Gynæcologist to St. Luke's Hospital; President Chicago Gynæcological Society, etc. Fourth Edition. Revised, Rewritten and Enlarged. With 306 Illustrations, over 100 of which are original. Octavo. 832 pages. Cloth, \$5.00; Leather, \$6.00
On the Uterus. Chronic Inflammation and Displacement. Cloth, \$1.25
- CAIRD and CATHCART.** *Surgical Handbook* for the use of Practitioners and Students. By F. MITCHELL CAIRD, M.B., F.R.C.S., and C. WALKER CATHCART, M.B., F.R.C.S., Asst. Surgeons Royal Infirmary. With over 200 Illustrations. 32mo. 400 pages. Pocket size. Leather covers, \$2.50
- CAMERON.** *Oils and Varnishes.* A Practical Handbook, by JAMES CAMERON, F.I.C. With Illustrations, Formulæ, Tables, etc. 12mo. Cloth, \$2.50
Soap and Candles. A New Handbook for Manufacturers, Chemists, Analysts, etc. Compiled from all reliable and recent sources. 54 Illustrations. 12mo. Cloth, 2.25
- CARPENTER.** *The Microscope and Its Revelations.* By W. B. CARPENTER, M.D., F.R.S. Seventh Edition. Revised and Enlarged, with over 500 Illustrations and Lithographs. *New Edition in Press.*
- CAZEAUX and TARNIER'S Midwifery.** With Appendix, by Mundé. Eighth Revised and Enlarged Edition. With Colored Plates and numerous other Illustrations. The Theory and Practice of Obstetrics; including the Diseases of Pregnancy and Parturition, Obstetrical Operations, etc. By P. CAZEAUX, Member of the Imperial Academy of Medicine, Adjunct Professor in the Faculty of Medicine in Paris. Remodeled and rearranged, with revisions and additions, by S. TARNIER, M.D., Professor of Obstetrics and Diseases of Women and Children in the Faculty of Medicine of Paris. Eighth American, from the Eighth French and First Italian Edition. Edited and Enlarged by ROBERT J. HESS, M.D., Physician to the Northern Dispensary, Phila., etc., with an Appendix by PAUL F. MUNDÉ, M.D., Professor of Gynæcology at the New York Polyclinic, and at Dartmouth College; Vice-President American Gynæcological Society, etc. Illustrated by Chromo-Lithographs, Lithographs, and other Full-page Plates, seven of which are beautifully colored, and numerous Wood Engravings. *Students' Edition.* One Vol., 8vo. Cloth, \$5.00; Full Leather, \$6.00

- FOWLER'S** *Dictionary of Practical Medicine.* By Various Writers. An Encyclopaedia of Medicine. Edited by JAMES KINGSTON FOWLER, M.A., M.D., F.R.C.P., Senior Asst. Physician to the Middlesex Hospital and the Hospital for Consumption, Brompton, London. 8vo. *Just Ready.* Cloth, ; Half Morocco,
- FOX.** *Water, Air and Food.* Sanitary Examinations of Water, Air and Food. By CORNELIUS B. FOX, M.D. 110 Engravings. 2d Ed., Revised. Cloth, \$4.00
- FOX AND GOULD.** *Compend on Diseases of the Eye and Refraction*, including Treatment and Surgery. By L. WEBSTER FOX, M.D., Chief Clinical Assistant, Ophthalmological Department, Jefferson Medical College Hospital; Ophthalmic Surgeon, Germantown Hospital, Philadelphia; late Clinical Assistant at Moorfields, London, England, etc., and GEO. M. GOULD, M.D. Second Edition. Enlarged. 71 Illustrations and 39 Formulæ. *Being No. 8, ? Quiz-Compend ? Series.* Cloth, \$1.00. Interleaved for the addition of notes, \$1.25

- FRANKLAND'S Water Analysis.** For Sanitary Purposes, with Hints for the Interpretation of Results. By E. FRANKLAND, M.D., F.R.S. Illustrated. 12mo. Cloth, \$1.00
- FULLERTON. Obstetrical Nursing.** A Handbook for Nurses, Students and Mothers. By ANNA M. FULLERTON, M.D., Demonstrator of Obstetrics in the Woman's Medical College; Physician in charge of, and Obstetrician and Gynæcologist to, the Woman's Hospital, Philadelphia, etc. 34 Illustrations, several of which are original. 12mo. 212 pages. Cloth, \$1.25
- GALABIN'S Midwifery.** A Manual for Students and Practitioners. By A. LEWIS GALABIN, M.D., F.R.C.P., Professor of Midwifery at and Obstetric Physician to, Guy's Hospital, London. 227 Illustrations. Cloth, \$3.00; Leather, \$3.50
- GAMGEE. Wounds and Fractures,** and their Treatment. By SAMPSON GAMGEE, F.R.S.E., etc. Second Edition. 44 Illustrations. 8vo. Cloth, \$3.50
- GARDNER. The Brewer, Distiller and Wine Manufacturer.** A Handbook for all Interested in the Manufacture and Trade of Alcohol and Its Compounds. Edited by JOHN GARDNER, F.C.S. Illustrated. Cloth, \$1.75
Bleaching, Dyeing, and Calico Printing. With Formulæ. Illustrated. \$1.75
Acetic Acid, Vinegar, Ammonia and Alum. Illustrated. Cloth, \$1.75
- GARROD. On Rheumatism.** A Treatise on Rheumatism and Rheumatic Arthritis. By ARCHIBALD EDWARD GARROD, M.A. Oxon., M.D., M.R.C.S. Eng., Asst. Physician, West London Hospital. Illustrated. Octavo. Cloth, \$6 00
- GIBBES'S Practical Histology and Pathology.** By HENEAGE GIBBES, M.B. 12mo. Third Edition. Cloth, \$1.75
- GILLIAM'S Pathology.** The Essentials of Pathology; a Handbook for Students. By D. TOD GILLIAM, M.D., Professor of Physiology, Starling Medical College, Columbus, O. With 47 Illustrations. 12mo. Cloth, \$2.00
- GLISAN'S Modern Midwifery.** A Text-book. By RODNEY GLISAN, M.D., Emeritus Professor of Midwifery and Diseases of Women and Children in Willamette Univ., Portland, Oregon. 129 Illus. 8vo. 2d Edition. Cloth, \$3.00
- GOODHART and STARR'S Diseases of Children.** The Student's Guide to the Diseases of Children. By J. F. GOODHART, M.D., F.R.C.P., Physician to Evelina Hospital for Children; Demonstrator of Morbid Anatomy at Guy's Hospital. Second American from the Third English Edition. Rearranged and Edited, with notes and additions, by LOUIS STARR, M.D., Clinical Professor of Diseases of Children in the University of Pennsylvania; Physician to the Children's Hospital. With many new prescriptions. Cloth, \$3.00; Leather, \$3.50
- GORGAS'S Dental Medicine.** A Manual of Materia Medica and Therapeutics. By FERDINAND J. S. GORGAS, M.D., D.D.S., Professor of the Principles of Dental Science, Dental Surgery and Dental Mechanism in the Dental Department of the University of Maryland. Third Edition. Enlarged. 8vo. Cloth, \$3.50
- GOULD'S New Medical Dictionary.** Including all the Words and Phrases used in Medicine, with their proper Pronunciation and Definitions, based on Recent Medical Literature. By GEORGE M. GOULD, B.A., M.D., Ophthalmic Surgeon to the Philadelphia Hospital, etc., With Tables of the Bacilli, Micrococci, Leucomaines, Ptomaines, etc., of the Arteries, Muscles, Nerves, Ganglia and Plexuses; Mineral Springs of U. S., Vital Statistics, etc. Small octavo, 520 pages. Half Dark Leather, \$3.25; Half Morocco, Thumb Index, \$4.25
- GOWERS, Manual of Diseases of the Nervous System.** A Complete Text-book. By WILLIAM R. GOWERS, M.D., Prof. Clinical Medicine, University College, London. Physician to National Hospital for the Paralyzed and Epileptic. 341 Illustrations and 1360 pages. Octavo. Cloth, \$6.50; Leather, \$7.50

This work is published in two volumes in London. By special arrangement with the author, we have reprinted it in one, using the original illustrations.

GOWERS, Diagnosis of Diseases of the Brain. 8vo. Second Edition. Illustrated. Cloth, \$2.00

Diagnosis of Diseases of the Spinal Cord. 4th Edition. *Preparing.*

Medical Ophthalmoscopy. A Manual and Atlas, with Colored Autotype and Lithograph Plates of Original Drawings, Wood Cuts, etc. 3d Edition, revised by DR. W. S. COLMAN. Octavo. *In Press.*

Syphilis and the Nervous System. Being the Lettsomian Lectures for 1889. 8vo. *In Press.*

GROSS'S Biography of John Hunter. John Hunter and His Pupils. By Professor S. D. GROSS, M.D. With a Portrait. 8vo. Paper, .75; Cloth, \$1.25

GREENHOW. Addison's Disease. Illustrated by Plates and Reports of Cases. By E. HEADLAM GREENHOW, M.D. 8vo. Cloth, \$3.00

Chronic Bronchitis, especially as connected with Gout, Emphysema, and Diseases of the Heart. 12mo. Paper, .75; Cloth, \$1.25

GRIFFITH'S Graphic Clinical Chart. Designed by J. P. CROZER GRIFFITH, M.D., Instructor in Clinical Medicine in the University of Pennsylvania. *Printed in three colors.* Sample copies free. Put up in loose packages of 50, \$.50
Price to Hospitals, 500 copies, \$4.00; 1000 copies, \$7.50. With name of Hospital printed on, 50 cents extra.

GROVES AND THORP. Chemical Technology. A new and Complete Work. The Application of Chemistry to the Arts and Manufactures. Edited by CHARLES E. GROVES, F.R.S., and WM. THORP, B.Sc., F.I.C. In about eight volumes, with numerous illustrations. *Each volume sold separately.*

Vol. I. FUEL. By Dr. E. J. MILLS, F.R.S., Professor of Chemistry, Anderson College, Glasgow; and Mr. F. J. ROWAN, assisted by an American expert. 607 Illustrations and 4 plates. Octavo. Cloth, 7.50; Half Morocco, \$9.00

HABERSHON. On Some Diseases of the Liver. By S. O. HABERSHON, M.D., F.R.C.P., late Senior Physician to Guy's Hospital. A New Edition. Cloth, \$1.50

HADDON'S Embryology. An Introduction to the Study of Embryology. For the Use of Students. By A. C. HADDON, M.A., Prof. of Zoölogy, Royal College of Science, Dublin. 190 Illustrations. Cloth, 6.00

HALE. On the Management of Children in Health and Disease. A Book for Mothers. By AMIE M. HALE, M.D. New Enlarged Edition. 12mo. Cloth, .75

HARE. Mediastinal Disease. The Pathology, Clinical History and Diagnosis of Affections of the Mediastinum other than those of the Heart and Aorta, with tables giving the Clinical History of 520 cases. The essay to which was awarded the Fothergillian Medal of the Medical Society of London, 1888. By H. A. HARE, M.D. (Univ. of Pa.), Demonstrator of Therapeutics and Instructor in Physical Diagnosis in the Medical Department, and Instructor in Physiology in the Biological Department, Univ of Pa. 8vo. Illustrated by Six Plates. Cloth, \$2.00

HARLAN. Eyesight, and How to Care for It. By GEORGE C. HARLAN, M.D., Prof. of Diseases of the Eye, Philadelphia Polyclinic. Illustrated. Cloth, .50

HARLEY. Diseases of the Liver, With or Without Jaundice. Diagnosis and Treatment. By GEORGE HARLEY, M.D. With Colored Plates and Numerous Illustrations. 8vo. Price reduced. Cloth, \$3.00; Leather, \$4.00

HARRIS. On the Chest. Including the Principal Affections of the Pleuræ, Lungs, Pericardium, Heart and Aorta. By VINCENT D. HARRIS, F.R.C.P., Physician to the Victoria Park Hospital for Diseases of the Chest, London. With 55 Illustrations. Cloth, \$2.50

- HARRIS'S Principles and Practice of Dentistry.** Including Anatomy, Physiology, Pathology, Therapeutics, Dental Surgery and Mechanism. By CHAPIN A. HARRIS, M.D., D.D.S., late President of the Baltimore Dental College, author of "Dictionary of Medical Terminology and Dental Surgery." Twelfth Edition. Revised and Edited by FERDINAND J. S. GORGAS, A.M., M.D., D.D.S., author of "Dental Medicine;" Professor of the Principles of Dental Science, Dental Surgery and Dental Mechanism in the University of Maryland. Two Full-page Plates and 1086 Illustrations. 1225 pages. 8vo. Cloth, \$7.00; Leather, \$8.00
- Medical and Dental Dictionary.** A Dictionary of Medical Terminology, Dental Surgery, and the Collateral Sciences. Fourth Edition, carefully Revised and Enlarged. By FERDINAND J. S. GORGAS, M.D., D.D.S., Prof. of Dental Surgery in the Baltimore College. 8vo. Cloth, \$6.50; Leather, \$7.50
- HARTRIDGE. Refraction.** The Refraction of the Eye. A Manual for Students. By GUSTAVUS HARTRIDGE, F.R.C.S., Consulting Ophthalmic Surgeon to St. Bartholomew's Hospital; Ass't Surgeon to the Royal Westminster Ophthalmic Hospital, etc. 96 Illustrations and Test Types. Fourth Edition. Cloth, \$2.00
- HARTSHORNE. Our Homes.** Their Situation, Construction, Drainage, etc. By HENRY HARTSHORNE, M.D. Illustrated. Cloth, .50
- HATFIELD. Diseases of Children.** By MARCUS P. HATFIELD, Professor of Diseases of Children, Chicago Medical College. *Being No. 14, ? Quiz-Compend ? Series.* 12mo. Cloth, \$1.00
Interleaved for the addition of notes, 1.25
- HEADLAND'S Action of Medicines.** On the Action of Medicines in the System. By F. W. HEADLAND, M.D. Ninth American Edition. 8vo. Cloth, \$3.00
- HEATH'S Operative Surgery.** A Course of Operative Surgery, consisting of a Series of Plates, Drawn from Nature by M. Léveillé, of Paris. With Descriptive Text of Each Operation. By CHRISTOPHER HEATH, F.R.C.S., Holme Professor of Clinical Surgery in University College, London. Quarto. Second Edition. Revised. *Sold by Subscription.* Cloth, \$12.00
- Minor Surgery and Bandaging.** Ninth Edition. Revised and Enlarged. With 142 Illustrations. 12mo. Cloth, \$2.00
- Practical Anatomy.** A Manual of Dissections. Seventh London Edition. 24 Colored Plates, and nearly 300 other Illustrations. Cloth, \$5.00
- Injuries and Diseases of the Jaws.** Third Edition. Revised, with over 150 Illustrations. 8vo. Cloth, \$4.50
- Lectures on Certain Diseases of the Jaws,** delivered at the Royal College of Surgeons of England, 1887. 64 Illustrations. 8vo. Boards, \$1.00
- HENRY. Anæmia.** A Practical Treatise. By FRED'K P. HENRY, M.D., Prof. Clinical Med. Phila. Polyclinic, Physician to Episcopal and Phila. Hospitals, to Home for Consumptives, etc. 12mo. Half Cloth, .75
- HIGGENS' Ophthalmic Practice.** A Manual for Students and Practitioners. By CHARLES HIGGENS, F.R.C.S. Ophthalmic Surgeon at Guy's Hospital. *Practical Series. See Page 19.* Cloth, \$1.75
- Ophthalmic Practice.** A Handbook. Second Edition. 32mo. Cloth, .50
- HILL AND COOPER. Venereal Diseases.** The Student's Manual of Venereal Diseases, being a concise description of those Affections and their Treatment. By BERKELEY HILL, M.D., Professor of Clinical Surgery, University College, and ARTHUR COOPER, M.D., Late House Surgeon to the Lock Hospital, London. 4th Edition. 12mo. Cloth, \$1.00
- HILLIER. Diseases of Children.** A Clinical Treatise. By THOMAS HILLIER, M.D. 8vo. Cloth, \$1.25

HOLDEN'S Anatomy. A Manual of the Dissections of the Human Body. By LUTHER HOLDEN, F.R.C.S. Fifth Edition. Carefully Revised and Enlarged. Specially concerning the Anatomy of the Nervous System, Organs of Special Sense, etc. By JOHN LANGTON, F.R.C.S., Surgeon to, and Lecturer on Anatomy at, St. Bartholomew's Hospital. 208 Illustrations. 8vo.

Oilcloth Covers, for the Dissecting Room, \$4.50; Cloth, \$5.00; Leather, \$6.00

Human Osteology. Comprising a Description of the Bones, with Colored Delineations of the Attachments of the Muscles. The General and Microscopical Structure of Bone and its Development. JONES' Aural Surgery. A Practical Handbook on Aural Surgery. By H. MACNAUGHTON JONES, M.D., Surgeon to the Cork Ophthalmic and Aural Hospital. Illustrated. Second Edition, with new Wood Engravings. 12mo. Cloth, \$2.75

- JOURNAL of Laryngology and Rhinology.** A Monthly Analytical Record, devoted to Diseases of the Throat and Nose. Edited by MORELL MACKENZIE, M.D. *Sample Nos., 25 cents.* Subscription per annum, \$3.00
- KEATING. How to Examine for Life Insurance.** A Practical Handbook. By JOHN M. KEATING, President of the Association of Life-Insurance Medical Directors. With 3 Full-page Plates and other Illustrations. 8vo. Cloth, *net*, \$2.00
- KIRKES' Physiology.** (*Authorized Edition.*) A Handbook of Physiology. Twelfth London Edition, Revised and Enlarged. By W. MORRANT BAKER, M.D. 460 Illustrations. 12mo. Cloth, \$4.00; Leather, \$5.00
- LANDIS' Compend of Obstetrics ;** especially adapted to the Use of Students and Physicians. By HENRY G. LANDIS, M.D., Professor of Obstetrics and Diseases of Women, in Starling Medical College, Columbus, Ohio. Fourth Edition. Enlarged. With Many Illustrations. *No. 5 ? Quiz-Compend ? Series.* Cloth, \$1.00; interleaved for the addition of Notes, \$1.25
- LANDOIS. A Text-Book of Human Physiology ;** including Histology and Microscopical Anatomy, with special reference to the requirements of Practical Medicine. By DR. L. LANDOIS, Professor of Physiology and Director of the Physiological Institute in the University of Greifswald. Third American, translated from the Sixth German Edition, with additions, by WM. STIRLING, M.D., D.Sc., Brackenbury Professor of Physiology and Histology in Owen's College, Manchester ; Examiner in Physiology in University of Oxford, England. With 692 Illustrations. 8vo. Cloth, \$6.50; Leather, \$7.50
- LEBER AND ROTTENSTEIN. Dental Caries and Its Causes.** An Investigation into the Influence of Fungi in the Destruction of the Teeth. By Drs. LEBER and ROTTENSTEIN. Illustrated. Paper, .75; Cloth, \$1.25
- LEE. The Microtomist's Vade Mecum.** Second Edition. A Handbook of Methods of Microscopical Anatomy. By ARTHUR BOLLES LEE, Asst. in the Russian Laboratory of Zoölogy, at Villefranche-sur-Mer (Nice). 660 Formulæ, etc. Enlarged and Revised. Cloth, \$4.00
- LEFFMANN'S Compend of Chemistry, Inorganic and Organic.** Including Urine Analysis. By HENRY LEFFMANN, M.D., Prof. of Chemistry and Metallurgy in the Penna. College of Dental Surgery, and in the Wagner Free Institute of Science, Philadelphia. *No. 10 ? Quiz-Compend ? Series.* Third Edition. Rewritten and Adapted for Students of Medicine and Dentistry. 12mo. Cloth, \$1.00. Interleaved for the addition of Notes, \$1.25
- LEFFMANN & BEAM. Examination of Water for Sanitary and Technical Purposes.** By HENRY LEFFMANN, M.D., Professor of Chemistry and Metallurgy, Penna. College of Dental Surgery, Hygienist and Food Inspector Penna. State Board of Agriculture, etc.; and WILLIAM BEAM, A.M., formerly Chief Chemist B. & O. R. R. Illustrated. 12mo. Cloth, \$1.25
- LEGG on the Urine.** Practical Guide to the Examination of the Urine, for Practitioner and Student. By J. WICKHAM LEGG, M.D. Sixth Edition, Enlarged. Illustrated. 12mo. Cloth, .75
- LEWERS. On the Diseases of Women.** Second Edition. With over 120 Engravings. *Practical Series. See Page 19.* 12mo. Cloth, \$2.50
- LEWIN on Syphilis.** The Treatment of Syphilis. By Dr. GEORGE LEWIN, of Berlin. Translated by CARL PROEGLER, M.D., and E. H. GALE, M.D., Surgeons U. S. Army. Illustrated. 12mo. Paper, .75; Cloth, \$1.25
- LEWIS, (BEVAN). Mental Diseases.** A text-book having special reference to the Pathological aspects of Insanity. By BEVAN LEWIS, L.R.C.P., M.R.C.S., Medical Director, West Riding Asylum, Wakefield, England. 18 Lithographic plates and other Illustrations. 8vo. Cloth, \$6.00
- LIEBREICH'S Atlas of Ophthalmoscopy,** composed of 12 Chromo-Lithographic Plates (containing 59 Figures), with Text. Translated by H. R. SWANZY, M.D. Third Edition. 4to. Boards, \$15.00
- LINCOLN. School and Industrial Hygiene.** By D. F. LINCOLN, M.D. Cloth, .50
- LIZARS, (JOHN). On Tobacco.** The Use and Abuse of Tobacco. Cloth, .50

- LONGLEY'S Pocket Medical Dictionary** for Students and Physicians. Giving the Correct Definition and Pronunciation of all Words and Terms in General Use in Medicine and the Collateral Sciences, with an Appendix, containing Poisons and their Antidotes, Abbreviations Used in Prescriptions, and a Metric Scale of Doses. By ELIAS LONGLEY. Cloth, \$1.00; Tucks and Pocket, \$1.25
- LÜCKES. Hospital Sisters and their Duties.** By EVA C. E. LÜCKES, Matron to the London Hospital; Author of "Lectures on Nursing." 12mo. Cloth, \$1.00
- MAC MUNN. Chemistry of Urine. Illustrated.** Outlines of the Clinical Chemistry of Urine. By C. A. MAC MUNN, M.A., M.D., Dublin. Sixty-four Woodcuts and Plate of Spectra. Octavo. \$3.00
- On the Spectroscope in Medicine. With 3 Chromo-lithographic Plates of Physiological and Pathological Spectra, and 13 Wood Cuts. Cloth, \$3.00
- MACNAMARA. On the Eye.** A Manual of the Diseases of the Eye. By C. MACNAMARA, M.D. Fourth Edition, Carefully Revised; with Additions and Numerous Colored Plates, Diagrams of Eye, Wood-cuts, and Test Types. Demi 8vo. Cloth, \$4.00
- MACALISTER'S Human Anatomy. 800 Illustrations.** A New Text-book for Students and Practitioners. Systematic and Topographical, including the Embryology, Histology and Morphology of Man. With special reference to the requirements of Practical Surgery and Medicine. By ALEX. MACALISTER, M.D., F.R.S., Professor of Anatomy in the University of Cambridge, England; Examiner in Zoölogy and Comparative Anatomy, University of London; formerly Professor of Anatomy and Surgery, University of Dublin. With 816 Illustrations, 400 of which are original. Octavo. Cloth, \$7.50; Leather, \$8.50
- MACDONALD'S Microscopical Examinations** of Water and Air. A Guide to the Microscopical Examination of Drinking Water, with an Appendix on the Microscopical Examination of Air. By J. D. MACDONALD, M.D. With 25 Lithographic Plates, Reference Tables, etc. Second Ed., Revised. 8vo. Cloth, \$2.75
- MACKENZIE. The Œsophagus, Nose, Naso-Pharynx, etc.** By SIR MORELL MACKENZIE, M.D., Senior Physician to the Hospital for Diseases of the Chest and Throat, London. Illus. Being Vol. II of the First Edition of his Treatise on the Throat and Nose. Complete in itself. Cloth, \$3.00; Leather, \$4.00
- The Pharmacopœia** of the Hospital for Diseases of the Throat and Nose. Fourth Edition, Enlarged, Containing 250 Formulæ, with Directions for their Preparation and Use. 16mo. Cloth, \$1.25
- MANN'S Manual of Psychological Medicine** and Allied Nervous Diseases. Their Diagnosis, Pathology, Prognosis and Treatment, including their Medico-Legal Aspects; with chapter on Expert Testimony, and an abstract of the laws relating to the Insane in all the States of the Union. By EDWARD C. MANN, M.D., member of the New York County Medical Society. With Illustrations of Typical Faces of the Insane, Handwriting of the Insane, and Micro-photographic Sections of the Brain and Spinal Cord. Octavo. Cloth, \$5.00; Leather \$6.00
- MARSHALL'S Physiological Diagrams, Life Size, Colored.** Eleven Life-size Diagrams (each 7 feet by 3 feet 7 inches). Designed for Demonstration before the Class. By JOHN MARSHALL, F.R.S., F.R.C.S., Professor of Anatomy to the Royal Academy; Professor of Surgery, University College, London, etc.
- In Sheets Unmounted, \$40.00
Backed with Muslin and Mounted on Rollers, \$60.00
Ditto, Spring Rollers, in Handsome Walnut Wall Map Case (Send for Special Circular), \$100.00
Single Plates, Sheets, \$5.00; Mounted, \$7.50; Explanatory Key, 50 cents.
- No. 1—The Skeleton and Ligaments. No. 2—The Muscles and Joints, with Animal Mechanics. No. 3—The Viscera in Position. The Structure of the Lungs. No. 4—The Heart and Principal Blood-vessels. No. 5—The Lymphatics or Absorberents. No. 6—The Digestive Organs. No. 7—The Brain and Nerves. Nos. 8 and 9—The Organs of the Senses. Nos. 10 and 11—The Microscopic Structure of the Textures and Organs.

- MARSHALL & SMITH.** *On the Urine.* The Chemical Analysis of the Urine. By JOHN MARSHALL, M.D., and Prof. EDGAR F. SMITH, of the Chemical Laboratories, University of Pennsylvania. Phototype Plates. 12mo. Cloth, \$1.00
- MASON'S** *Compend of Electricity*, and its Medical and Surgical Uses. By CHARLES F. MASON, M.D., Assistant Surgeon U. S. Army. With an Introduction by CHARLES H. MAY, M.D., Instructor in the New York Polyclinic. Numerous Illustrations. 12mo. Cloth, \$1.00
- MAXWELL.** *Terminologia Medica Polyglotta.* By Dr. THEODORE MAXWELL, assisted by others in various countries. 8vo. Cloth, \$4.00
- The object of this work is to assist the medical men of any nationality in reading medical literature written in a language not their own. Each term is usually given in seven languages, viz.: English, French, German, Italian, Spanish, Russian and Latin.
- MAYS' Therapeutic Forces**; or, The Action of Medicine in the Light of the Doctrine of Conservation of Force. By THOMAS J. MAYS, M.D. Cloth, \$1.25
- Theine in the Treatment of Neuralgia.** Being a Contribution to the Therapeutics of Pain. 16mo. ½ bound, .50
- MEADOWS' Obstetrics.** A Text-Book of Midwifery. Including the Signs and Symptoms of Pregnancy, Obstetric Operations, Diseases of the Puerperal State, etc. By ALFRED MEADOWS, M.D. Third American, from Fourth London Edition. Revised and Enlarged. With 145 Illustrations. 8vo. Cloth, \$2.00
- MEDICAL Directory of Philadelphia and Camden, 1889.** Containing lists of Physicians of *all Schools of Practice*, Dentists, Veterinarians, Druggists and Chemists, with information concerning Medical Societies, Colleges and Associations, Hospitals, Asylums, Charities, etc. Morocco, Gilt edges, \$2.50
- MEIGS.** *Milk Analysis and Infant Feeding.* A Practical Treatise on the Examination of Human and Cows' Milk, Cream, Condensed Milk, etc., and Directions as to the Diet of Young Infants. By ARTHUR V. MEIGS, M.D., Physician to the Pennsylvania Hospital, Philadelphia. 12mo. Cloth, \$1.00
- MEIGS and PEPPER on Children.** A Practical Treatise on the Diseases of Children. By J. FORSYTH MEIGS, M.D., Fellow of the College of Physicians of Philadelphia, etc., etc., and WILLIAM PEPPER, M.D., Professor of the Principles and Practice of Medicine in the Medical Department, University of Pennsylvania. Seventh Edition. Cloth, \$5.00; Leather, \$6.00
- MERRELL'S Digest of Materia Medica.** Forming a Complete Pharmacopœia for the use of Physicians, Pharmacists and Students. By ALBERT MERRELL, M.D. Octavo. Half dark Calf, \$4.00
- MEYER.** *Ophthalmology.* A Manual of Diseases of the Eye. By DR. EDOUARD MEYER, Prof. à L'École de la Faculté de Médecine de Paris, Chev. of the Legion of Honor, etc. Translated from the Third French Edition, with the assistance of the author, by A. FREEDLAND FERGUS, M.B., Assistant Surgeon Glasgow Eye Infirmary. With 270 Illustrations, and two Colored Plates prepared under the direction of DR. RICHARD LIEBREICH, M.R.C.S., Author of the "Atlas of Ophthalmoscopy." 8vo. Cloth, \$4.50; Leather, \$5.50
- MILLER and LIZAR'S Alcohol and Tobacco.** Alcohol. Its Place and Power. By JAMES MILLER, F.R.C.S.; and, Tobacco, Its Use and Abuse. By JOHN LIZARS, M.D. The two essays in one volume. Cloth, \$1.00; Separate, each .50
- MILLS.** *Fuel and Its Applications.* By E. J. MILLS, D.Sc., F.R.S., and E. J. ROWAN, C.E. (See Groves and Thorp Technology.) 8vo. Clo., \$7.50; Half Mor. \$9.00
- MONEY.** *On Children.* Treatment of Disease in Children, including the Outlines of Diagnosis and the Chief Pathological Differences between Children and Adults. By ANGEL MONEY, M.D., M.R.C.P., Asst. Physician to the Hospital for Sick Children, Great Ormond St., and to the Victoria Park Chest Hospital, London. *Practical Series.* See Page 19. 12mo. 560 pages. Cloth, \$3.00
- MORRIS.** *Compend of Gynæcology.* By HENRY MORRIS, M.D., Demonstrator of Obstetrics, Jefferson Medical College, Phila., etc. *Being ? Quiz-Compend ? No. 7.* *Nearly Ready.*

- MORTON on Refraction of the Eye.** Its Diagnosis and the Correction of its Errors. With Chapter on Keratoscopy, and Test Types. By A. MORTON, M.B. Third Edition, Revised and Enlarged. Cloth, \$1.00
- MURRELL. Massotherapeutics.** Massage as a Mode of Treatment. By WM. MURRELL, M.D., F.R.C.P., Lecturer on Pharmacology and Therapeutics at Westminster Hospital. 5th Edition. Revised. 12mo. Cloth, \$1.50
- Chronic Bronchitis and its Treatment.** A Clinical Study. 12mo. 176 pages. Cloth, \$1.50
- MÜTER. Practical and Analytical Chemistry.** By JOHN MÜTER, F.R.S., F.C.S., etc. Third Edition. Revised and Illustrated. Cloth, \$2.00
- NEW SYDENHAM SOCIETY Publications.** Three to Six Volumes published each year. *List of Volumes upon application.* Per annum, \$9.00
- OBERSTEINER, The Central Nervous System.** A Guide to the study of their structure in Health and Disease. By Professor H. OBERSTEINER, of the University of Vienna. Translated, with annotations and additions, by Alex. Hill, M.A., M.D., Master of Downing College, Cambridge. 198 Illustrations. Cloth, \$6.00
- OPHTHALMIC REVIEW.** A Monthly Record of Ophthalmic Science. Published in London. *Sample Numbers, 25 cents.* Per annum, \$3.00
- OSGOOD. The Winter and Its Dangers.** By HAMILTON OSGOOD, M.D. Cloth, .50
- OSLER. Cerebral Palsies of Children.** A Clinical Study from the Infirmary for Nervous Diseases, Philadelphia. By WILLIAM OSLER, M.D., F.R.C.P., London, etc. 8vo. Cloth, \$2.00
- OSTROM. Massage and the Original Swedish Movements.** Their Application to Various Diseases of the Body. A Manual for Students, Nurses and Physicians. By KURRE W. OSTROM, from the Royal University of Upsala, Sweden; Instructor in Massage and Swedish Movements in the Hospital of the University of Pennsylvania, and in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. Illustrated by Wood Engravings, drawn especially for this purpose. 12mo. Cloth, .75
- OVERMAN'S Practical Mineralogy, Assaying and Mining,** with a Description of the Useful Minerals, etc. By FREDERICK OVERMAN, Mining Engineer. Eleventh Edition. 12mo. Cloth, \$1.00
- PACKARD'S Sea Air and Sea Bathing.** By JOHN H. PACKARD, one of the Physicians to the Pennsylvania Hospital, Philadelphia. Cloth, .50
- PAGE'S Injuries of the Spine and Spinal Cord,** without apparent Lesion and Nervous Shock. In their Surgical and Medico-Legal Aspects. By HERBERT W. PAGE, M.D., F.R.C.S. Third Edition, Revised. Octavo. *Preparing.*
- PARKES' Practical Hygiene.** By EDWARD A. PARKES, M.D. The Seventh Revised and Enlarged Edition. With Many Illustrations. 8vo. Cloth, \$4.50
- PARKES. Hygiene and Public Health.** A Practical Manual. By LOUIS C. PARKES, M.D., D.P.H. London Hospital; Assistant Professor of Hygiene and Public Health, at University College, etc. 12mo. Second Edition. Cloth, \$2.50
- PARRISH'S Alcoholic Inebriety.** From a Medical Standpoint, with Illustrative Cases from the Clinical Records of the Author. By JOSEPH PARRISH, M.D., President of the Amer. Assoc. for Cure of Inebriates. Paper, .75; Cloth, \$1.25
- PARVIN'S Winckel's Diseases of Women.** (See Winckel, page 24).
- PARVIN. Lectures on Obstetric Nursing.** Delivered at the Training School for Nurses of the Philadelphia Hospital. By THEOPHILUS PARVIN, M.D., Professor of Obstetrics and Diseases of Women and Children, at Jefferson Medical College; Obstetrician to Philadelphia Hospital. 12mo. Cloth, .75
- PENNSYLVANIA Hospital Reports.** Edited by a Committee of the Hospital Staff: J. M. DaCOSTA, M.D., and WILLIAM HUNT. Containing Original Articles by the Staff. With many other Illustrations. Paper, .75; Cloth, \$1.25

Perpetual Edition, without Dates and with Special Memorandum Pages.			
For 25 Patients, interleaved, tucks, pocket and pencil,	\$1.25	
50 " " " " " "	1.50	

Monthly Edition, without Dates. Can be commenced at any time and used until full. Requires only one writing of patient's name for the whole month.

Plain binding, without flap or Pencil, .75

Leather cover, Pocket and Pencil, \$1.00

EXTRA Pencils will be sent, postpaid, for 25 cents per half dozen.

 This List combines the several essential qualities of strength, compactness, durability and convenience. It is made in all sizes and styles to meet the wants of all physicians. It is not an elaborate, complicated system of keeping accounts, but a plain, simple record, that may be kept with the least expenditure of time and trouble—hence its popularity. A special circular, descriptive of contents and improvements, will be sent upon application.

PEREIRA'S Prescription Book. Containing Lists of Terms, Phrases, Contractions and Abbreviations used in Prescriptions, Explanatory Notes, Grammatical Construction of Prescriptions, Rules for the Pronunciation of Pharmaceutical Terms. By JONATHAN PEREIRA, M.D. Sixteenth Edition. Cloth, \$1.00; Tucks \$1.25

PIGGOTT Copper Mining and Copper Ore. 12mo. Cloth, \$1.00

PORTER'S Surgeon's Pocket-Book. By SURGEON-MAJOR J. H. PORTER, late Professor of Military Surgery in the Army Medical School, Netley, England. Revised, and partly Rewritten, by SURGEON-MAJOR C. H. GODWIN, of the Army Medical School (Netley, England). Third Edition. Small 12mo. Leather Covers, \$2.25

POWER, HOLMES, ANSTIE and BARNES (Drs.). Reports on the Progress of Medicine, Surgery, Physiology, Midwifery, Diseases of Women and Children, Materia Medica, Medical Jurisprudence, Ophthalmology, etc. Reported for the New Sydenham Society. 8vo. Paper, .75; Cloth, \$1.25

POTTER. A Handbook of Materia Medica, Pharmacy and Therapeutics, including the Action of Medicines, Special Therapeutics, Pharmacology, etc. Including over 600 Prescriptions and Formulæ. By SAMUEL O. L. POTTER, M.A., M.D., Professor of the Practice of Medicine, Cooper Medical College, San Francisco; late A. A. Surgeon U. S. Army. Second Edition, Revised and Enlarged. 8vo. *With Thumb Index in each copy.* Cloth, \$4.00; Leather, \$5.00

Speech and Its Defects. Considered Physiologically, Pathologically and Remedially; being the Lea Prize Thesis of Jefferson Medical College, 1882. Revised and Corrected. 12mo. Cloth, \$1.00

THE PRACTICAL SERIES.

THREE NEW VOLUMES.

PARKES. Hygiene and Public Health. A Practical Manual. By LOUIS C. PARKES, M.D., D.P.H., London Hospital; Fellow of the Sanitary Institute; Assistant Professor of Hygiene and Public Health, at University College, etc. 12mo. Second Edition. Cloth, \$2.50

LEWERS. On the Diseases of Women. A Practical Treatise. By Dr. A. H. N. LEWERS, Assistant Obstetric Physician to the London Hospital; and Physician to Out-patients, Queen Charlotte's Lying-in Hospital; Examiner in Midwifery and Diseases of Women to the Society of Apothecaries of London. With 139 Engravings. Second Edition, Revised. Cloth, \$2.50

BUXTON. On Anæsthetics. A Manual of their Uses and Administration. By DUDLEY WILMOT BUXTON, M.D., B.S., Ass't to Prof. of Med., and Administrator of Anæsthetics, University College Hospital, London. Illustrated.

Second Edition in Press.

MONEY. On Children. Treatment of Disease in Children, including the Outlines of Diagnosis and the Chief Pathological Differences between Children and Adults. By ANGEL MONEY, M.D., M.R.C.P., Ass't Physician to the Hospital for Sick Children, Great Ormond St., and to the Victoria Park Chest Hospital, London. 12mo. 560 pages. Cloth, \$3.00

PRITCHARD. On the Ear. Handbook of Diseases of the Ear. By URBAN PRITCHARD, M.D., F.R.C.S., Professor of Aural Surgery, King's College, London, Aural Surgeon to King's College Hospital, Senior Surgeon to the Royal Ear Hospital, etc. 12mo. Cloth, \$1.50

BARRETT. Dental Surgery for General Practitioners and Students of Medicine and Dentistry. Extraction of Teeth, etc. By A. W. BARRETT, M.D. 2d Edition, Revised and Enlarged. 80 Illustrations. Cloth, \$1.25

COLLIE On Fevers. A Practical Treatise on Fevers, Their History, Etiology. Diagnosis, Prognosis and Treatment. By ALEXANDER COLLIE, M.D., M.R.C.P., Lond. Medical Officer of the Hoxton, and of the London Fever Hospitals. Colored Plates. Cloth, \$2.50

RALFE. Diseases of the Kidney and Urinary Derangements. By C. H. RALFE, M.D., F.R.C.P., Ass't Physician to the London Hospital. Illustrated. 12mo. Cloth, \$2.75

REEVES. Bodily Deformities and their Treatment. A Handbook of Practical Orthopædics. By H. A. REEVES, M.D., Senior Ass't Surgeon to the London Hospital, Surgeon to the Royal Orthopædic Hospital. 228 Illus. Cloth, \$2.25

HIGGINS. Ophthalmic Practice. A Manual for Students and Practitioners. By CHARLES HIGGINS, F.R.C.P., Ophthalmic Surgeon to Guy's Hospital. Illustrated. 274 pages. Cloth, \$1.75

. The volumes of this series, written by well-known physicians and surgeons of large private and hospital experience, embrace the various branches of medicine and surgery. They are of a thoroughly practical character, calculated to meet the requirements of the practitioner, and present the most recent methods and information in a compact shape and at a low price.

Bound Uniformly, in a Handsome and Distinctive Cloth Binding, and mailed to any address, on receipt of the price.

- POTTER.** *Compend of Anatomy, including Visceral Anatomy.* Formerly published separately. *Based upon Gray.* Fourth Edition, Revised, and greatly Enlarged. With an Index and 117 Illustrations. *Being No. 1 ? Quiz-Compend ? Series.* Cloth, \$1.00; Interleaved for taking Notes, \$1.25
- Compend of Materia Medica, Therapeutics and Prescription Writing,** arranged in accordance with the last Revision U. S. Pharmacopœia, with special reference to the Physiological Action of Drugs. Fifth Revised and Improved Edition, with Index. *Being No. 6 ? Quiz-Compend ? Series.* Cloth, \$1.00. Interleaved for taking Notes, \$1.25
- PRITCHARD on the Ear.** Handbook of Diseases of the Ear. By URBAN PRITCHARD, M.D., F.R.C.S., Professor of Aural Surgery, King's College, London, Aural Surgeon to King's College Hospital, Senior Surgeon to the Royal Ear Hospital, etc. 12mo. *Practical Series. See Page 19.* Cloth, \$1.50
- PROCTER'S Practical Pharmacy.** Lectures on Practical Pharmacy. With 43 Engravings and 32 Lithographic Fac-simile Prescriptions. By BARNARD S. PROCTER. Second Edition. Cloth, \$4.50
- RADCLIFFE on Epilepsy, Pain, Paralysis, and other Disorders of the Nervous System.** By CHARLES BLAND RADCLIFFE, M.D. Illus. Paper, .75; Cloth, \$1.25
- RALFE.** *Diseases of the Kidney and Urinary Derangements.* By C. H. RALFE. Illustrated. 12mo. *Practical Series. See Page 19.* Cloth, \$2.75
- REESE'S Medical Jurisprudence and Toxicology.** A Text-book for Medical and Legal Practitioners and Students. By JOHN J. REESE, M.D., Editor of Taylor's Jurisprudence, Professor of the Principles and Practice of Medical Jurisprudence, including Toxicology, in the University of Pennsylvania Medical Department. 2d. Ed. Enlarged. Crown Octavo. Cloth, \$3.00; Leather, \$3.50
- REEVES.** *Bodily Deformities and their Treatment.* A Handbook of Practical Orthopædics. By H. A. REEVES, M.D. *Practical Series. See Page 19.* Cl. \$2.25
- RICHARDSON.** *Long Life, and How to Reach It.* By J. G. RICHARDSON, Prof. of Hygiene, University of Penna. Cloth, .50
- RICHARDSON'S Mechanical Dentistry.** A Practical Treatise on Mechanical Dentistry. By JOSEPH RICHARDSON, D.D.S. Fifth Edition. Thoroughly Revised. With 569 Illustrations. 8vo. Cloth, \$4.50; Leather, \$5.50
- RIGBY'S Obstetric Memoranda.** 4th Ed. By MEADOWS. 32mo. Cloth, .50
- RICHTER'S Inorganic Chemistry.** A Text-book for Students. By Prof. VICTOR VON RICHTER, University of Breslau. Third American, from Fifth German Edition. Authorized Translation by EDGAR F. SMITH, M.A., PH.D., Prof. of Chemistry, University of Pennsylvania, Member of the Chemical Societies of Berlin and Paris. 89 Illustrations and a Colored Plate. 12mo. Cloth, \$2.00
- Organic Chemistry.** A Text-book for Students. Translated from the Fourth German Ed., by Prof. Edgar F. Smith. Illus. Cloth, \$3.00; Leather, \$3.50
- ROBERTS.** *Bow-Legs.* Clinical Lectures on Orthopædic Surgery. By A. SYDNEY ROBERTS, M.D., Instructor in Orthopædic Surg. in the Univ. of Penn'a, Surg. to the Univ. Hospital. Illustrated. 12mo. Cloth, .50; Boards, .50
- ROBERTS.** *Practice of Medicine.* The Theory and Practice of Medicine. By FREDERICK ROBERTS, M.D., Professor of Therapeutics at University College, London. Seventh Edition, with Illustrations. 8vo. Cloth, \$5.50; Leather, \$6.50
- Materia Medica and Pharmacy.** A Compend for Students. Cloth, \$2.00
- ROBERTS (John B.).** *Crooked and Deformed Noses.* 8vo. Cloth, .75; Paper, .50
- ROBINSON.** *Latin Grammar of Pharmacy and Medicine.* By H. D. ROBINSON, PH.D., Professor of Latin Language and Literature, University of Kansas, Lawrence. With an Introduction by L. E. SAYRE, PH.G., Professor of Pharmacy in, and Dean of the Dept. of Pharmacy, University of Kansas. 12mo. *Nearly Ready.*
- SANDERSON'S Physiological Laboratory.** A Handbook of the Physiological Laboratory. Being Practical Exercises for Students in Physiology and Histology. By J. BURDON SANDERSON, M.D., E. KLEIN, M.D., MICHAEL FOSTER, M.D., F.R.S., and T. LAUDER BRUNTON, M.D. With over 350 Illustrations and Appropriate Letter-press Explanations and References. One Volume. Cloth, \$5.00

- SANSOM'S Diseases of the Heart.** Valvular Disease of the Heart. By ARTHUR ERNEST SANSOM, M.D. Illustrated. 12mo. Cloth, \$1.25
On Chloroform. Its Action and Administration. Paper, .75; Cloth, \$1.25
- SCANZONI. Sexual Organs of Women.** A Practical Treatise on the Diseases of the Sexual Organs of Women. By F. W. VON SCANZONI, Prof. of Midwifery and Diseases of Females, University of Würzburg, etc. Edited by A. K. GARDNER, A.M., M.D. 60 Illustrations. Fourth Edition. Octavo. Cloth, \$4.00
- SCHNÉE. Diabetes,** its Cause and Permanent Cure. From the standpoint of experience and Scientific Investigation. By EMIL SCHNÉE, Consulting Physician at Carlsbad. Translated from the German by R. L. TAFEL, A.M., PH.D. Revised and Enlarged by the author. Octavo. Cloth, \$2.00
- SEWELL. Dental Surgery,** including Special Anatomy and Surgery. By HENRY SEWELL, M.R.C.S., L.D.S., President Odontological Society of Great Britain. 3d Edition, greatly enlarged, with about 200 Illustrations. *Nearly Ready.*
- SMITH'S Wasting Diseases of Infants and Children.** By EUSTACE SMITH, M.D., F.R.C.P., Physician to the East London Children's Hospital. Fifth London Edition, Enlarged. 8vo. Cloth, \$3.00
Clinical Studies of Diseases in Children. Second Edition. Cloth, \$2.50
- SMITH. Abdominal Surgery.** Being a Systematic Description of all the Principal Operations. By J. GREIG SMITH, M.A., F.R.S.E., Surg. to British Royal Infirmary. Illustrated. Third Edition. Cloth, \$7.00
- SMITH. Electro-Chemical Analysis.** By EDGAR F. SMITH, Prof. of Analytical Chemistry, University of Penna. 26 Illustrations. 12mo. Cloth, \$
- SMITH (TYLER). Lectures on Obstetrics.** Delivered at St. Mary's Hospital. With an Introductory Lecture on the History and Art of Midwifery, and Copious Annotations. By A. K. GARDNER, A.M., M.D. 233 Illus. 3d Ed. 8vo. Cloth, \$4.00
- SMYTHE (G. C.). Medical Heresies.** Historically Considered. 12mo. Cloth, \$1.25
- STAMMER. Chemical Problems,** with Explanations and Answers. By KARL STAMMER. Translated from the 2d German Edition, by Prof. W. S. HOSKINSON, A.M., Wittenberg College, Springfield, Ohio. 12mo. Cloth. .75
- STARR and WALKER. Physiological Action of Medicines.** Prepared for the use of Students of the Medical Department, University of Penna. By LOUIS STARR, M.D., J. B. WALKER, M.D. and W. M. POWELL, M.D. Third Edition. Enlarged. 32mo. Cloth, .75
- STARR. The Digestive Organs in Childhood.** The Diseases of the Digestive Organs in Infancy and Childhood. With Chapters on the Investigation of Disease and the Management of Children. By LOUIS STARR, M.D., Clinical Prof. of Diseases of Children in the Hospital of the University of Penn'a; Physician to the Children's Hospital, Phila. 8vo. Cut or uncut edges. Cloth, \$2.50
- The Hygiene of the Nursery,** including the General Regimen and Feeding of Infants and Children, and the Domestic Management of the Ordinary Emergencies of Early Life. Second Edition. Enlarged. 24 Illustrations. 12mo. 280 pages, Cloth, \$1.00
- See also Goodhart and Starr. *Page 10.*
- STEWART'S Compend of Pharmacy.** Based upon "Remington's Text-Book of Pharmacy." By F. E. STEWART, M.D., PH.G., Quiz Master in Chem. and Theoretical Pharmacy, Phila. College of Pharmacy; Demonstrator and Lect. in Pharmacology, Medico-Chirurgical College, and in Woman's Medical College. 2d. Ed. ? *Quiz-Compend? Series.* Cloth, \$1.00; Interleaved for the addition of notes, \$1.25
- STIRLING. Outlines of Practical Physiology.** Including Chemical and Experimental Physiology, with Special Reference to Practical Medicine. By W. STIRLING, M.D., Sc.D., Prof. of Phys., Owens College, Victoria University, Manchester. Examiner in Honors School of Science, Oxford, England. 142 Illustrations. 309 pages. Cloth, \$2.25
- Outlines of Practical Histology.** A Manual for Students. With 344 Illustrations. 12mo. Cloth, \$4.00

- STOCKEN'S Dental Materia Medica.** Dental Materia Medica and Therapeutics, with Pharmacopœia. By JAMES STOCKEN, D.D.S. Third Edition. Cloth, \$2.50
- STRAHAN. Extra-Uterine Pregnancy.** The Diagnosis and Treatment of Extra-Uterine Pregnancy. Being the Jenks Prize Essay of the College of Physicians of Philadelphia. By JOHN STRAHAN, M.D. (Univ. of Ireland), late Res. Surgeon Belfast Union Infirmary and Fever Hospital. Octavo. Cloth, \$1.50
- SUTTON'S Volumetric Analysis.** A Systematic Handbook for the Quantitative Estimation of Chemical Substances by Measure, Applied to Liquids, Solids and Gases. By FRANCIS SUTTON, F.C.S. Fifth Edition, Revised and Enlarged, with Illustrations. 8vo. Cloth, \$4.50
- SUTTON. Ligaments.** Their Nature and Morphology. By JOHN BLAND SUTTON, F.R.C.S., Lecturer on Pathology, Royal College of Surgeons; Assistant Surgeon and Demonstrator of Anatomy, Middlesex Hospital, London. Illustrated. 12mo. Cloth, 1.25
- SWAIN. Surgical Emergencies,** together with the Emergencies Attendant on Parturition and the Treatment of Poisoning. A Manual for the Use of General Practitioners. By W. F. SWAIN, F.R.C.S. Fourth Edition. Illustrated. 1.50
- SWAYNE'S Obstetric Aphorisms,** for the Use of Students commencing Midwifery Practice. By JOSEPH G. SWAYNE, M.D. Ninth Edition. Illus. Cloth, \$1.25
- SYMONDS. Manual of Chemistry,** for the special use of Medical Students. By BRANDRETH SYMONDS, A.M., M.D., Asst. Physician Roosevelt Hospital, Out-Patient Department; Attending Physician Northwestern Dispensary, New York. 12mo. Cloth, \$2.00; Interleaved for Notes, \$2.40
- TAFT'S Operative Dentistry.** A Practical Treatise on Operative Dentistry. By JONATHAN TAFT, D.D.S. Fourth Revised and Enlarged Edition. Over 100 Illustrations. 8vo. Cloth, \$4.25; Leather, \$5.00
- Index of Dental Periodical Literature** 8vo. Cloth, \$2.00
- TALBOT. Irregularities of the Teeth,** and Their Treatment. By EUGENE S. TALBOT, M.D., Professor of Dental Surgery Woman's Medical College, and Lecturer on Dental Pathology in Rush Medical College, Chicago. Second Edition, Revised and Enlarged by about 100 pages. Octavo. 234 Illustrations. (169 of which are original). 261 pages. Cloth, \$3.00
- TANNER'S Index of Diseases** and their Treatment. By THOS. HAWKES TANNER, M.D., F.R.C.P. Second Edition, Revised and Enlarged. By W. H. BROADBENT, M.D. With Additions. Appendix of Formulæ, etc. 8vo. Cloth, \$3.00
- Memoranda of Poisons** and their Antidotes and Tests. Sixth American, from the Last London Edition. Revised by HENRY LEFFMANN, M.D., Professor of Chemistry in Pennsylvania College of Dental Surgery and in the Philadelphia Polyclinic. 12mo. Cloth, .75
- TAYLOR. Practice of Medicine.** A Manual. By FREDERICK TAYLOR, M.D., Physician to, and Lecturer on Medicine at Guy's Hospital, London; Physician to Evelina Hospital for Sick Children, and Examiner in Materia Medica and Pharmaceutical Chemistry, University of London. Cloth, \$4.00
- TEMPERATURE Charts** for Recording Temperature, Respiration, Pulse, Day of Disease, Date, Age, Sex, Occupation, Name, etc. Put up in pads; each .50
- THOMPSON. Lithotomy and Lithotripsy.** Practical Lithotomy and Lithotripsy; or an Inquiry into the best Modes of Removing Stone from the Bladder. By Sir HENRY THOMPSON, F.R.C.S., Emeritus Professor of Clinical Surgery in University College. Third Edition. With 87 Engravings. 8vo. Cloth, \$3.50
- Urinary Organs.** Diseases of the Urinary Organs. Containing 32 Lectures. Eighth London Ed. Octavo. 470 pages. Cloth, \$3.50
- On the Prostate.** Diseases of the Prostate. Their Pathology and Treatment. Sixth London Edition. 8vo. Illustrated. Cloth, \$2.00
- Calculus Diseases.** The Preventive Treatment of Calculous Disease, and the Use of Solvent Remedies. Third Edition. 16mo. Cloth, \$1.00
- Surgery of the Urinary Organs.** Some Important Points connected with the Surgery of the Urinary Organs. Illus. Paper, .75; Cloth, \$1.25

- THORBURN.** *Surgery of the Spinal Cord.* A Contribution to the study of. By WILLIAM THORBURN, B.S., B.Sc., M.D., Lond., F.R.C.S., Eng. With Illustrations. Octavo. Cloth, \$4.50
- THORNTON.** *The Surgery of the Kidney.* By JOHN KNOWSLEY THORNTON, M.B. Edin. With 19 Illustrations. Cloth, \$1.75
- TIDY.** *Modern Chemistry, Inorganic and Organic.* A Handbook for the Use of Students. By CHAS. MEYMOTT TIDY, F.R.C., Prof. of Chemistry and Medical Jurisprudence and Public Health at London Hospital; Medical Officer of Health and Public Analyst of the City of London. 8vo. 2d Edition. Cloth, \$5.50
- TILT'S** *Change of Life in Women, in Health and Disease.* A Practical Treatise on the Diseases incidental to Women at the Decline of Life. By EDWARD JOHN TILT, M.D. Fourth London Edition. 8vo. Paper cover, .75; Cloth, \$1.25
- TOMES' Dental Anatomy.** A Manual of Dental Anatomy, Human and Comparative. By C. S. TOMES, D.D.S. 212 Illustrations. 3d Ed. 12mo. Cloth, \$4.00
- Dental Surgery.** A System of Dental Surgery. By JOHN TOMES, F.R.S. Third Edition, Revised and Enlarged. By C. S. TOMES, D.D.S. With 292 Illustrations. 12mo. 772 pages. Cloth, \$5.00
- TRANSACTIONS of the College of Physicians of Philadelphia.** Third Series. Vols. I, II, III, IV, V, Cloth, each, \$2.50. VI, VII, Cloth, each, \$3.50. Vol. VIII, 1886, Cloth, \$3.75. Vol. IX, Cloth, \$2.50.
- TRANSACTIONS American Surgical Association.** Illustrated. Royal 8vo. Price of Vol. I, II, III, IV, V, each, Cloth, \$3.00. Vol. VI, Cloth, \$4.50. Vol. VII, Cloth, \$3.00.
- TRANSACTIONS of the Association of American Physicians.** Vols. I and II, Cloth, \$2.50 each; Vol. III, Cloth, \$3.50. Vol. IV, Cloth, \$3.00.
- TREVES.** *German-English Medical Dictionary.* By FREDERICK TREVES, F.R.C.S., assisted by DR. HUGO LANG, B.A., (Munich). 12mo. $\frac{1}{2}$ Russian, \$3.75
- TRIMBLE.** *Practical and Analytical Chemistry.* Being a complete course in Chemical Analysis. By HENRY TRIMBLE, PH.G., Professor of Analytical Chemistry in the Philadelphia College of Pharmacy. Second Edition. Enlarged. Illustrated. 8vo. Cloth, \$1.50
- TURNBULL'S Artificial Anæsthesia.** The Advantages and Accidents of Artificial Anæsthesia; Its Employment in the Treatment of Disease; Modes of Administration; Considering their Relative Risks; Tests of Purity; Treatment of Asphyxia; Spasms of the Glottis; Syncope, etc. By LAURENCE TURNBULL, M.D., PH. G., Aural Surgeon to Jefferson College Hospital, etc. Third Edition, Revised and Enlarged. 40 Illustrations. 12mo. Cloth, \$3.00
- TUSON.** *Veterinary Pharmacopœia.* Including the Outlines of Materia Medica and Therapeutics. For the Use of Students and Practitioners of Veterinary Medicine. By RICHARD V. TUSON, F.C.S. Third Edition. 12mo. Cloth, \$2.50
- TYSON.** *Bright's Disease and Diabetes.* With Especial Reference to Pathology and Therapeutics. By JAMES TYSON, M.D., Professor of Pathology and Morbid Anatomy in the University of Pennsylvania. Including a Section on Retinitis in Bright's Disease. By WM. F. NORRIS, M.D., Clin. Prof. of Ophthalmology, in Univ. of Penna. With Colored Plates and many Wood Engravings. 8vo. Cloth, \$3.50
- Guide to the Examination of Urine.** Sixth Edition. For the Use of Physicians and Students. With Colored Plates and Numerous Illustrations Engraved on Wood. Sixth Edition. Revised. 12mo. 250 pages. Cloth, \$1.50
- Cell Doctrine.** Its History and Present State. With a Copious Bibliography of the subject. Illustrated. Second Edition. 8vo. Cloth, \$2.00
- VALENTIN'S Qualitative Analysis.** A Course of Qualitative Chemical Analysis. By WM. G. VALENTIN, F.C.S. Seventh Edition. Illustrated. Octavo. Cloth, \$3.00

- VAN HARLINGEN on Skin Diseases.** A Practical Manual of Diagnosis and Treatment. By ARTHUR VAN HARLINGEN, M.D., Professor of Diseases of the Skin in the Philadelphia Polyclinic; Clinical Lecturer on Dermatology at Jefferson Medical College. Second Edition. Revised and Enlarged. With Formulæ. Eight Colored and other full page plates, and New Illustrations. Cloth, 2.50
- VAN NÜYS on The Urine.** Chemical Analysis of Healthy and Diseased Urine, Qualitative and Quantitative. By T. C. VAN NÜYS, Professor of Chemistry Indiana University. 39 Illustrations. Octavo. Cloth, \$2.00
- VIRCHOW'S Post-mortem Examinations.** A Description and Explanation of the Method of Performing them in the Dead House of the Berlin Charité Hospital, with especial reference to Medico-legal Practice. By Prof. VIRCHOW. Translated by Dr. T. P. SMITH. Third Edition, with Additions. Cloth, \$1.00
- Cellular Pathology,** as based upon Physiological and Pathological Histology. 20 Lectures delivered at the Pathological Institute of Berlin. Translated from the 2d Ed. by F. CHANCE, M.D. 134 Illus. 8th Am. Ed. Cloth, \$4.00
- WALSHAM. Manual of Practical Surgery.** For Students and Physicians. By WM. J. WALSHAM, M.D., F.R.C.S., Asst. Surg. to, and Dem. of Practical Surg. in, St. Bartholomew's Hospital, Surg. to Metropolitan Free Hospital, London. With 236 Engravings. *New Series of Manuals.* Cloth, \$3.00; Leather, \$3.50
- WARING. Practical Therapeutics.** A Manual for Physicians and Students. By Edward J. Waring, M.D. Fourth Edition. Revised, Rewritten and Rearranged by DUDLEY W. BUXTON, M.D., Assistant to the Professor of Medicine, University College, London. Crown Octavo. Cloth, \$3.00; Leather, \$3.50
- WARNER. Case Taking.** A Manual of Clinical Medicine and Case Taking. By FRANCIS WARNER, M.D. Second Edition. Cloth, \$1.75
- WARREN. Compend Dental Pathology and Dental Medicine.** Containing all the most noteworthy points of interest to the Dental student. By GEO. W. WARREN, D.D.S., Clinical Chief, Penn'a College of Dental Surgery, Phila. Illus. *Being No. 13 ? Quiz-Compend ? Series.* 12mo. Cloth, \$1.00
- Interleaved for the addition of notes, 1.25
- WATSON on Amputations of the Extremities and Their Complications.** By B. A. WATSON, A.M., M.D., Surgeon to the Jersey City Charity Hospital and to Christ's Hospital, Jersey City, N. J.; Member of the American Surgical Association. 250 Wood Engravings and two Full-page Colored Plates. Cloth, \$5.50
- Concussions.** An Experimental Study of Lesions arising from Severe Concussions. 8vo. Paper cover, \$1.00
- WATTS' Inorganic Chemistry.** A Manual of Chemistry, Physical and Inorganic. (Being the 13th Edition of FOWNE'S PHYSICAL AND INORGANIC CHEMISTRY.) By HENRY WATTS, B.A., F.R.S., Editor of the Journal of the Chemical Society; Author of "A Dictionary of Chemistry," etc. With Colored Plate of Spectra and other Illustrations. 12mo. 595 pages. Cloth, \$2.25
- Organic Chemistry.** Second Edition. By WM. A. TILDEN, D.Sc., F.R.S. (Being the 13th Edition of FOWNE'S ORGANIC CHEMISTRY.) Illustrated. 12mo. Cloth, \$2.25
- WELCH'S Enteric Fever.** Its Prevalence and Modifications; Ætiology, Pathology and Treatment. By FRANCIS H. WELCH, F.R.C.S. 8vo. Cloth, \$2.00
- WHITE. The Mouth and Teeth.** By J. W. WHITE, M.D., D.D.S. Editor of the Dental Cosmos. Illustrated. Cloth, .50
- WILLIAMS. Pulmonary Consumption.** Its Etiology, Pathology and Treatment, with an Analysis of 1000 Cases to Exemplify its Duration and Modes of Arrest. By C. J. B. WILLIAMS, M.D. Second Edition. Enlarged and Rewritten. By C. THEODORE WILLIAMS, M.D. With 4 Colored Plates and other Illustrations. Octavo. Cloth, 5.00
- WILSON'S Text-Book of Domestic Hygiene and Sanitary Information.** A Guide to Personal and Domestic Hygiene. By GEORGE WILSON, M.D., Medical Officer of Health. Edited by JOS. G. RICHARDSON, M.D., Professor of Hygiene at the University of Pennsylvania. Cloth, \$1.00

- WILSON. Handbook of Hygiene** and Sanitary Science. With Illustrations. Sixth Edition, Revised and Enlarged. 8vo. Cloth, \$2.75
- WILSON. The Summer** and Its Diseases. By JAMES C. WILSON, M.D. Cloth, .50
- WINCKEL. Diseases of Women.** Second Edition. Including the Diseases of the Bladder and Urethra. By Dr. F. WINCKEL, Professor of Gynæcology, and Director of the Royal University Clinic for Women, in Munich. Translated by special authority of Author and Publisher, by Dr. J. H. WILLIAMSON, Resident Physician of Allegheny General Hospital, Allegheny, Pa., under the supervision of, and with an Introduction by, THEOPHILUS PARVIN, M.D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College, Philadelphia. With 150 Engravings on Wood, most of which are original 2d Edition, Revised and Enlarged. Cloth, \$3.00; Leather, \$3.50
- Text-Book of Obstetrics;** Including the Pathology and Therapeutics of the Puerperal State. Authorized Translation by J. CLIFTON EDGAR, A.M., M.D., Adjunct Professor to the Chair of Obstetrics, Medical Department, University, City of New York. With nearly 200 Handsome Illus., the majority of which are original with this work. Octavo. Cloth, \$6.00; Leather, \$7.00
- WOAKES. Post-Nasal Catarrh** and Diseases of the Nose, causing Deafness. By EDWARD WOAKES, M.D., Senior Aural Surgeon to the London Hospital for Diseases of the Throat and Chest. 26 Illustrations. Cloth, \$1.50
- Nasal Polypus, with Neuralgia, Hay Fever and Asthma** in Relation to Ethmoiditis. 12mo. Cloth, \$1.25
- On Deafness, Giddiness** and Noises in the Head, or the Naso-Pharyngeal aspect of Ear Disease. Third Edition. Illustrated. *In Press.*
- WOLFF. Manual of Applied Medical Chemistry** for Students and Practitioners of Medicine. By LAWRENCE WOLFF, M.D., Demonstrator of Chemistry in Jefferson Medical College, Philadelphia. Cloth, \$1.00
- WOOD. Brain Work and Overwork.** By Prof. H. C. WOOD, Clinical Professor of Nervous Diseases, University of Pennsylvania. 12mo. Cloth, .50
- WOODY. Essentials of Chemistry and Urinalysis.** By SAM E. WOODY, A.M., M.D., Professor of Chemistry and Public Hygiene, and Clinical Lecturer on Diseases of Children, in the Kentucky School of Medicine. Third Edition. Illustrated. 12mo. Cloth,
- WOODMAN and TIDY. Medical Jurisprudence.** Forensic Medicine and Toxicology. By W. BATHURST WOODMAN, M.D., Physician to the London Hospital, and CHARLES MEYMOTT TIDY, F.C.S., Professor of Chemistry and Medical Jurisprudence at the London Hospital. With Chromo-lithographic Plates, and 116 other Illustrations. Octavo. Leather, \$8.50
- WYNTER and WETHERED. Clinical and Practical Pathology.** A Manual of Clinical and Practical Pathology. By W. ESSEX WYNTER, M.D., Medical Registrar and late Demonstrator of Anatomy and Chemistry at the Middlesex Hospital, and FRANK J. WETHERED, M.D., Asst. Physician to the City of London Hospital for Diseases of the Chest. With 4 Colored Plates and 67 other Illustrations. 8vo. Cloth, \$4.00
- WYTHER on the Microscope.** A Manual of Microscopy and Compendium of the Microscopic Sciences, Micro-mineralogy, Biology, Histology and Practical Medicine, with Index and Glossary and the genera of microscopic plants. By JOSEPH H. WYTHER, A.M., M.D. Fourth Edition. 252 Illus. Cloth, \$3.00
- Dose and Symptom Book.** The Physician's Pocket Dose and Symptom Book. Containing the Doses and Uses of all the Principal Articles of the Materia Medica, and Official Preparations. 17th Edition, Revised and Rewritten. Cloth, \$1.00; Leather, with Tucks and Pocket, \$1.25
- YEO'S Manual of Physiology.** Fourth Edition. A Text-book for Students of Medicine. By GERALD F. YEO, M.D. F.R.C.S., Professor of Physiology in King's College, London. Fourth Edition; revised and enlarged by the author. With New Illustrations. 321 carefully printed Wood Engravings. A Glossary and Complete Index. Crown Octavo. *Being No. 4, New Series of Manuals.* Cloth, \$3.00; Leather, \$3.50

New Series of Manuals.

FOR MEDICAL STUDENTS AND PHYSICIANS.

Demi-Octavo. Price of each book, Cloth, \$3.00; Leather, \$3.50.

The object held in view in the preparation of this Series was to make books that should be concise and practical, not burdened by useless theories and discussions, but containing all that is needed or necessary for the student and practitioner. No pains have been spared to bring them up to the times, and the very low price at which they have been published is an additional point in their favor. Full circular, descriptive of the Series, will be sent upon application.

WALSHAM'S PRACTICAL SURGERY. A Manual for Students and Physicians. By WM. J. WALSHAM, M.D., Asst. Surgeon to, and Demonstrator of Surgery in, St. Bartholomew's Hospital; Surgeon to Metropolitan Free Hospital, London, etc. 236 Illust. 656 pp.

Cloth, \$3.00; Leather, \$3.50

From the Polyclinic.

"While evidently intended to be a text-book for students, and therefore small in size and compactly written, is nevertheless full enough for the use of those practitioners who desire a short account of the various surgical principles and operations involved in the treatment of the ordinary run of surgical cases. The author seems to be a conservative and judicious surgeon with advanced ideas."

PARVIN'S-WINCKEL'S DISEASES OF WOMEN. Second Edition. A Treatise on the Diseases of Women. Including the Diseases of the Bladder and Urethra. By DR. F. WINCKEL, Professor of Gynecology and Director of the Royal University Clinic for Women, in Munich. Revised and Edited by THEOPHILUS PARVIN, M.D., Professor of Obstetrics and Diseases of Women and Children in Jefferson Medical College. Illustrated by 150 fine Engravings on Wood, most of which are new. 760 pp.

Cloth, \$3.00; Leather, \$3.50

GALABIN'S MIDWIFERY. A Manual of Midwifery. By ALFRED LEWIS GALABIN, M.A., M.D., Obstetric Physician and Lecturer on Midwifery and the Diseases of Women at Guy's Hospital, London; Examiner in Midwifery to the Conjoint Examining Board of England. 227 Illustrations. 753 pages.

Cloth, \$3.00; Leather, \$3.50

From the Archives of Gynecology, New York.

"The illustrations are mostly NEW and WELL EXECUTED, and we heartily commend this book as far superior to any manual upon this subject."

YEO'S MANUAL OF PHYSIOLOGY. Fourth Edition. A New Text-book for Students. By GERALD F. YEO, M.D., F.R.C.S., Professor of Physiology in King's College, London. 321 Illustrations and a Glossary. 758 pages.

Cloth, \$3.00; Leather, \$3.50

RICHTER'S ORGANIC CHEMISTRY. By PROF. VICTOR VON RICHTER, University of Breslau. Authorized translation. First American, from the Fourth German Edition. By EDGAR F. SMITH, M.D., PH.D., Translator of Richter's Inorganic Chemistry; Prof. of Chemistry in Wittenberg College, Springfield, Ohio; formerly in the Laboratories of the University of Pennsylvania; Member of the Chemical Societies of Berlin and Paris, of the Academy of Natural Sciences of Philadelphia, etc. Illustrated. 710 pages.

Cloth, \$3.00; Leather, \$3.50

GOODHART AND STARR, DISEASES OF CHILDREN. Second Edition. By J. F. GOODHART, M.D., Physician to the Evelina Hospital for Children; Assistant Physician to Guy's Hospital, London. Second American from third English Edition. Revised and Edited by LOUIS STARR, M.D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania, and Physician to the Children's Hospital, Phila. With many new Prescriptions and Directions for making Artificial Human Milk, for the Artificial Digestion of Milk, etc. 760 pages.

Cloth, \$3.00; Leather, \$3.50

From The New York Medical Record.

"As it is said of some men, so it might be said of some books, that they are 'born to greatness.' This new volume has we believe, a mission, particularly in the hands of the young members of the profession. In these days of prolixity in medical literature, it is refreshing to meet with an author who knows both what to say and when he has said it."

WARING'S PRACTICAL THERAPEUTICS. Fourth Edition. A Manual of Practical Therapeutics, considered with reference to Articles of the Materia Medica. Containing, also, an Index of Diseases, with a list of Medicines applicable as Remedies, and a full Index of the Medicines and Preparations noticed in the work. By EDWARD JOHN WARING, M.D., F.R.C.P., F.L.S., etc. 4th Edition. Rewritten and Revised. Edited by DUDLEY W. BUXTON, M.D., Asst. to the Prof. of Medicine at University College Hospital; Member of the Royal College of Physicians of London. 666 pages.

Cloth, \$3.00; Leather, \$3.50

From The Kansas City Medical Record.

"As a work of reference it excels, on account of the several complete indexes added to this edition. It was deservedly popular in former editions, and will be more so in the one before us, on account of the careful arrangement of the subjects."

REESE'S MEDICAL JURISPRUDENCE AND TOXICOLOGY. Second Edition. By JOHN J. REESE, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania; late President of the Medical Jurisprudence Society of Philadelphia; Physician to St. Joseph's Hospital; Member of the College of Physicians of Phila.; Corresponding Member of the New York Medico-Legal Society, etc. 2d Edition. Revised and Enlarged. 654 pages.

Cloth, \$3.00; Leather, \$3.50

THE MOST PRACTICAL SERIES OF TEXT-BOOKS.

JUST PUBLISHED. THIRD EDITION.

HUMAN PHYSIOLOGY.

BY LANDOIS AND STIRLING.

With 692 Illustrations.

THIRD AMERICAN, FROM THE SIXTH GERMAN EDITION.

A Text-Book of Human Physiology, including Histology and Microscopical Anatomy, with special reference to the requirements of Practical Medicine. - By Dr. L. LANDOIS, Professor of Physiology and Director of the Physiological Institute, University of Greifswald. Translated from the Fifth German Edition, with additions by WM. STIRLING, M.D., Sc.D., Brackenbury, Professor of Physiology and Histology in Owen's College and Victoria University, Manchester; Examiner in the Honors' School of Science, University of Oxford, England. Third Edition, revised and enlarged. 692 Illustrations.

"A BRIDGE BETWEEN PHYSIOLOGY AND PRACTICAL MEDICINE."

One Volume. Royal Octavo. Cloth, \$6.50; Leather, \$7.50.

From the Prefaces to the English Edition.

The fact that Prof. Landois' book has passed through four large editions in the original since 1880, and that in barely six months' time a second edition of the English has been called for, shows that in some special way it has met a want. The characteristic which has thus commended the work will be found mainly to lie in its eminent practicability; and it is this consideration which has induced me to undertake the task of putting it into English. Landois' work, in fact, forms a *Bridge* between Physiology and the Practice of Medicine. It never loses sight of the fact that the student of to-day is the practicing physician of to-morrow. In the same way, the work offers to the busy physician in practice a ready means of refreshing his memory on the theoretical aspects of Medicine. He can pass backward from the examination of pathological phenomena to the normal processes, and, in the study of these, find new indications and new lights for the appreciation and treatment of the cases under consideration. With this object in view, all the methods of investigation which may, to advantage, be used by the practitioner, are carefully and fully described. Many additions, and about one hundred illustrations, have been introduced into this second English edition, and the whole work carefully revised.

PRESS NOTICES.

"Most effectively aids the busy physician to trace from morbid phenomena back the course of divergence from healthy physical operations, and to gather in this way new lights and novel indications for the COMPREHENSION AND TREATMENT of the maladies with which he is called upon to cope."—*American Journal of Medical Sciences.*

"I know of no book which is its equal in the applications to the needs of clinical medicine."—*Prof. Harrison Allen, late Professor of Physiology, University of Pennsylvania.*

"We have no hesitation in saying that THIS IS THE WORK to which the PRACTITIONER will turn whenever he desires light thrown upon the phenomena of a COMPLICATED or IMPORTANT CASE."—*Edinburgh Medical Journal.*

"So great are the advantages offered by Prof. LANDOIS' TEXT-BOOK, from the EXHAUSTIVE and EMINENTLY PRACTICAL manner in which the subject is treated, that it has passed through FOUR large editions in the same number of years. . . . Dr. STIRLING'S annotations have materially added to the value of the work. Admirably adapted for the PRACTITIONER. . . . With this Text-book at command, NO STUDENT COULD FAIL IN HIS EXAMINATION."—*The Lancet.*

"One of the MOST PRACTICAL works on Physiology ever written, forming a 'bridge' between Physiology and Practical Medicine. . . . Its chief merits are its completeness and conciseness. . . . The additions by the Editor are able and judicious. . . . EXCELLENTLY CLEAR, ATTRACTIVE and SUCCINCT."—*British Medical Journal.*

"The great subjects dealt with are treated in an admirably clear, terse, and happily illustrated manner."—*Practitioner.*

"Unquestionably the most admirable exposition of the relations of Human Physiology to Practical Medicine ever laid before English readers."—*Students' Journal.*

"As a work of reference, LANDOIS and STIRLING'S Treatise OUGHT TO TAKE THE FOREMOST PLACE among the text-books in the English language. The wood-cuts are noticeable for their number and beauty."—*Glasgow Medical Journal.*

"Landois' Physiology is, without question, the best text-book on the subject that has ever been written."—*New York Medical Record.*

"The chapter on the Brain and Spinal Cord will be a most valuable one for the general reader, the translator's notes adding not a little to its importance. The sections on Sight and Hearing are exhaustive. . . . The Chemistry of the Urine is thoroughly considered. . . . In its present form, the value of the original has been greatly increased. . . . The text is smooth, accurate, and unusually free from Germanisms; in fact, it is good English."—*New York Medical Journal.*

"It is not for the physiological student alone that Prof. Landois' book possesses great value, for IT HAS BEEN ADDRESSED TO THE PRACTITIONER OF MEDICINE as well, who will find here a direct application of physiological to pathological processes."—*Medical Bulletin.*

P. BLAKISTON, SON & CO., Publishers, 1012 Walnut St., Philadelphia.

DISEASES OF THE SKIN.

BY T. MCCALL ANDERSON, M.D.,

Professor of Clinical Medicine in the University of Glasgow.

ASSISTED BY

DR. JAMES CHRISTIE, Sec'y London Epidemiological Society for Indian Ocean and East Africa; Mem. Medical Soc. of Bombay, etc. DR. HECTOR C. CAMERON, Surgeon and Lecturer to Western Infirmary, Glasgow; Surgeon to Glasgow Hospital for Children, etc. WILLIAM MACEWEN, M.B., M.D., Lecturer on Systematic and Clinical Surgery, Royal Infirmary; Surgeon to Royal Infirmary and Children's Hospital, Glasgow, etc.

WITH COLORED PLATES AND NUMEROUS WOOD ENGRAVINGS.

Octavo. 650 Pages. Cloth, \$4.50; Leather, \$5.50.

A treatise on Diseases of the Skin, with reference to Diagnosis and Treatment, including an Analysis of 11,000 Consecutive Cases. Thoroughly illustrated by new and handsome wood engravings, and several colored and steel plates prepared, under the direction of the author, from special drawings by Dr. John Wilson.

PARTICULARLY STRONG IN TREATMENT.

Special attention is given to the Differential Diagnosis of Skin Diseases and to the treatment. There are over 150 prescriptions, which will serve as hints to the physician in dealing with obstinate and chronic cases.

There has been no complete treatise on Dermatology issued for several years; Professor Anderson has, therefore, chosen an opportune time to publish his book.

ILLUSTRATING ONE OF THE DISEASES OF THE HAIR (See Fig. 6, page 7).

For nearly twenty-five years Professor Anderson has been a general practitioner and a hospital physician, with unusual opportunities for the study of this class of diseases, though not a "specialist," as the term is understood. His experience is, therefore, of great value, and the physician will feel that, in consulting this work, he is reading the experiences of a man situated as himself—with the same difficulties of diagnosis and treatment, and who has surmounted them successfully. We believe this to be a valuable feature of the book that will be recognized at once; for it is undoubtedly a fact that a work like the present contains much practical information and many hints not to be found elsewhere. Professor Anderson is particularly happy in illustrating the important relations subsisting between the general economy and its covering, and his ideas of pathology and therapeutics, including a consideration of all the general and local manifestations of the common diseases of the economy which are manifested upon the surface, will find many appreciative readers.

Diseases of the hair receive full systematic treatment.

"We welcome Dr. Anderson's work not only as a friend, but as a benefactor to the profession, because the author has stricken off mediæval shackles of insuperable nomenclature and made crooked ways straight in the diagnosis and treatment of this hitherto but little understood class of diseases. The chapter on Eczema is, alone, worth the price of the book."—*Nashville Medical News.*

? QUIZ-COMPENDS. ?

A SERIES OF PRACTICAL MANUALS FOR THE PHYSICIAN AND STUDENT.

Compiled in accordance with the latest teachings of prominent lecturers
and the most popular Text-books.

Bound in Cloth, each \$1.00. Interleaved, for the Addition of Notes, \$1.25.

They form a most complete, practical and exhaustive set of manuals, containing information nowhere else collected in such a practical shape. Thoroughly up to the times in every respect, containing many new prescriptions and formulæ, and over 300 illustrations, many of which have been drawn and engraved specially for this series. The authors have had large experience as quiz-masters and attachés of colleges, with exceptional opportunities for noting the most recent advances and methods. The arrangement of the subjects, illustrations, types, etc., are all of the most approved form. They are constantly being revised, so as to include the latest and best teachings, and can be used by students of any college of medicine, dentistry and pharmacy.

No. 1. Human Anatomy. Fourth Edition, including Visceral Anatomy, formerly published separately. Over 100 Illustrations. By SAMUEL O. L. POTTER M.A., M.D., late A. A. Surgeon, U. S. Army. Professor of Practice, Cooper Med. College, San Francisco.

Nos. 2 and 3. Practice of Medicine. Fourth Edition, Enlarged. By DANIEL E. HUGHES, M.D., late Demonstrator of Clinical Medicine in Jefferson Med. College, Phila.; Physician-in Chief, Philadelphia Hospital. In two parts.

PART I.—Continued, Eruptive and Periodical Fevers, Diseases of the Stomach, Intestines, Peritoneum, Biliary Passages, Liver, Kidneys, etc. (including Tests for Urine), General Diseases, etc.

PART II.—Diseases of the Respiratory System (including Physical Diagnosis), Circulatory System and Nervous System; Diseases of the Blood, etc.

*These little books can be regarded as a full set of notes upon the Practice of Medicine, containing the Synonyms, Definitions, Causes, Symptoms, Prognosis, Diagnosis, Treatment, etc., of each disease, and including a number of prescriptions hitherto unpublished.

No. 4. Physiology, including Embryology. Fifth Edition. By ALBERT P. BRUBAKER, M.D., Prof. of Physiology, Penn'a College of Dental Surgery; Demonstrator of Physiology in Jefferson Med. College, Phila. Revised, Enlarged and Illustrated.

No. 5. Obstetrics. Illustrated. Fourth Edition. For Physicians and Students. By HENRY G. LANDIS, M.D., Prof. of Obstetrics and Diseases of Women, in Starling Medical College, Columbus. Revised Edition. New Illustrations.

No. 6. Materia Medica, Therapeutics and Prescription Writing. Fifth Revised Edition. With especial Reference to the Physiological Action of Drugs, and a complete article on Prescription Writing. Based on the Last Revision (Sixth) of the U. S. Pharmacopœia, and including many unofficial remedies. By SAMUEL O. L. POTTER, M.A., M.D., late A. A. Surg. U. S. Army; Prof. of Practice, Cooper Med. College, San Francisco. 5th Edition. Improved and Enlarged.

No. 7. Gynæcology. A Compend of Diseases of Women. By HENRY MORRIS, M.D., Demonstrator of Obstetrics, Jefferson Medical College, Philadelphia. *In Press.*

No. 8. Diseases of the Eye and Refraction, including Treatment and Surgery. By L. WEBSTER FOX, M.D., Chief Clinical Assistant Ophthalmological Dept., Jefferson Medical College, etc., and GEO. M. GOULD, A.B. 71 Illustrations, 39 Formulæ. 2d Edition.

No. 9. Surgery. Illustrated. Third Edition. Including Fractures, Wounds, Dislocations, Sprains, Amputations and other operations; Inflammation, Suppuration, Ulcers, Syphilis, Tumors, Shock, etc. Diseases of the Spine, Ear, Bladder, Testicles, Anus, and other Surgical Diseases. By ORVILLE HORWITZ, A.M., M.D., Demonstrator of Surgery, Jefferson Medical College. Third Edition. Revised 77 Formulæ and 91 Illustrations.

No. 10. Medical Chemistry. Third Edition. Inorganic and Organic, including Urine Analysis. For Medical and Dental Students. By HENRY LEFFMANN, M.D., Prof. of Chemistry in Penn'a College of Dental Surgery, Phila. Third Edition. Revised and Enlarged.

No. 11. Pharmacy. Based upon "Remington's Text-Book of Pharmacy." By F. E. STEWART, M.D., PH.G., Professor of Pharmacy, Powers College of Pharmacy; late Quiz-Master at Philadelphia College of Pharmacy. Second Edition. Revised.

No. 12. Veterinary Anatomy and Physiology. Illustrated. By WM. R. BALLOU, M.D., Prof. of Equine Anatomy, New York College of Veterinary Surgeons, etc. 29 Illustrations.

No. 13. Warren. Dental Pathology and Dental Medicine. Containing all the most noteworthy points of interest to the Dental student. By GEO. W. WARREN, D.D.S., Clinical Chief, Penn'a College of Dental Surgery, Philadelphia. Illus.

No. 14. Hatfield. Diseases of Children. By MARCUS P. HATFIELD, Professor of Diseases of Children, Chicago Medical College.

 These books are constantly revised to keep up with the latest teachings and discoveries.

"IT STANDS WITHOUT AN EQUAL AS THE MOST COMPLETE WORK ON PRACTICE IN THE ENGLISH LANGUAGE."—*New York Medical Journal*.

FAGGE'S PRACTICE OF MEDICINE.

Two Large Royal Octavo Volumes. Containing over 1900 Pages.

PRICE, HANDSOMELY BOUND IN CLOTH, \$8.00.

The Principles and Practice of Medicine.

By CHARLES HILTON FAGGE, M.D., F.R.C.P., F.R.M.C.S.,

*Examiner in Medicine, University of London; Physician to, and Lecturer on Pathology in, Guy's Hospital;
Senior Physician to Evelina Hospital for Sick Children, etc.*

EDITED AND ARRANGED FOR THE PRESS

By P. H. PYE-SMITH, M.D., F.R.C.P.,

Lecturer on Medicine in Guy's Hospital, London, etc.,

WITH A SECTION ON CUTANEOUS AFFECTIONS, BY THE EDITOR, A CHAPTER ON CARDIAC DISEASES, BY SAMUEL WILKES, M.D., F.R.S., AND TWO INDEXES, ONE OF AUTHORS AND ONE OF SUBJECTS, BY ROBERT EDMUND CARRINGTON.

Two Volumes.

Royal Octavo.

1900 Pages.

Price in Cloth, \$8.00. Full Leather, \$10.00. Half Morocco, \$12.00. Half Russia, \$12.00.

It is based on laborious researches into the pathological and clinical records of Guy's Hospital, London, during the twenty years in which the author has held office there as Medical Registrar, as Pathologist, and as Physician. Familiar beyond most, if not all, of his contemporaries, with modern medical literature, a diligent reader of French and German periodicals, Dr. Fagge, with his remarkably retentive memory and methodical habits, was able to bring to his work of collection and criticism almost unequalled opportunities of extensive experience in the wards and dead house. The result is that which will probably be admitted to be a fuller, more original, and more elaborate text-book on medicine than has yet appeared. It is the first of importance emanating from Guy's Hospital, and the only two-volume work on the Practice of Medicine that has been issued for a number of years. Several subjects, such as Syphilis, that are usually omitted or but slightly spoken of in a general work of this character, receive full attention.

Dr. Walter Moxon, one of Dr. Fagge's contemporaries, and a great personal friend, writes of him, in a recent number of the *London Lancet*:—

"Fagge was, to my mind, the type of true medical greatness. I believe he was capable of any kind of excellence. His greatness as a physician became evident to observers of character very soon after his brilliant student career had placed him on the staff of Guy's Hospital: he did not merely group already known facts, but he found new facts. Former volumes of Guy's Hospital Reports contain ample and most valuable proof of his greatness as a physician. His power of observation was sustained by immense memory, and brought into action by vivid and constant suggestiveness of intelligence. He was a physician by grace of nature, and being gifted with a quickness of perception, a genius for clinical facts and a patience in observation, he was at once recognized as a successful practitioner and a leading figure in the hospital and among the profession.

NOW READY. 39TH YEAR.

THE PHYSICIAN'S VISITING LIST.

(LINDSAY & BLAKISTON'S.)

CONTENTS.

ALMANAC for 1890 and 1891.

TABLE OF SIGNS to be used in keeping accounts.

MARSHALL HALL'S READY METHOD IN ASPHYXIA.

POISONS AND ANTIDOTES, revised for 1890.

THE METRIC OR FRENCH DECIMAL SYSTEM OF WEIGHTS AND MEASURES.

DOSE TABLE, revised and rewritten for 1890, by HEBERT AMORY HARE, M.D., Demonstrator of Therapeutics, University of Pennsylvania.

LIST OF NEW REMEDIES for 1890, by same author.

AIDS TO DIAGNOSIS AND TREATMENT OF DISEASES OF THE EYE, DR. L. WEBSTER FOX, Clinical Asst. Eye Dept., Jefferson Medical College Hospital, and G. M. GOULD, M.D.

DIAGRAM SHOWING ERUPTION OF MILK TEETH, DR. LOUIS STARR, Prof. of Diseases of Children, University Hospital, Philadelphia.

POSOLOGICAL TABLE, MEADOWS.

DISINFECTANTS AND DISINFECTING.

EXAMINATION OF URINE, DR. J. DALAND, *based upon Tyson's "Practical Examination of Urine."* 6th Edition.

INCOMPATIBILITY, DR. S. O. L. POTTER.

A NEW COMPLETE TABLE FOR CALCULATING THE PERIOD OF UTERO-GESTATION.

SYLVESTER'S METHOD FOR ARTIFICIAL RESPIRATION. Illustrated.

DIAGRAM OF THE CHEST.

BLANK LEAVES, suitably ruled, for Visiting Lists, Monthly Memoranda, Addresses of Patients and others; Addresses of Nurses, their references, etc.; Accounts asked for; Memoranda of Wants; Obstetric and Vaccination Engagements; Record of Births and Deaths; Cash Account, etc.

REGULAR EDITION.

For 25 Patients weekly.

Tucks, pockets and Pencil, \$1.00

50	"	"		"	"	"	1.25

				{ July to Dec. }			

PERPETUAL EDITION, without Dates.

No. 1. Containing space for over 1300 names, with blank page opposite each Visiting List page. Bound in Red Leather cover, with pocket and Pencil, \$1.25

No. 2. Containing space for 2600 names, with blank page opposite each Visiting List page. Bound like No. 1, with Pocket and Pencil, 1.50

MONTHLY EDITION, without Dates.

No. 1. Bound without Flap or Pencil,75

No. 2. " with Tucks, Pencil, etc.,1.00

These lists, without dates, can be commenced at any time, and used until full, and are particularly useful to young physicians unable to estimate the number of patients they may have during the first years of Practice, and to physicians in localities where epidemics occur frequently. In the Monthly Edition the patient's name has to be entered but once each month.

"For completeness, compactness, and simplicity of arrangement it is excelled by none in the market."—*N. Y. Medical Record*.

"The book is convenient in form, not too bulky, and in every respect the very best Visiting List published."—*Canada Medical and Surgical Journal*.

"After all the trials made, there are none superior to it."—*Gaillard's Medical Journal*.

"The most popular Visiting List extant."—*Buffalo Medical and Surgical Journal*.

"We have used it for years, and do not hesitate to pronounce it equal, if not superior, to any."—*Southern Clinic*.

This is not a complicated system of keeping accounts, but a plain, systematic record which, with the least expenditure of time and trouble, keeps an accurate and concise list of daily visits, engagements, etc.

NEW TEXT-BOOKS.

Macalister's Human Anatomy. 816 Illustrations (400 of which are Original). Just Ready.

A NEW TEXT-BOOK for Students and Practitioners, Systematic and Topographical, including the Embryology, Histology and Morphology of Man. With special reference to the requirements of Practical Surgery and Medicine. By ALEX. MACALISTER, M.D., F.R.S., F.S.A., Professor of Anatomy in the University of Cambridge, England; Examiner in Zoölogy and Comparative Anatomy, University of London; formerly Professor of Anatomy and Surgery, University of Dublin. With 816 Illustrations, 400 of which are original. Octavo.

Cloth, \$7.50; Leather, \$8.50

. Professor Macalister's reputation as an Anatomist and Zoölogist is such that nothing need be said of the scientific value of this book. Regarding the illustrations, printing and binding we may say, however, that the workmanship is of the best character in every respect. No expense has been spared to make a handsome volume, the 400 original illustrations adding greatly to its appearance as well as to its practical value as a working book for students and physicians.

Potter's Materia Medica, Pharmacy and Therapeutics. Second Edition. Revised and Enlarged.

A HANDBOOK OF MATERIA MEDICA, PHARMACY AND THERAPEUTICS—including the Physiological Action of Drugs, Special Therapeutics of Diseases, Official and Extemporaneous Pharmacy, etc. By SAM'L O. L. POTTER, M.A., M.D., Professor of the Practice of Medicine in Cooper Medical College, San Francisco; Late A. A. Surgeon, U. S. Army, Author of "Speech and its Defects," and the "Quiz-Compend's" of Anatomy and Materia Medica, etc. Revised, Enlarged and Improved. Octavo. *With Thumb Index in each copy.*

Cloth, \$4.00; Leather, \$5.00

"The author has aimed to embrace in a single volume the essentials of practical materia medica and therapeutics, and has produced a book small enough for easy carriage and easy reference, large enough to contain a carefully digested, but full, clear and well-arranged mass of information. He has not adhered to any pharmacopœia, as is the case of certain recent manuals, thereby limiting his work, and in this day of new remedies causing constant disappointment, but has brought it up to date in the most satisfactory way. No new remedy of any acknowledged value is omitted from this list. Under each the section on physiological action and therapeutics has been written with care. . . . In the enumeration of drugs suited to different disorders a very successful effort at discrimination has been made, both in the stage of disease and in the cases peculiarly suited to the remedy. It is no mere list of diseases followed by a catalogue of drugs, but is a digest of modern therapeutics, and as such will prove of immense use to its possessor."—*The Therapeutic Gazette.*

Winckel's Obstetrics. Original Illustrations.

A TEXT-BOOK OF OBSTETRICS, INCLUDING THE PATHOLOGY AND THERAPEUTICS OF THE PUERPERAL STATE. By DR. F. WINCKEL, Professor of Gynæcology, and Director of the Royal University Clinic for Women, in Munich. Authorized Translation, by J. CLIFTON EDGAR, M.D., Adjunct Professor to the Chair of Obstetrics, Medical Dept., University, of the City of New York, with nearly 200 handsome illustrations, the majority of which are original with this work. Octavo.

Cloth, \$6.00; Leather, \$7.00
